The transformer current values shown in figure 7 are of interest also. In the region of one-half frequency phenomena these currents may reach values of 35 times normal magnetizing current in the vicinity of $x_{co}/x_m=0.015$. These currents are the same in magnitude in all three phases. In this range it might be possible to blow potential transformer fuses under such abnormal conditions. In the region of fundamental frequency phenomena the currents are smaller in general, and furthermore, the current in one phase is lower than normal. It is a significant fact that while the voltage conditions in this range of x_{co}/x_m approximate those obtained during a single line-to-ground fault, the currents flowing in the Y winding of the potential transformer may be 10 or 15 times as high as those obtained during a single line-to-ground fault condition, depending upon the ratio of x_{co}/x_m.

Figure 8 shows the results of inserting resistance, R, in the break in the Δ secondary. The curves show that the heaviest burden (lowest resistance) to insure stable operation is required when x_{co}/x_m is about 0.02 or slightly less depending upon the normal system operating voltage. At the lowest point, $R/x_m=0.15$ for operation at $E=1.0$ and $R/x_m=0.34$ for operation at $E=0.58$. These values are on a basis of resistance per leg in per unit of magnetizing impedance per leg for $E=1.0$ on the saturation curves of figure 2. Therefore the curve gives the resistance required per phase for Y-connected secondaries. The value of impedance required across the break in the case of broken Δ secondaries as in figure 1 is three times the quantity R/x_m of figure 8.

The effect of normal operating voltage E on the R/x_m ratio required for stabilization is shown in figure 9. It is of importance to note that as E decreases, the ratio of R/x_m required for stability increases. The values of x_{co}/x_m used in preparing these curves were purposely selected in the range requiring the lowest ratios of R/x_m as indicated in figure 8.

The effect of an inductive reactance burden x_L (power factor=0.2) is indicated in figure 10. A lower ratio of x_L/x_m is required for stabilization than of R/x_m as discussed in the preceding paragraph. The ratio of x_L/x_m at its lowest point is 0.04 for operation at $E=1.0$ and 0.28 for operation at $E=0.58$.

The effect of a leading power factor (capacitive) burden in the break in the Δ was investigated and the results indicated that pure capacitance was not satisfactory. The same conclusion holds for wave traps

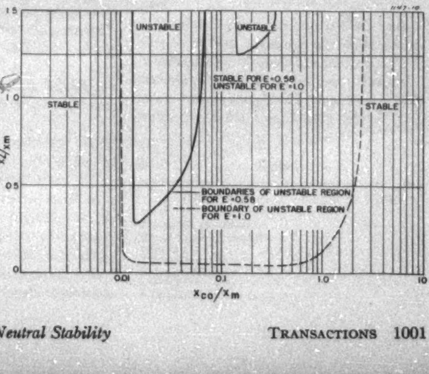

Figure 10. Effect of inductive reactance burden x_L (0.2 power factor) in the broken delta on regions of instability

Saturation curve 1 of figure 2

Note: The total amount of reactance in the delta is three times the amount of x_L indicated by the curves since x_L/x_m is on a per leg basis which were made up of a reactance and capacitance tuned to the third harmonic. These were not effective because other complicating phenomena were encountered which were difficult to account for. Consequently a resistance burden appears to be the simplest and most effective means of insuring stability by means of a secondary burden. Reactance was effective, although a reactance ohmic value would have to be smaller than that of a resistance to insure stability.

Conclusions

1. In using Y grounded primary broken Δ or Y-connected secondary potential transformers for metering or relaying, it is necessary to consider the amount of capacitance to ground that may be permanently or temporarily connected at the terminals of the transformer in order to avoid the possibility of abnormal voltage conditions brought about by circuit instability which might cause incorrect indications of faults. For line-to-line voltage rated potential transformers connected line-to-neutral, corresponding to general practice in the application of such devices ($E=0.58$ in the paper), the range of possible abnormality is defined approximately by $0.012<x_{co}/x_m<0.6$. If a given circuit is found to fall within this range, normal behavior can be insured by:

(*a*). Adding shunt capacitance to ground on the system side of the transformer until the resultant ratio of x_{co}/x_m becomes equal to or less than 0.012, or

(*b*). Connecting load across the break in the broken Δ secondary or in each phase in the case of Y-connected secondary. If resistance is used, it should have a value per phase of 33% of the magnetizing reactance x_m per phase or less; if reactance is used, its ohmic value per phase should not be greater than 28% of x_m per phase. In either case, x_m is referred to the secondary side in accordance with the transformer turn ratio. The impedances required for stabilization are high enough so as not to interfere with the normal functioning of the device.

For these criteria, x_{co} is the zero sequence capacitive reactance to ground on the Y grounded side of the transformer and x_m is the magnetizing reactance per leg corresponding to $E=1.0$ on the saturation curve 1 of figure 2.

2. The regions of abnormality as well as the abnormal phenomena observed are practically unaffected by resistance in the transformer windings or by losses in transformer iron over a practical range.

3. Increasing the steepness of the saturation curve tends to increase the range of possible abnormal circuit behavior. In particular, the region of abnormality is extended to lower values of x_{co}/x_m as the steepness of saturation is increased.

4. For conditions of operation above transformer flux densities corresponding to the normal practice of using *L-N* connected potential transformer with *L-L* voltage rating ($E=0.58$ in the paper), abnormal circuit behavior is extended to include a range of $0.01<x_{co}/x_m<3.0$ approximately for $E=1.0$. Furthermore, the impedance in the open Δ must be made smaller if stability is to be insured. For $E=1.0$, a resistance in the break in the Δ not greater than 45% of x_m (15% of x_m per phase) or a reactance not greater than 12% of x_m (4% of x_m per phase) would be required to avoid abnormal circuit behavior independent of x_{co}/x_m.

Field Testing of Generator Insulation

EEI SUBJECT COMMITTEE ON GENERATOR INSULATION AND TESTING

I—Introduction

NEED for a practical as well as a reliable nondestructive test that will determine the condition of generator insulation has long been recognized by the industry. Simple methods now in general use, the high voltage proof test and the insulation resistance test, do not accurately or positively disclose the overall condition of windings, indicate the degree of deterioration, or necessarily locate weak spots. This lack of suitable insulation tests has been emphasized recently by the return to service of a number of machines either after long shutdown periods during the depression years or from standby service to low pressure elements used in connection with topping units; in these cases knowledge of insulation condition is vital.

As a result of this situation the Edison Electric Institute electrical equipment committee undertook active work on the problem in 1935.[1] In 1937 a special subject committee was appointed on "Generator Insulation and Testing," with the ultimate object of developing a reliable test procedure for determining the condition of generator insulation. The investigation has been carried out by various member companies of the EEI and others in the industry interested in the problem, under the guidance of the subject committee. Close contact has also been maintained with the manufacturers who have made many valuable suggestions, assisted in testing, and given aid in analyzing data.

The study is by no means complete and this paper should not be construed as a final report with definite conclusions, but rather as a progress report on an investigation still under way.

II—Present Status of Insulation Testing

Present testing practice in this country was surveyed in 1938, revealing a wide variation in testing methods and procedure. High voltage proof testing which consists merely of the stressing of the insulation by the application of an alternating potential according to the rules in the AIEE Standards is generally used for acceptance tests for new and repaired machines. There is no general agreement as to advisability of routine proof testing nor magnitude nor frequency when such tests are applied to machines in service. Insulation resistance testing is a common practice though generally a definite routine is not followed. In the past the procedure often has consisted of a "crank and read" type of measurement. Today, increasing recognition is being given the fact that insulation resistance values may be misleading unless careful account is taken of the many factors which may affect the results. No definite practice seems to be established regarding other methods of test, such as high voltage d-c resistance, dielectric loss or power factor tests.

Comparatively few operating companies maintain regular schedules of periodic insulation testing, from which records may be obtained to serve as a guide of the progressive condition of the insulation. Such special tests as are made are carried out usually after a machine winding has been repaired or an inspection indicates it to be in questionable condition.

Foreign practice in this respect also indicates a lack of uniformity. In some countries, notably Germany and Switzerland, experiments have been made with dielectric loss measurements, and it is felt there that this type of measurement has some promise of value as an index of changing insulation condition. A few experiments have made use of a recording instrument giving a curve of dielectric losses versus time during machine operation. It has been suggested that this method may give a definite index of changing conditions within the insulation. The method has not received broad use.

III—Scope of Work

Originally it was the objective of the subject committee to conduct destructive and nondestructive tests on insulation of machines about to be scrapped, rewound, or repaired and to develop from these a workable nondestructive method of determining insulation condition. Valuable information has been obtained from these tests but inasmuch as many of the data consist of "spot" readings taken under a variety of conditions, it has not been possible to correlate all of the data nor to draw definite conclusions. Real need for periodic and standardized measurements has become apparent. The scope of the investigation has been broadened to include and encourage the collection of periodic nondestructive test data on machines in service. By this means information is being accumulated on all classes of insulation, from the old to the new.

Insulation characteristics of both armature and field windings are undergoing investigation. Table I summarizes the machines tested or under test. The machine ratings vary from 1,500 kva, 2,700 volts to 200,000 kva, 16,500 volts.

Table I

Type of Test	Number of Machines
Insulation resistance	106
Power factor of insulation	27
Ionization	8
Voltage strength a-c	21
Voltage strength a-c versus d-c	6*

* Includes 2–2.3 kv motors.

Paper 41-17, recommended by the AIEE standards committee, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 6, 1940; made available for preprinting December 6, 1940.

Personnel of EEI subject committee on generator insulation and testing: C. M. Gilt and B. Van Ness, Jr., subject sponsors; R. L. Webb, chairman; J. E. Allen, E. F. Dissmeyer, O. E. Fawcett, A. P. Hayward, R. J. Woodrow.

The subject committee wishes to acknowledge the assistance and co-operation rendered in this work by EEI member companies and engineers, by other engineers and utility companies, and by the manufacturers.

[1] For all numbered references, see list at end of paper.

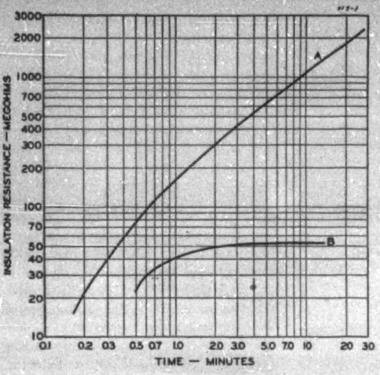

Figure 1. Armature-winding insulation resistance versus time

A—200,000-kva single-barrel generator, 16.5 kv, 60 cycles, 1,800 rpm (insulation dry)

B—18,750-kva single-barrel generator, 13.2 kv, 60 cycles, 1,800 rpm (insulation moist)

The subject committee, recognizing the need for uniform practice in insulation testing, has prepared a guide to be used in making such tests. Copies of this are available to the industry through EEI headquarters.

IV—D-C Insulation Resistance

Although d-c insulation resistance is among the most commonly used methods for testing the insulation of electrical apparatus, records obtained have been baffling of interpretation, and the factors which affect the results are to some extent unknown and often unappreciated. The fundamental that different types of insulating materials may have different volume resistances is obvious; but there are other variables which affect successive tests on a given piece of apparatus and cause widely varying results.

Tests have been directed to establish the manner in which the insulation resistance varies with

(*a*). Differences in insulation materials and structures
(*b*). Duration of voltage application
(*c*). Existing charge in windings
(*d*). Insulation temperature
(*e*). Test voltage magnitude
(*f*). Insulation moisture content
(*g*). Previous operating condition of the generator
(*h*). Various types of winding damage or deterioration

These investigations have confirmed findings obtained in similar experiments made by others and have gone somewhat further in extending the limits to which such tests have been conducted in the field.

INSTRUMENTS

Experiments made so far have indicated that any one of several types of test instruments will give satisfactory insulation resistance results. Commercial forms of insulation resistance testers perform satisfactorily provided they are calibrated periodically and tested to assure their voltage output is proper. The maximum voltage at which measurements have been made with these instruments is 5,000 volts, d-c. Motor driven devices or other constant voltage generators are necessary for taking long time insulation resistance curves. Hand operated units may be used for short time readings.

The voltmeter method may be used with fair accuracy if the insulation resistance is less than 10 megohms. To insure accuracy of readings a high resistance voltmeter should be used.

Considerable success has been attained with electronic rectifier sets having d-c outputs from 100 to 5,000 volts and with dry cell battery sets up to 1,500 volts. These use a voltmeter and a microammeter for measurements which permit calculation of insulation resistance. They must be carefully shielded and guarded.

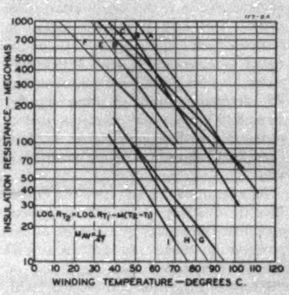
Higher voltages may be obtained from Kenotron test sets. Tests may be carried to any reasonable limit of voltage with this type of equipment, though 5,000 volts appears to be the present limit for sets portable by hand. In all rectifier sets it is essential that a steady supply of voltage be available to prevent fluctuation in charging current to the generator winding capacitance, an automatic voltage regulator being used if necessary.

Where protective resistors are used in test instruments their effect on the voltage magnitude applied to the insulation should be carefully taken into account.

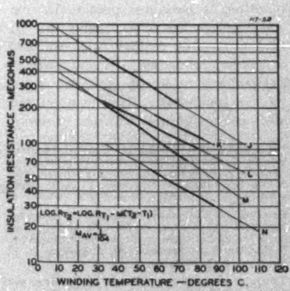
DURATION OF VOLTAGE APPLICATION

While many insulation resistance measurements have been taken by the "crank and read" method, Wieseman[3] and others have shown that the insulation resistance of a winding varies with duration of voltage application. Insulation resistance of a dry winding in good condition may continue to increase for as long as a day or more with the test voltage applied continuously at a steady value. Normally an approximately final value, which is termed "apparent insulation resistance" may be reached after 10 to 15 minutes. Insulation resistance after 30 seconds to 60 seconds may be as little as 10 per cent to 20 per cent of the 15-minute reading.

In figure 1 insulation resistance versus time curves, commonly referred to as dielectric absorption curves, are shown for different conditions of generator insulation. Curve *A* is a good example of the effects of "bone dry" and clean insulation on the final value of insulation resistance and on the shape of the dielectric absorption curve. This curve represents an unusually high insulation resistance for a machine whose rating is 200,000 kva, 16,500 volts, in one stator winding. Curve *B* was taken on an 18,750-kva, 13,200-



Family having more common slope. Data taken at 500 to 20,000 volts after ten minutes



Family having lowest slopes. Data taken at 1,000 to 8,000 volts after one to ten minutes

Figure 2. Insulation resistance versus temperature

volt generator which had been exposed to varying degrees of atmospheric humidity for several years. Considering size alone this smaller unit would be expected to have a higher insulation resistance than the larger unit. However, the insulation conditions are such that the reverse is the case. Leakage resistance effects predominate and the curve flattens rapidly between the 30-second and the 3-minute readings.

Information contained in curves of this nature discloses the reason for at least one difficulty in past attempts to correlate insulation resistance readings, for it is obvious that "spot readings" made without regard to definite time of voltage application can give widely varying results.

Many dielectric absorption curves have been collected. While it is believed that these data give information as to dryness and cleanliness of winding, spot curves have not disclosed a positive relation between insulation resistance and insulation condition. Therefore, periodic curves are being taken and the behavior of the dielectric absorption factor over a long period is being observed and analyzed.

Effect of Existing Charge on Winding

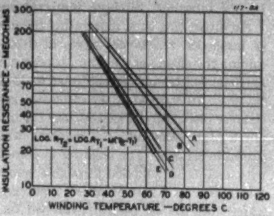
Comparative values of winding insulation resistance are markedly affected by residual charges retained in a winding. For this reason windings should be grounded and discharged for at least ten minutes before applying insulation resistance tests.

Insulation Temperature

Tests have indicated that the insulation resistance of windings is affected greatly by temperature. The most marked effect occurs in class *A* windings but even in class *B* insulation structures, the insulation resistance may vary as much as 10 to 1 for a winding temperature change from approximately 25 degrees centigrade to 75 degrees centigrade, the insulation resistance being lower at the higher temperature.

It is desirable that insulation resistance readings be taken at temperatures as close to 75 degrees centigrade as possible, to secure an indication of resistance at operating temperatures, eliminating the effect of humidity and requiring minimum temperature correction.

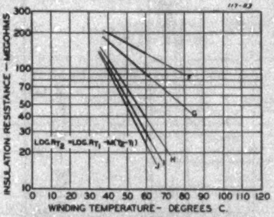
Figure 2 gives the results of field tests undertaken with the objective of establishing factors which will permit readings taken at one temperature to be transferred to a lower or higher temperature. The results so far indicate two families of curves, with similar characteristics of insulation resistance versus temperature in each group. The curves may be represented by the formula:



68,750-kva turbogenerator, 13.2 kv, 60 cycles, 1,800 rpm

Data taken following acceptance test run

A Insulation resistance at 10 min.—$M = {}^1/_{48}$
B Insulation resistance at 4 min.—$M = {}^1/_{60}$
C Insulation resistance at 1 min.—$M = {}^1/_{41}$
D Insulation resistance at 30 sec.—$M = {}^1/_{39}$
E Insulation resistance at 15 sec.—$M = {}^1/_{38}$
Avg.—$M = {}^1/_{44}$



Data taken following about two years of base-load service

F Insulation resistance at 10 min.—$M = {}^1/_{116}$
G Insulation resistance at 4 min.—$M = {}^1/_{76}$
H Insulation resistance at 1 min.—$M = {}^1/_{41}$
I Insulation resistance at 30 sec.—$M = {}^1/_{36}$
J Insulation resistance at 15 sec.—$M = {}^1/_{34}$
Avg.—$M = {}^1/_{60}$

Figure 3. Insulation resistance versus temperature for different periods of voltage application

$$\log R_{t_2} = \log R_{t_1} - M(t_2 - t_1)$$

where R_{t_2} and t_2 are the unknown resistance and temperature at which the resistance is desired, R_{t_1} and t_1 are the measured resistance and the related winding temperature and *M* is a constant equal to the reciprocal of change in temperature for $\log R = 1$. Insulation resistance doubles for each 14 degree centigrade reduction in winding temperature for the curve whose $M = {}^1/_{47}$, and doubles for each 31 degree centigrade reduction for the curve whose $M = {}^1/_{104}$.

Although it might be assumed that the two families of curves bear definite relation to insulation class, this is not the case. Machines with both class *A* and class *B* windings appear in each group. Operating conditions apparently have a large effect on these characteristics, for data indicate that even after years of operation changes in the value of *M* for a given machine may occur from year to year. This is evident from figure 3 in which the curves having an average value for $M = {}^1/_{44}$ were taken in 1938 shortly after a new generator was placed in service. The curves having an average value for $M = {}^1/_{60}$ were taken on this same machine approximately two years later. The machine had been operated about 72 per cent of the elapsed time at an average of 95 per cent of rated capacity and had been run for several days, well loaded, before the last test. It is apparent, therefore that the value of *M* may vary for a given machine but it is not known definitely whether this variation is due to differences in moisture or volatile matter content in the insulation, or whether it is due to some aging or curing action which has been under way during the many continuous hours of high load operation. It is believed that moisture is the most likely cause of the variation.

While extrapolation of the curves of figure 3 appears to meet in a point at low temperatures other data indicate parallelism or a meeting at high temperatures. The reason for and meaning of these variations are not known.

No definite formula applicable to all machines, or even to the same machine under various conditions, can be given at this time for the relation of insulation resistance to temperature. Two readings taken at the same date on a machine will establish a curve for that machine for a definite condition of the insulation. A change in slope of an insulation resistance-temperature curve indicates a change in the insulation condition.

Effect of Moisture Content

Accurate insulation resistance data are very useful in determining the progress of drying machine insulation. It is customary to dry a machine until the insulation resistance readings at constant temperature approach a constant value when plotted with regard to time. When drying out, the attainment of a constant insulation resistance at a constant temperature is a better indication of dryness than is the attainment of some previously selected value.

Figure 4 indicates the variation of insulation resistance of a new turbo-generator whose winding is being dried. Each point of insulation resistance was taken after ten minutes application of test voltage. The insulation resistance dropped rapidly as the winding temperature increased and then recovered as the moisture was driven from the insulation. When the test was terminated, the insulation resistance rose rapidly as the winding temperature decreased.

Figure 5 gives another method of plotting similar data as taken on the initial dry-out run of a 37,500-kva water-wheel generator and illustrates the value of the one- and ten-minute readings in obtaining a clear picture of the conditions during machine dry-out. It will be noted that as the run progressed the separation between the curves increased, indicating an effective drying of the insulation and the resulting increase of absorption effect in the dielectric.

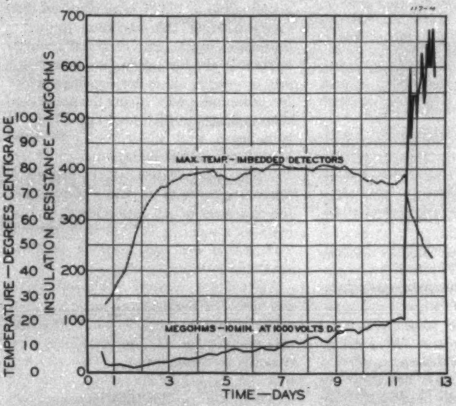


Figure 4. Change in ten-minute insulation resistance with time during generator dry-out

35,300-kva turbogenerator, 13.8 kv, 60 cycles, 1,800 rpm

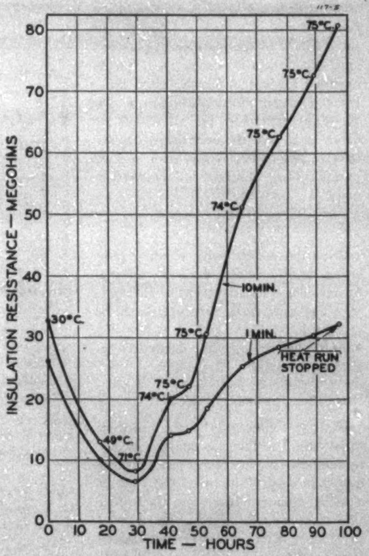

Figure 5 (right). Change in one-minute and ten-minute insulation resistance with time during generator dry-out

37,500-kva hydrogenerator, 13.3 kv, 25 cycles, 100 rpm

The degree of moisture content in the outer layers of generator winding insulation has a very marked effect on the insulation resistance. A machine which has been running regularly will generally have a much higher insulation resistance at room temperature than the same machine after being idle for several weeks in a humid atmosphere. A relatively low insulation resistance resulting from exposure to moist air does not necessarily mean that the insulation is inferior or that the machine is not safe for operation. If the insulation resistance is still reasonably high for the machine in question as shown by reference to periodic test data it may be returned to service and the moisture will be driven from its windings by the increased machine temperature.

An interesting case, illustrating the use of insulation resistance curves in determining the effects of moisture, concerns a machine which had been subjected to flood waters. After dry-out, the insulation resistance increased to a satisfactory though not a high value and the machine was placed in service. The unit was operated with cooling air supplied through a spray system equipped with baffles for removing water from the air before it reached the generator. Later, after fairly continuous service, the generator was found to have low insulation resistance. The cooling air was suspected of carrying moisture into the machine and preventing thorough drying. The unit was operated under test load for two hours using relatively dry turbine room air for generator cooling to learn of its effect on insulation resistance. Curves *A* and *B* of figure 6 show the insulation resistance results before and after this change in cooling air. As a result of these tests the unit, and several others in the same plant were equipped with surface coolers and a closed ventilating system, with improvement in insulation resistance as shown by curve *C* of figure 6.

Spray type air washers have not caused similar trouble at certain other locations where the same type of tests were made on generators whose windings had not been submerged.

Effect of Test-Voltage Magnitude

Insulation resistance measurements at 75 degrees centigrade of dry insulation in good condition will be affected very little by wide variations in test voltage. The effect appears to increase somewhat at lower temperatures as will be noted on figure 7. Windings having high leakage due to moisture or dirt, or other types of deterioration, may show a more pronounced reduction in insulation resistance as the test voltage is increased.

Results of complete tests on two machines, have indicated there may be some merit in comparisons between insulation resistance measurements at two different d-c voltages, at the same winding temperature. A 25,000-kw generator winding section was given a dielectric absorption test at 2.5 kv and at 15 kv d-c. The coils were then punctured on a 60-cycle high potential test and the insulation resistance values at the two voltages were again taken. The first test gave a ratio of approximately 2 to 1 with the 2,500-volt measurement being higher. The second test gave an insulation resistance ratio of approximately 6 to 1 after the insulation had been punctured. This test was repeated on another coil group and the ratio changed from approximately 2 to 1 to a ratio of approximately $4^1/_2$ to 1.

The stator winding of a 30,000-kva synchronous condenser was found in very

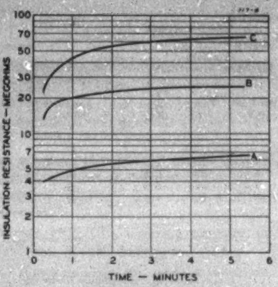

Figure 6. Armature-winding insulation resistance versus time

B—After using turbine-room air at approximately 38 per cent humidity during a two-hour load run made immediately after test *A*

C—After using a closed ventilation system and surface coolers for about one month

bad condition on visual inspection in a plant where two machines of the same rating and age were operating. The insulation resistance of the winding which had to be replaced was found to have a ratio of more than 7 to 1 between the 2,500-volt and 20,000-volt tests, respectively. The insulation resistance of the other machine was found to have a relation of approximately 1.25 to 1 for the 500-volt and 10,000-volt tests and 1.2 to 1 for the 2,500-volt and 10,000-volt tests, respectively. The winding of this machine appeared to be in excellent condition.

While sufficient data have not been accumulated to permit final conclusions, they do indicate that a wide difference in insulation values determined by low and high voltage tests should lead one to suspect irregularities in the insulation. Efforts at conducting voltage tests under staged conditions by mechanical damage have met with poor success because of the difficulty of keeping reductions in the dielectric strength of armature bar insulation under control.

V—Insulation Power Factor

Power factor testing of generator windings is not in common use. Experiments have been made, however, to determine whether some test of this type may be useful and practical. The 60-cycle power factor of generator insulation has been studied for different winding temperatures and impressed voltages.

Equipment

Any well constructed and properly shielded power factor measuring equipment is satisfactory. Circuits of the test instruments must be thoroughly shielded and guarded to prevent interference from other energized equipment. Use of the ordinary wattmeter, voltmeter, and ammeter is not likely to give satisfactory results. Suitable commercial measuring equipment is available from several sources. A testing supply of ample capacity to furnish the charging current at the measurement voltage should be used.

Park and Skeats[4] have shown that generator winding capacitance can be determined fairly accurately by use of the formula $C=K_c\dfrac{\text{MVA}}{\sqrt{kv}(1+0.08\ \text{kv})}$ microfarads per phase.

The constant K_e has the following values:

	K_c	Assumed Peripheral Speed Ft/Min
Solid round rotors	0.0187	22,000
Salient-pole generators without amortisseurs	0.0347	10,000
Salient-pole generators with amortisseurs	0.0317	11,000

C is approximately inversely proportional to peripheral speed.

Capacitance of connecting cables must be added if included in the test.

Charging current at high voltage may be 25 per cent to 100 per cent above that determined by the capacitance constant alone, depending upon the extent of the corona losses, which vary with the impressed voltage.

Results

Power factor measurements on machine insulation may be affected by many conditions, most of which are similar to those outlined for d-c insulation resistance. The time of voltage application appears to have little effect on winding power factor unless it causes heating within the insulation. Winding temperature and moisture content will have a pronounced effect, and winding capacitance is, of course, an important factor. Voltage magnitude has an effect on power factor causing it to increase as the voltage is increased over the normal test range.

Insulation power factor should be nearly constant at each voltage below the ionization value.

Figure 8 shows the typical variations of winding power factor with different values of applied alternating voltage at different temperatures.

Power factor measurements have thus far produced little data which may be used to indicate insulation condition, other than moisture content.

No experiments have been conducted on dielectric loss characteristics by the subject committee. European engineers have had some success with this method, particularly as applied to control of manufacturing processes. It has received little attention as a means for supervising the insulation characteristics of an operating machine.

VI—Ionization Measurements

Both qualitative and quantitative ionization measurements[5] have been investigated to determine whether such measurements can be used to detect insulation irregularities in generator insulation. The quantitative tests were designed to obtain a characteristic showing the relative magnitudes of ionization discharge from a generator winding as the applied a-c voltage was varied, and to determine whether this might have any relation to the physical condition of the insulation or to its dielectric strength. Qualitative tests were designed to locate ionization points in the winding on the supposition that ionization would be present at weak points in the insulation.

Apparatus used for the qualitative tests is shown in figure 9. Equipment for the quantitative measurements was connected as indicated in figure 10. Complete shielding of the apparatus is necessary, and even then external disturbances due to radiations from energized equipment nearby are bothersome. For the quantitative tests the radiations in the radio frequency range were amplified, rectified, and measured by a sensitive d-c instrument. The measurements were relative only and not of any definite figure in amperes of ionization current.

Results of Qualitative Measurements

The qualitative ionization tests determined not only the impressed voltage at which ionization began, but were reasonably successful in determining the locations at which more severe ionization was present. On 6.6-kv and 11.4-kv generators having old winding designs varying in insulation structure from 100 per cent class *B* to all class *A* construction in the slot section, the voltage at which ionization was noted varied from about 1,000 volts to approximately 7,000 volts. The

* Insulation resistance data on 40 machines not listed because of lack of full rating information.

machine on which ionization was detected at 7,000 volts and 21 degrees centigrade, was a 7.8-kv class *A* insulated unit. When this winding temperature was raised to 47 degrees centigrade, ionization could be detected at about 5,000 volts.

Ionization was detected at 1,000 volts on a 6.6-kv machine with mica insulation at a point where the coil passed through an air duct at the center of the stator winding. Though signs of corona pitting were expected in the insulation and heavy paper protective covering actually no evidence of such damage was found.

Where an aerial was used for detection, the only radiations due to ionization which were picked up in the slot sections of the stators were at air ducts and at the outer edges of the stator iron, even though the voltage was raised to more than two times machine rated voltage. This may be explained partially by the shielding effect that the stator conductors receive in the slot sections. Ionization was detected at the end turns of all machines tested by this method, at voltages varying from 25 per cent to 50 per cent of machine rated voltage.

An attempt was made with the search aerial to locate points where intentional damage had been inflicted to the insulation of various generators, by bruising the insulation with hammer blows, by cracking the insulation in bending, and by cutting into the insulation structure with a knife. The qualitative measurements gave no clear indication that ionization had increased or that it developed at a lower voltage.

RESULTS OF QUANTITATIVE MEASUREMENTS

Quantitative ionization tests were made to determine the relation of ionization discharge with change in impressed voltage and to determine whether the rate of change could be used to detect insulation damage or deterioration. Figure 11 shows the curves obtained on a class *A* insulated machine for all three phases, two phases separately, and for a section of another phase winding whose insulation had been intentionally damaged as previously described. It was thought that the curve would show a step type characteristic giving sudden increases of ionization units at increasingly rapid steps as the impressed voltage was increased. This characteristic does seem to be partially realized in the curves for the two separate phase tests, though not to the degree anticipated. The results on the winding section which had been damaged were somewhat surprising since the winding failed to ground as the voltage was approaching 16 kv. This is only 1,000 volts above the highest voltage at which a measurement of ionization units was made. The curve shape gives no indication of approaching failure.

VII—High-Voltage Tests—A-C and D-C

A survey of coil insulation strengths was made on a number of machines where the machine was being removed permanently from service or where the winding was to be replaced. The work consisted of a-c high potential tests, to breakdown, on different phases and different coil sections and, in some cases, was supplemented by tests using d-c voltage from Kenotron testing equipment. These tests were made in conjunction with other measurements on winding sections as found and on coil sections which had been subjected to various types of mechanical damage intentionally inflicted. Special attention was also given to determination of the relative a-c and d-c strength of winding insulation.

EFFECT OF AGE ON DIELECTRIC STRENGTH

Generator armature winding insulation strengths were found remarkably high even after 20 to 30 years of service, as will be noted by reference to table II. There were occasional failures at voltages less than twice normal rated voltage attributable to mechanical injury which had developed in the insulation and which could not be seen until the winding was disassembled. Most of the breakdown voltages were far in excess of the voltage specified for new machines in the AIEE Standards. A 6.6-kv generator with 1915 class *B* insulation failed at the end-turns at approximately $6^1/_2$ times rated terminal voltage on several tests. This is the machine on which ionization was detected in the slot section at the air duct with an impressed potential of only 1,000 volts. It was impossible to obtain a failure on one of the armature bars after the end-turn brackets had been disassembled, though the voltage was raised momentarily to 72 kv and held at 68 kv (over 10 times normal) for a period of 5 minutes. This case is exceptional and is not intended to convey the thought that armature bar insulation has this safety factor as a general thing.

ROTOR DIELECTRIC TESTS

Ten turbogenerator fields were tested to destruction, with breakdown voltages varying from 1 to 5.5 kv. Six of the fields punctured at values between 1 and 2 kv which indicates that, in order to prevent undue stress, routine field testing should preferably be done with a 500-volt source rather than with a 1,000-volt source.

DIELECTRIC STRENGTH—A-C VERSUS D-C

Numerous tests have been made to determine the relative strengths of generator insulation as determined by breakdown voltage using a-c and d-c test equipment. An established ratio between the two types of tests will permit use of low capacity d-c testing equipment on large armature windings.

Such tests were made by selecting a group of four to six coils, each at different locations, around the periphery of the stator for each type of test. Unusually low breakdown strengths were disregarded as being caused by abnormal weaknesses in the coil. Experiments made to date have given the following results:

Table III

	Average Insulation Breakdown Strength		
Machine	A-C Voltage (RMS) Kv	D-C Voltage Kv	Ratio D-C/A-C (RMS)
2.3-kv motor	13.2	20.8	1.6
2.3-kv motor	11.7	21.0	1.8
13.8-kv, 30-mva synchronous condenser	28.3	38.5	1.46
6.6-kv, 30-mva turbogenerator	34.0	46.7	1.38

Similar tests have been performed in the laboratory on a group of spare generator coils, no end-turn supports were used. The slot sections of the coil were grounded carefully by clamping them into metal troughs. The average 60-cycle breakdown was 65 kv. The d-c value varied from 150 to 175 kv. The ratio is approximately 2.5, which approximates values to be expected in cable insulations. It is thought the test set-up, by reducing ionization, may have more nearly represented a cable structure than it did a generator coil structure.

RELATION BETWEEN INSULATION RESISTANCE AND DIELECTRIC STRENGTH

Since the ultimate objective of this investigation has been to determine a test method or a group of tests which could be used to determine the true quality of generator insulation with regard to its ability to withstand high voltage, much time has been spent in attempting to find a relation between dielectric strength as determined by a-c and d-c breakdown and various d-c insulation resistance measure-

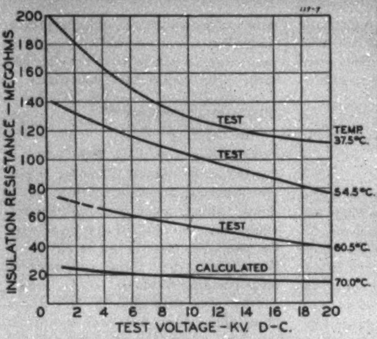

Figure 7. Insulation resistance versus test voltage at different winding temperatures

30,000-kw turbogenerator, 6.6 kv, 25 cycles, 1,500 rpm

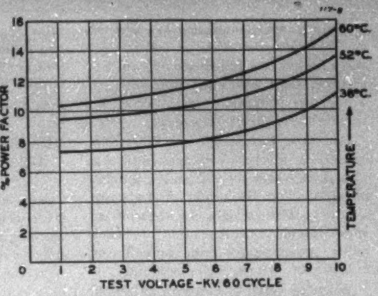

Figure 8 (right). Insulation power factor versus test voltage at different winding temperatures

30,000-kw turbogenerator, 6.6 kv, 25 cycles, 1,500 rpm

ments made at non-destructive voltages. In the early work, insulation resistance magnitudes were compared with 60-cycle breakdown strength on many coils. The investigation has been enlarged to include comparisons between insulation strength determined by a-c breakdown tests with dielectric absorption curve shapes and variations in insulation resistance characteristics at widely varying values of d-c voltage. Comparative insulation resistance and a-c breakdown tests have also been made under many conditions of deliberate mechanical damage to the insulation.

At present, no claim can be made that the ultimate objective has been attained. Comparisons between single insulation resistance measurements and dielectric strength seem to have little or no value and, under certain circumstances, the insulation resistance at moderate d-c voltages has been found to increase after the winding has been punctured on an a-c high potential test.

Location of Dielectric Failures

Stator winding insulation failures on breakdown tests occurred frequently at the end-turns. In some machines several coils were punctured, using both a-c and d-c, without a single failure occurring in the slot section. As indicated in table II the insulation strengths varied widely but invariably if a number of coils were tested, it was found that the weakest portion of the winding structure was at the end-turns.

Most end-turn failures occurred from the winding to the supporting brackets which always involved a flash through a short air gap. The insulation recovery after these failures was such that insulation resistance measurements did not detect any change in the winding characteristics. The failures which occurred in the slot sections appeared at the end of the slot or at the edge of an air duct in the stator iron. It is possible that ionization or swelling of the insulation at these points caused damages which reduced the dielectric strength but we have not been able to confirm the predominating cause. Very few machines have shown severe distress as a result of corona. In the few cases where effects of corona have been noted, the class *A* outer layer only has been affected. There has been no case where direct injury to mica insulation due to corona action has been discovered.

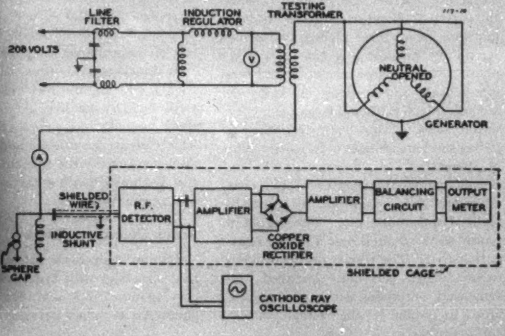
VIII—Conclusions

1. The industry will obtain increased value from its insulation testing if the known causes for variations in the results are carefully taken into account.

2. Insulation resistance varies widely with type and speed of machine, type and condition of winding, degree of cleanliness, temperature, moisture content, and extent of d-c charge on the winding. "Spot" readings, particularly, may be misleading unless carefully corrected for various factors affecting the reading. However, periodic

Figure 9 (left). Ionization detection apparatus ready for use

Figure 10. Connections of apparatus for measurement of ionization intensity in generator windings



readings may indicate a trend of the general condition of the insulation.

3. There is at present insufficient data to permit accurate correction of insulation resistance readings for all factors affecting these readings.

4. Slopes of the resistance-time curves may be of value as an indicator of insulation condition. They are satisfactory indices of excessive moisture content in the insulation.

5. Insulation resistance-time curves are extremely useful to indicate the progress of winding dry-out.

6. Comparisons of insulation resistance-time curves taken at widely different d-c voltages may prove of value in determining insulation condition.

7. The voltage effect on winding insulation resistance appears to be greater as the winding temperature is reduced, or as the moisture content is increased.

8. Power factor tests have given little indication of value in locating faults or incipient faults in generator windings. However, power factor measurements may prove to be an indicator of the trend of the general condition of the insulation including moisture content in a given machine if records are kept of periodic readings.

9. Sixty-cycle ionization tests have given no indication of value in predicting generator insulation condition or locating weak spots in windings.

10. D-c/a-c (rms) relative dielectric strength of generator insulation appears to approach $\sqrt{2}$. Additional tests must be made to establish this more accurately.

11. Dielectric strengths of old armature windings have been found to be generally high.

12. The end-turns of old generator windings appear to be weaker dielectrically than the slot sections.

13. Preferably, field windings should not be stressed to more than 500 volts d-c in routine testing.

Synopsis: The quality of electric service as reflected through variations in motor speeds resulting principally from voltage surges is about as important to many manufacturing processes as is the continuity of such service. This paper sets forth the effects of voltage surges on an extremely speed-sensitive manufacturing process and describes how the effect can be minimized to the extent of becoming harmless. Test data are given which show the effects of voltage surges, of varying duration and magnitude, on the process, and the voltage surge is shown engraved in the finished product as the purchaser sees it. The maximum tolerable driving motor speed variation, without impairment to the product, is established and means are described for preventing a greater variation irrespective of the voltage surge intensity. An alarm system is described which is capable of instantly responding when variations in speed exceed tolerable limits. Use of a synchronous condenser, to supply energy during the interim of severe voltage disturbances or brief power failures, is effective in preventing motor-speed variations from exceeding the tolerable limits. These and other recent improvements will provide highly reliable electric service for the requirements of those manufacturing processes which are very exacting as to speed variations.

ACCORDING to reliable statistics, approximately 85 per cent of automatic interruptions to overhead power circuits result from transient disturbances which are removed within a fraction of a second after the circuit is de-energized, leaving the circuit undamaged. Experience backed by tests conducted in various classes of industrial plants has established the fact that power failures of from one-half to one second duration do not constitute a failure of service, provided the energy stored in current consuming apparatus is utilized during the interim such apparatus is disconnected from the normal power supply. It follows, therefore, that when a power circuit is interrupted from transient causes, if reconnected to the normal power source quickly enough, an interruption to service is averted. Under this practice the circuit breaker employed for controlling the power circuit, in effect, becomes a device which removes disturbances from the power system without impairing service. This paper describes the use of circuit breakers in this manner, together with related factors in the order of their contribution to the improvement in reliability and quality of electric service.

I. High-Speed Circuit Reclosure

A series of tests was made on the Georgia Power Company's system in June 1931 for establishing the feasibility of high-speed circuit reclosure. An automatic circuit breaker reclosing relay, providing for reclosing the breaker without delay after its initial tripping, was applied to a circuit breaker through which some 6,000 kw of industrial load was supplied over a 38-kv overhead circuit. The breaker controlling this circuit was capable of making the complete operation, from closed position to open and closed position again, in about 40 cycles. (All references to frequency are on a 60-cycle basis.)

Time-delay undervoltage-type push-button stations were installed for controlling several motor contactors in one of the textile plants served from this circuit, replacing conventional instantaneous-type push-button stations. The 38-kv circuit was then short circuited several times by drawing pieces of fuse wire across phases. In every test the arc was extinguished by the circuit breaker opening and did not restrike when the circuit was reconnected to the power source, after having been disconnected for about 40 cycles. All motors in the plant equipped with instantaneous-type push-button stations were shut down from the voltage disturbances, but those controlled by the time-delay undervoltage devices continued in operation. The maximum speed drop of these particular motors which were driving twisting frames varied between 10 and 15 per cent during the interim. According to textile experts these speed variations did not appreciably lower the quality of the yarn, and the strain on the motors appeared to be less severe than restarting them from a standstill.

The tests attracted considerable interest and new reclosing relays, or modified conventional reclosing relays, were developed for this new reclosing practice, which was quickly adopted by several power companies in the Southeast.

High-speed circuit reclosing with a duty cycle of 0–15–120 seconds was applied on most of the circuit breakers controlling overhead circuits on Georgia Power Company's system. Certain motor operated breakers necessitated delaying the second reclosure for 45 seconds or more, in order to provide time for the operating mechanism to relatch after tripouts immediately following the first reclosure. After about 15,000 automatic operations of circuit breakers equipped for high-speed circuit reclosure, not one breaker failure has been traced to this reclosing practice.

An early obstacle to the application of high-speed circuit reclosing was the time required for certain types of protective relays to part contact after closing to trip the breaker. The geared-type relays, in particular, then required about three-fourths of a second to part contact and obviously would retrip the breaker upon the initial reclosure. New contact arrangements providing for contact separation in one-fourth second or less were employed.

More than 12,000 interruptions to circuits supplying loads varying from a few hundred kilowatts up to 25,000 kw have been prevented on the Georgia system through the medium of high-speed circuit reclosure during its ten years' use, the effects of circuit tripouts being no more harmful than ordinary voltage surges. Below is a table showing the ten years' performance of certain circuits equipped for high-speed reclosure:

Number of Circuit Tripouts	10,090	100%
Successful Reclosures:		
1st instantaneous	8,400	83.25%
2nd 15–45 seconds	1,084	10.05%
3rd 120 seconds	143	1.42%
Circuit Lockouts	533	5.28%

Actually, the proportion of successful first reclosures including all operations is

Paper 41-164, recommended by the AIEE committee on protective devices, and presented at the AIEE Southern District meeting, New Orleans, La., December 3–5, 1941. Manuscript submitted August 29, 1941; made available for preprinting September 24, 1941.

J. T. LOGAN and JOHN H. MILES are both with Georgia Power Company, Atlanta, Ga. 1. For all numbered references, see list at end of paper.

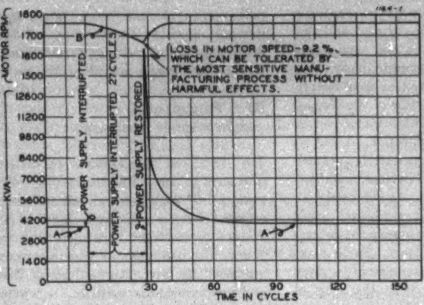

Figure 1. Results from oscillographic analysis of effectiveness of high-speed circuit reclosure in preventing interruptions

Note that load, curve *A*, after circuit tripout and reclosure is practically normal within one-half second after being reconnected to the power supply, and that the speed variation, curve *B*, of a 7.5-horsepower motor is negligible

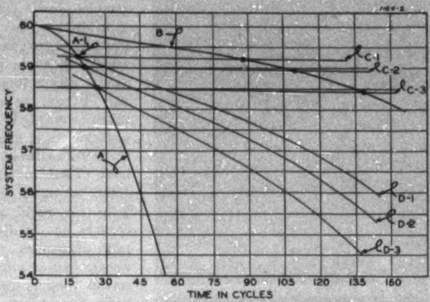

Figure 2. Inertia-relay operating characteristics

Curves *A* and *B* represent, respectively, speed changes for complete and partial loss of power source. Curves C-1, C-2, C-3, and D-1, D-2, D-3 represent, respectively, three of several possible relay-response slopes without and with the inertia element damped. The relay closes contact where slope, say C-1, crosses curve *A* or *B*

above 85 per cent instead of the 83.25 per cent shown, because the tabulation includes 2.3-kv and 4-kv circuits, the performances of which are hampered by tree grounds; and omits some 5,000 operations of 38-kv and 44-kv circuits supplied from automatic or semiautomatic stations where the records might be questioned for lack of devices capable of accurately recording the sequence of breaker operations.

Power consumers, particularly the industrial class, receive the greatest benefits from high-speed circuit-reclosing practices. According to records and observations a power failure, if for only a few seconds, stops completely or seriously curtails the average industrial plant output for five to ten minutes and in many cases as much as one-half hour.[1]

The portion of the load that actually "coasts through" the time required for clearing faults from and reconnecting the circuit to the power source varies, but when motor controls are adapted for this practice, as described under section II following, the service interrupted is negligible, the effects being no more harmful than disturbances that cause moderate light flicker. Figure 1 shows oscillographic results of a test for determining the amount of load actually interrupted during the interim the circuit is disconnected from the power source. The load was disconnected from the normal power source for 27 cycles during which time stored energy supplied the requirements. The fact that the magnitude of the load was practically normal within one-half second after being reconnected to the normal power source is proof enough that for all practical purposes there was no service interruption.

II. Application of Time-Delay Undervoltage Devices

Control apparatus usually supplied with motors incorporates undervoltage protection for the larger or more important motors. Unless specified by the purchaser, this protection is generally of the instantaneous response type and will shut down the motors for voltage dips on the power supply.[2,3] This necessitates restarting the motors after each voltage dip, with resulting loss in production and, in many cases where continuity is essential, of upsetting the entire process for extended periods of time with consequent heavy loss in raw material. Application of suitable time-delay undervoltage protective apparatus will reduce such losses to the practical minimum.

This improved type of undervoltage protection is becoming standard practice, the older instantaneous types having proved entirely unsatisfactory for use on important motors supplied from large interconnected power systems, because of the large number of voltage surges resulting from atmospheric disturbances usually in the form of lightning or sleet. The great majority of these voltage disturbances are cleared from power systems within one second or less, or the fault is so far removed that the surge voltage at the particular location does not drop below 65 per cent of normal. Consequently, the disturbances should be of little concern when the motors are properly protected by time-delay undervoltage devices

Voltage surge tests conducted in many textile plants employing speed-sensitive manufacturing processes indicate that the drop in motor speed in event of a

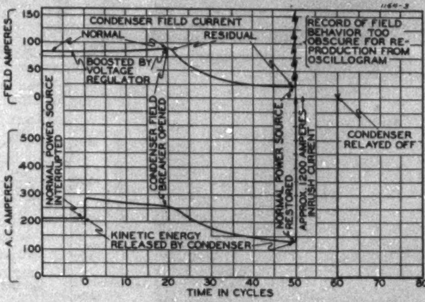

Figure 3. Graphic representation showing effects of high-speed circuit reclosure on synchronous condensers left connected to the circuit with the excitation source removed

Slow decay in field current makes this an unsafe practice. Condenser should be disconnected some 10 to 15 cycles in advance of restoring normal power source

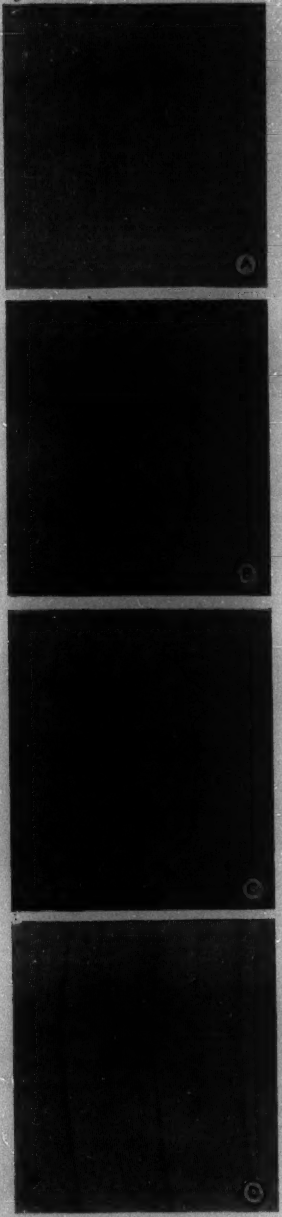

Figure 4. Swatches of hosiery tubing knit from yarn produced under conditions of repeated voltage surges imposed on the power supply

	Surge Voltage (Per Cent)	Surge Duration (Cycles)	Motor-Speed Variation (Per Cent)	Yarn Quality
A	60.0	61	2.2	Good
B	0.0	31	10.2	Good
C	14.7	61	13.7	Defective
D	13.5	122	27.9	Poor

complete power failure for one second is generally less than 20 per cent and that shutting down motors for such speed variations would do more harm than good, even ignoring the trouble of restarting. In fact, the practice of allowing essential motors to be shut down for voltage disturbances of any duration, so long as the motor continues to rotate, is questionable. There are links in many manufacturing processes that are adversely affected by rapid and prolonged speed changes, but usually stopping the process only aggravates matters. Such processes or links in processes should be given special consideration with the view of preventing objectionable voltage surges from being reflected on to the power source driving the particular motors. Means for accomplishing this are discussed under section V.

Continuity of operating through voltage disturbances is not essential, from the standpoint of production or quality of the product, for certain motors in most industrial plants. Whether these motors should be protected by time-delay undervoltage devices is a matter of individual consideration.

Synchronous motors, of course, require special consideration and generally should be disconnected from the line as quickly as possible following an out-of-step condition, unless the motor has excellent pull-in torque characteristics. Even then it would probably be better to provide field removal and restoring features and, possibly, automatic unloading devices.

III. Treatment of Synchronous Apparatus

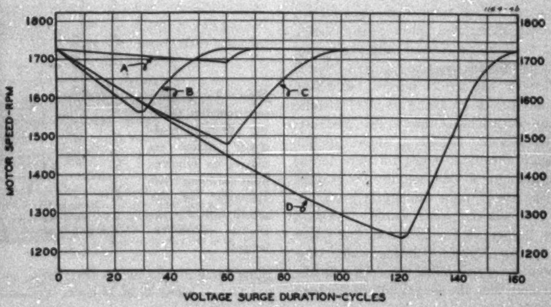
A 3,000-kva synchronous condenser connected to one of the circuits originally equipped for high-speed circuit reclosure required that the initial reclosing time be delayed to allow the fault more time to clear. The condenser in some instances prolonged the arc. An analysis of this problem revealed that suitable relays were not available for the purpose of removing the condenser from the line quickly enough, in order to avoid purposely delaying the initial reclosing time as much as one second or more, thereby defeating the purpose of high-speed circuit reclosure.

Reverse power and frequency responsive relays were tried but when adjusted to operate in about one-fourth of a second, the maximum allowable without purposely delaying the circuit initial reclosure, the condenser would often be unnecessarily disconnected.

In order to solve this problem, the authors developed a relay operating on a new principle, that is, the rate of speed or frequency change. This device, called an inertia relay, combines high speed response with reliability and is ideally suited for not only this application but for other uses discussed later.[4]

The relay differentiates between the relatively gradual rate of speed or frequency change on large power systems where millions of pound-feet[2] of inertia are involved and the rapid and erratic changes that occur on small portions of the system suddenly cut loose from the main power source and left without, or greatly deficient in, power supply.

Referring to figure 2, which shows the inertia-relay operating characteristics,



the relay can be adjusted to operate at any desired point along curve *A*, say at point *A*-1, for disconnecting synchronous condensers or an overloaded generating plant from circuits equipped for high-speed reclosing, this being accomplished in time to allow reconnecting the circuit to the system without delaying the reclosure. The maximum speed change expected on a power system under conditions of ordinary frequency disturbances follows some line usually well above curve *B*, to which the inertia relay will not respond if adjusted to operate on the slope represented by characteristic curves *D*-1, *D*-2, *D*-3 or some other of this family of curves. The relay can be adjusted to operate on the slope represented by curves *C*-1, *C*-2, *C*-3, and so on, if desired by simply lessening the damping effect on the inertia element. Also, the relay can be adjusted to respond within ten cycles or less for curve *A*. However, this would usually be undesirable because of waste in the kinetic energy stored in the rotors of spinning capacity so disconnected.

One of these relays is employed on the Georgia system for sectionalizing a 45,000-kw load in a manner for leaving load within capacity on a local 16,000-kw generating plant when the primary power source, a 110-kv transmission line, is involved by transient disturbances.[4] The relay detects the loss of the 110-kv source and accomplishes sectionalization in time to permit high-speed circuit reclosure to the transmission line without intentional delay, thus avoiding interrupting any portion of the load for transient faults involving the 110-kv source.

Five synchronous condensers and five small automatic hydroelectric plants connected to circuits equipped for high-speed circuit reclosure are also supervised by these relays. Four other installations for similar purposes are now under way.

Incidentally, the relay in addition to sectionalizing the 45,000-kw load area referred to above has proved to be faster and more positive than protective relays in disconnecting the faulted 110-kv line from the hydroelectric plant in time to prevent "swamping" the plant. This could not be done satisfactorily with conventional power directional relays, consequently, two other applications of the inertia relay for similar purposes are being studied.

Whether to disconnect synchronous condensers operating on circuits equipped for high-speed reclosure or to remove their sources of excitation only, during the interim the circuit is disconnected from the power source is a question frequently referred to the authors. Figure 3 shows the results of removing the excitation source only, and indicates that the magnetic energy stored in the machine is not dissipated in the field discharge resistor rapidly enough to make this a safe practice.

IV. Variation Tolerance in Motor Speeds

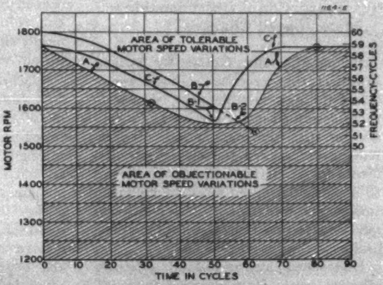
The foregoing sections of this paper deal primarily with improving the quality of electric service by reducing what otherwise would be momentary interruptions to electrical disturbances no more harmful than ordinary voltage surges.

Moderate voltage disturbances can be tolerated by the majority of users of electric service without harmful effects. However, some manufacturing processes are adversely affected from voltage surges to the extent that precautionary measures must be taken for minimizing the effects. In many instances the effects of voltage disturbances have been considered so damaging to the finished product that a local power supply is provided in preference to accepting the consequences of voltage surges that accompany electric service supplied from large transmission systems. A few of the processes which are unusually sensitive and adversely affected by voltage disturbances are employed in the manufacture of rayon and silk; high quality cloth; pulp and paper; broadcasting stations; printing presses.

The damaging effects of voltage disturbances are transmitted to the finished product generally through driving motor speed changes that result from the drop in voltage. Realizing the seriousness of this problem the authors have conducted extensive tests jointly with industries served by Georgia Power Company for the purpose of establishing what might be called a voltage "tolerance factor." The precision with which such a tolerance factor has been established for an unusually delicate or speed-sensitive process should be of interest, particularly to those who question the ability of a power system, subject to frequent lightning storms, to render satisfactory service to industries employing processes which require almost constant speed.

The test procedure provided for spinning yarn while the spinner driving motor power supply was being subjected to repeated artificial voltage disturbances of varying intensity and duration. Oscillographic records of the voltage disturbances and motor speeds were obtained for each series of tests and the yarn marked in a manner for identifying that made under each of four surge test conditions. The quality of the yarn with respect to variations in size and dyeing characteristics, was determined with uncanny accuracy by textile engineers. So accurate were the methods employed, that the yarn size could definitely be tied in with the motor speed, even to the extent of distinguishing that produced during the period of decreasing motor speeds from that produced during the period of accelerating speeds which followed immediately the restoration of normal voltage.

Sections of the four batches of yarn produced under power surge conditions were next knit into hosiery tubing and dyed in a sensitive shade for bringing out dyeing defects. Figure 4 is a reproduction of a photograph of the swatches of hosiery tubing which were knit from yarn spun during the four surge tests. Associated with each swatch is a motor speed curve, corresponding alphabetically with the swatch designation, showing the motor-speed variation for each artificial voltage surge which was repeated every 20 seconds during the test. The effects of the voltage surges as reflected through the driving motor can be seen as bars, faintly in swatch *C* and clearly in



Motor-speed variations in the area above curve *A*, do not damage material produced under extremely speed-sensitive processes. Curve *B* represents the frequency produced by a 2,000-kva synchronous condenser when supplying 2,700 kw of load. Curve *C* represents speed of motors so driven. Load was disconnected from condenser at *B*-1 and reconnected to the normal power source; otherwise, motor speed would have followed trend of *B*-2

Figure 5. Tolerable and objectionable motor-speed variations

swatch *D*. The yarn produced under surge conditions represented by swatches *A* and *B* is classed as normal production by the textile engineers.

A summary of conclusions reached after analyzing the test results follows:

1. The principal interest of the textile company in regard to the effects of electrical disturbances may be measured by the degree to which the spinning machine driving motor speed is affected. Motor-speed variations of not more than 10 per cent in one-half second can be accepted without great concern. Motor-speed variations of 15 per cent during a one-second period lead to variations in yarn size and dyeing disturbances which may be considered objectional. Speed variations on the order of 25 to 30 per cent during a two-second interval lead to pronounced loss of dye quality, due to marked variation in yarn size.

2. A signal system responding to motor-speed changes greater than that tolerable could be employed to advantage for advising the spinning production supervisor that yarn being spun was outside acceptable limits and should be segregated from regular production.

3. Voltage disturbances which do not reduce the driving motor torque below the pullout value are of little concern as the motor slip is increased less than ten per cent. Disturbances that reduce the torque below the pullout value, usually about 65 per cent normal voltage, must be limited to one-half second if the yarn spun is kept within acceptable limits.

4. The effects of voltage disturbances can be reduced to tolerable limits by means of high-speed clearing of faults, or the use of synchronous apparatus for maintaining voltage during system disturbances, to a value above the motor pullout point.

The signal system referred to in (2) above would require an initiating relay of unusual accuracy; otherwise yarn outside acceptable limits might get through unnoticed until too late, thereby causing a large shipment to be rejected as being outside acceptable limits. The inertia relay is ideally suited to initiate a signal for this purpose.

V. Prevention of Objectionable Motor-Speed Changes

Voltage-tolerance factors for various manufacturing processes can be established through suitable tests, similar to those described under section IV in connection with the manufacture of yarn. Having determined the voltage requirements for rendering satisfactory service to a particular speed-sensitive manufacturing process, means for restricting motor-speed variations to within tolerable limits can be considered.

High-speed clearing of faults offers an effective means for preventing damaging motor-speed changes. It was determined from tests described under section IV that zero voltage for one-half second was not objectionable in this particular extremely speed-sensitive process, in that the quality of the yarn was not appreciably lowered by subjecting the spinning motor power source to repeated power failures of one-half second duration. Refer to *B*, figure 4. For reasons more attractive than the prevention of damaging motor-speed variations, high-speed clearing of faults on transmission networks is very desirable and in many instances essential in order to promote system stability and reduce damages from power arcs. Unfortunately, however, this means for preventing motor-speed variations cannot be universally applied, principally because of fuse coordination problems which are encountered on most power circuits supplying industrial plants.

Objectionable motor-speed variations resulting from voltage disturbances reflected on to industrial plant power sources from the transmission system can be prevented where local generation is available and at a very reasonable cost. This may be accomplished by inserting a reactor between the plant bus and the transformer bank connecting the plant to the transmission system. The impedance of the reactor should be such that the local generating source can maintain voltage on the plant bus in excess of motor pullout values, usually about 65 per cent normal. Such an arrangement would limit motor-speed changes during the time of voltage disturbances on the transmission system to less than ten per cent or to within tolerable limits for even the most delicate or speed-sensitive manufacturing processes. Refer to *A*, figure 4. The reactor should preferably be normally short circuited by a high-speed circuit breaker controlled automatically by the transmission system voltage The circuit breaker should be opened only when the transmission system voltage, as measured on the transformer side of the reactor, is below motor pullout values.

Synchronous condensers offer a reliable means for preventing objectionable motor-speed variations. Kinetic energy stored in condenser rotors is generally sufficient for supplying a load equal to the kilovolt-ampere rating of the condenser for one second or more before the frequency drops to a value detrimental to speed-sensitive processes. This would involve high-speed switching, the load and synchronous condenser being disconnected from the main power source the instant the bus voltage dropped below motor pullout values. When voltage returned to normal on the main power source, the condenser would be disconnected from the load a few cycles in advance of transferring the load back to the main power source The condenser would then be returned to normal operation in the usual manner, preferably by automatic means

Figure 5 shows results when supplying 2,700 kw of load from a 2,000-kva synchronous condenser for 50 cycles, curve *B* representing the frequency supplied by the condenser. Motors driven from the synchronous condenser followed curve *C* which remained above curve *A*, the boundary of tolerable motor-speed variations for unusually speed-sensitive manufacturing processes. The condenser was disconnected from the load at *B*-1, a few cycles in advance of reconnecting the load to the main power source. Transfer of the load from the failing power source to the synchronous condenser and back again to the normal power source was accomplished smoothly by automatic control means. The voltage regulator controlling the condenser excitation prevented the bus voltage from dropping below 80 per cent normal which was well above the motor pullout value.

The use of synchronous apparatus connected to circuits equipped for high-speed reclosure for reducing voltage and frequency disturbances during the interim the circuit is disconnected from the normal power source is standard practice on the Georgia Power Company system. This practice is made possible through the inertia relay development which provides for positive isolation of the synchronous apparatus a few cycles in advance of reconnecting the circuit to its normal power source. The result gives the appearance of a short interval of reduced rather than apparent zero voltage. Best results are had by keeping the synchronous apparatus connected to the load until some 10 to 15 cycles prior to the restoration of the normal power source Reference to figure 3 shows that by this practice a great deal of kinetic energy can be fed into the load from synchronous machines thereby reducing the severity of voltage disturbances.

High-Pressure Gas as a Dielectric

GORDON C. NONKEN
ASSOCIATE AIEE

Synopsis: Impulse and 60-cycle breakdown strength of sphere gaps, rod gaps, and of samples built up of solid and fluid dielectrics are reported. The tests were made in nitrogen up to 200 pounds per square inch gauge pressure and in Freon up to 70 pounds per square inch gauge pressure. Dielectric strength values were compared with the breakdown of transformer oil between the same electrodes. Gap conditions were found for which the 60 cycle breakdown was twice its impulse breakdown.

RECENT interest in the dielectric strength of gases under pressure has been stimulated by the steadily increasing voltages used in power transmission as well as in X-ray and atomic physics work and by the shortcomings of atmospheric air and of oil insulation. Although scores of articles have been published on high pressure gas dielectrics during the last forty years, they contain practically no information on the impulse dielectric strength of gases at high pressure. This is a serious omission from the point of view of those interested in generating and distributing apparatus since the kind and amount of insulation in these apparatus are influenced greatly by impulse strength. The theoretical background related to the breakdown of gaps in gases is much too incomplete to permit the extrapolation of available data much beyond the exact conditions under which the data were obtained. Therefore, numerous general as well as specific breakdown data must be accumulated in order to make the proper utilization of high pressure gases as dielectrics.

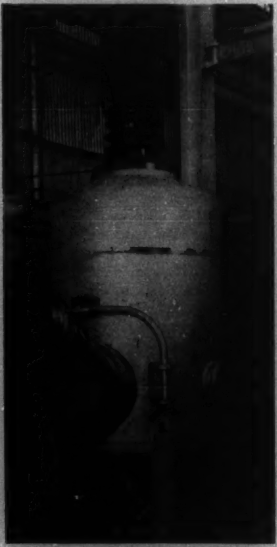

Figure 1. High-pressure electric test tank

This paper will present impulse and 60-cycle breakdown data between gaps in nitrogen up to 200 pounds pressure and in dichlorodifluoromethane (dichlorodifluoromethane, commercially known as "Freon" will be referred to in this paper as CCl_2F_2) up to 70 pounds gauge pressure. In each case, a comparison will be made with the breakdown of transformer oil at atmospheric pressure between the same gaps.

Recent Work

Several valuable contributions have been made to our fund of engineering knowledge of high pressure gas dielectrics during the last decade. Paschen's law, which was looked upon by many as a basic law of the dielectric strength of gaps at different spacing and pressure, has been shown to diverge far from the data at pressures above about six atmospheres. This law states that the sparkover voltage of a uniform field gap in a gas is directly proportional to the product of the gap spacing and the absolute pressure. The breakdown of a fixed gap is lower than the breakdown predicted by Paschen's law at pressures above 100 pounds per square inch. In fact the data[1,2] indicate that for air tested between spheres at a pressure of 600 pounds per square inch the actual sparkover is 55 percent of that predicted from atmospheric pressure data by Paschen's law.

Some gases have been found[3] which have as much as three times the 60 cycle dielectric strength of nitrogen when tested in a uniform field at atmospheric pressure. Notable among them are CCl_3F with a dielectric strength of three times that of nitrogen and CCl_2F_2 the gas commercially known as Freon and in common use in mechanical refrigerators, with a dielectric strength of 2.4 times that of nitrogen at atmospheric pressure.

Most of the earlier dielectric strength tests were made at low pressure or small spacings. Recently d-c breakdown tests[3] on spheres have been made at pressures up to 600 pounds per square inch and 450 kv breakdown. These data show also how slight roughnesses of the electrodes reduce the breakdown by as much as 50 per cent at 600 pounds pressure. Other investigators[4] made test in air and nitrogen up to 1,700 pounds per square inch. They indicate that the rate of increase of dielectric strength of air with increasing pressure continues to decrease at least up to 1,700 pounds per square inch pressure. This and other work[5] indicate that although the dielectric strength of air and nitrogen are practically the same at atmospheric pressure, the dielectric strength of nitrogen increases less rapidly than that of air with increased pressure, particularly above 100 pounds per square inch.

Apparatus

The experimental data presented in this paper were obtained by tests in the special pressure tank shown in figure 1. The pressure tank is four feet in diameter by seven feet high. Although it was tested hydrostatically up to 400 pounds per square inch pressure, it has not been used above 200 pounds gas pressure for safety reasons. It has three five-inch diameter sight windows made of discs of

1. For all numbered references, see list at end of paper.

methyl-methacrylate and an 18 inch steel door. A single high voltage bushing was used to carry the voltage into the pressure tank. This bushing was of the oil-filled type with a porcelain shell. The bushing was the same size both inside and outside the tank so that it could be used at maximum voltage with atmospheric pressure in the tank.

Two devices were used to adjust or change the electrodes inside the tank without opening the tank. One consisted of a screw which was operated by a shaft passing through the tank wall to a calibrated hand wheel. The gap electrode was mounted on the end of the screw and could be spaced accurately from the outside of the tank. The other consisted of a revolving platform installed in the bottom of the tank. The test samples which were made up of solid and gaseous dielectrics were good for only one breakdown determination. As many as twelve of these solid dielectric samples were placed on the revolving platform. These samples were connected, one at a time, to the voltage source by turning the turn table in the proper position with a driving mechanism which ran through a packing gland in the tank wall. These mechanisms saved a large amount of time by avoiding the necessity of opening the tank after each test.

Gases used were of a commercial grade obtained in high pressure tanks. The nitrogen was dried by passing it through a trap surrounded by liquid air. The CCl_2F_2 with high liquefying temperature was dried in columns of calcium chloride.

The CCl_2F_2 was drawn from the test tank through a compressor which recondensed the gas into its liquid phase and pumped it into a high pressure storage tank for future use.

The 60 cycle test voltage was supplied by a 350 kv, 1,000 kva testing transformer. The voltage was varied by controlling the field on the alternator connected to the testing transformer. The impulse voltage was supplied from a 500 kv impulse generator. The impulse voltage wave shape was checked and the breakdowns were observed with a cathode ray oscillograph connected across the test electrodes through a resistance divider. All impulse data presented herein were obtained with a $1^1/_2$–40 microsecond impulse wave.

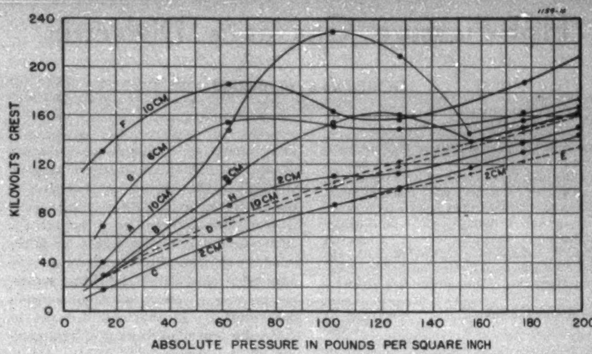

Figure 4. 60-cycle and impulse breakdown between one-half-inch square rod gaps in nitrogen

Curves *A*, *B*, and *C* = 60-cycle breakdown

Curves *D* and *E* = 60-cycle corona starting voltage

Curves *F*, *G*, and *H* = impulse breakdown

Test Results

Breakdown tests were made with the following three types of electrodes:

1. 6.25 centimeter diameter brass spheres.
2. Standard $^1/_2$ inch square brass rod gaps and
3. Electrode arrangements which included solid dielectrics.

The results of experiments made between the 6.25 centimeter spheres are summarized in figure 2. These data show the dielectric strength of nitrogen to increase as the 0.86 power of the pressure instead of increasing as the first power of the pressure in accordance with Paschen's law. The dielectric strength of CCl_2F_2 increases at a slightly smaller power of the absolute pressure than does the dielectric strength of nitrogen.

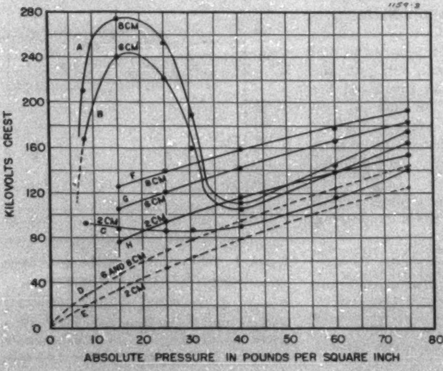

Figure 3. 60-cycle and impulse breakdown between one-half-inch square rod gaps in CCl_2F_2

Curves *A*, *B*, and *C* = 60-cycle breakdown

Curves *D* and *E* = 60-cycle corona starting voltage

Curves *F*, *G*, and *H* = impulse breakdown

These gas breakdown curves represent both the crest value of the 60 cycle breakdown voltage and the crest value of the impulse voltage breakdown with a $1^1/_2$–40 microsecond voltage applied. The 60 cycle tests were made by increasing the voltage at a rate such that the voltage increased from approximately half of breakdown voltage to breakdown in one minute. An elapsed time of one minute was allowed between successive voltage applications. The average of ten breakdown determinations was used to establish a single datum point. The maximum spread of individual values was rarely over five per cent for the 60 cycle tests.

The impulse tests were made by applying five impulses of the same voltage at five or more steps two per cent apart in voltage, above and below the breakdown voltage. The voltage was lowered in two per cent steps until none of the five impulses broke down the gap. The voltage was also raised in two per cent steps until each of the five impulses at a particular voltage broke down the gap. The statistical voltage at which half of the impulses resulted in breakdown was taken as the breakdown value of the gaps. The maximum spread of individual values was with few exceptions not greater than eight per cent of the breakdown value.

Observations showed that the breakdown of a gap was lower immediately after a breakdown. Therefore a procedure was followed such that a five minute interval elapsed between a flashover and the succeeding impulse application. Only one-minute interval was used after a voltage application that did not result in breakdown of the gap before another impulse was applied. This spread in the impulse data was probably increased by the fact that there was no effort to increase the free ion concentration within the tank by radioactive salts or an ultra-violet light source.

Breakdown of 6.25 centimeter spheres spaced one centimeter apart in 10-C transformer oil is plotted here for comparison. The oil breakdown tests were made at atmospheric pressure only. The transformer oil had a 60 cycle breakdown of 33 kv in a standard oil test cup with 0.1 inch gap spacing. The impulse strength of transformer oil with a $1^1/_2$–40 microsecond wave is slightly over two times its 60 cycle dielectric strength, while the impulse and 60 cycle breakdown strength of spheres in the high pressure gases are the same.

Rod-Gap Tests

Requirements of commercial high voltage apparatus other than the electrical insulation strength often dictate that the conductors adjacent to the insulation be made of some other shapes than spheres or curvatures of large radii. The standard $^1/_2$ inch square rod gap was therefore chosen for test electrodes to characterize the more severe conditions of non-uniform field encountered in high voltage apparatus.

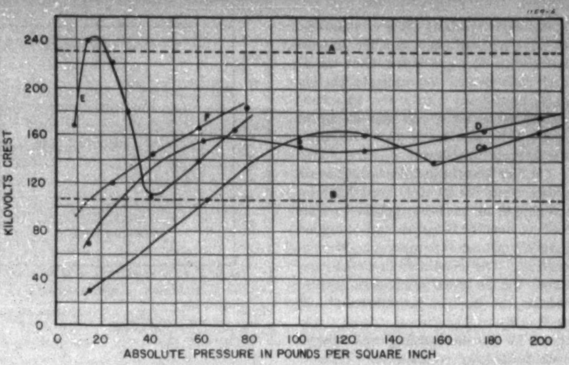

Figure 5. 60-cycle and impulse breakdown between one-half-inch square rod gaps spaced six centimeters in nitrogen, CCl_2F_2, and transformer oil

Curve *A* = impulse breakdown in oil
Curve *B* = 60-cycle breakdown in oil
Curve *C* = 60-cycle breakdown in nitrogen
Curve *D* = impulse breakdown in nitrogen
Curve *E* = 60-cycle breakdown in CCl_2F_2
Curve *F* = impulse breakdown in CCl_2F_2

60 cycle and impulse breakdown tests were made on this $^1/_2$ inch rod gap mounted in a vertical plane in the high pressure test tank, figure 1. Tests were made with both 60 cycle and $1^1/_2$–40 microsecond impulse voltages in nitrogen and CCl_2F_2 at various pressures and gap spacings. Figures 3 and 4 give the results of these tests. The corona starting voltage shown on figures 3 and 4 was taken by means of a cathode ray oscillograph which received its voltage from a high frequency amplifier placed across a shunt in series with the test gap

The 60 cycle breakdown of the rod gaps does not steadily increase with pressure. Figures 3 and 4 show how the breakdown voltage increases with pressure up to a critical pressure and then decreases with further increase in pressure until the breakdown of the gap is only slightly above the corona starting voltage of the gap. This critical pressure in the case of nitrogen is about 100 pounds per square inch gauge, while for CCl_2F_2 the critical pressure is only a few pounds above atmospheric pressure. The critical pressures are lower than those found by other investigators[1,4] on tests with point-plain electrodes. Goldman and Wul found the critical pressure for nitrogen to be about 150 pounds per square inch as compared with 100 pounds as shown in this report.

 ⑤ 4" LEAD FOIL ELECTRODE PORCELAIN TUBE 1" DIA. BY 1/4" WALL	60 CYCLE	102	100	78

The impulse breakdown of rod gaps in nitrogen and CCl_2F_2 under pressure has only a remote resemblance to the 60 cycle breakdown curves. The impulse breakdown for rod gaps in nitrogen spaced at six and ten centimeters has a negative slope between 70 and 120 pounds per square inch, while the impulse breakdown of rod gaps in CCl_2F_2 increases steadily with increasing pressure. Figure 5 gives the impulse and 60 cycle breakdown of rod gaps spaced six centimeters apart in CCl_2F_2, nitrogen, and in transformer oil. The 60 cycle breakdown of CCl_2F_2 is about 2.2 times the impulse breakdown at atmospheric pressure. It is very unusual to have a condition where the impulse breakdown of a gap is less than the 60 cycle breakdown. For example, the impulse breakdown with a $1^1/_2$-40 microsecond wave for a rod gap in air at atmospheric pressure is about 1.8 times the 60 cycle breakdown.

The fact that the impulse breakdown is greater than the 60 cycle breakdown for rod gaps in air has been explained on the basis of time lag before the gap is ionized in such a manner as to make it highly conducting. The condition in CCl_2F_2 gas where the 60 cycle breakdown greatly exceeds the impulse breakdown should be worthy of additional study. The reason for this unusual increase in the 60 cycle breakdown is not clear. There is evidence that the space charge in the gap is responsible for this unusually high breakdown.

Solid-Fluid Dielectric Combinations

Five different arrangements of solid and fluid dielectrics were tested for breakdown when immersed in 10-C oil, nitrogen, or CCl_2F_2. Schematic arrangements of the dielectrics and a comparison of voltage breakdowns are made in table I. Extreme care was taken in preparing the samples for these tests to see that the oil samples were completely impregnated and free from bubbles and that the gas-filled samples were thoroughly vacuum-dried and kept dry until they were tested. All of these dielectric arrangements have very non-homogeneous fields. The dielectric constants of the paper, pressboard, and porcelain used in these tests are all two or more times as large as the dielectric constant of transformer oil. Therefore, where the oil and solid insulation are in series, the oil must stand a disproportionately large part of the voltage stress. Since the dielectric constant of the compressed gases is substantially unity as compared with 2.2 for that of transformer oil, the voltage across the gas dielectric in series with solid insulation is considerably more than the voltage across the oil if it were made to replace the gas. This condition alone puts the gas dielectric to a considerable handicap when used in series with solid dielectrics.

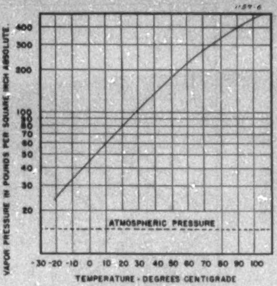

Figure 6. Vapor-pressure temperature curve of CCl_2F_2

It may be seen from table I that in general these combinations of solid and fluid dielectrics had higher dielectric strengths in transformer oil than they did in nitrogen at 200 pounds per square inch pressure or CCl_2F_2 at 70 pounds per square inch pressure.

Temperature Effects

High voltage apparatus filled with compressed gases may be subjected to a wide range of temperature either by virtue of their ambient conditions or by the heat liberated within them.

This change in temperature will change the dielectric strength of the gaseous dielectric in different ways according to the manner in which the gas is supplied to the vessel. The following are generalizations based upon theoretical considerations and checked experimentally for CCl_2F_2 between spheres.

(*a*). If gas were supplied in a manner such that a constant gas pressure was maintained, the dielectric strength of the gas would change inversely as the absolute temperature.

(*b*). If the total quantity of gas in the system is unchanged, the dielectric strength of the gas should remain unchanged with change in temperature. This follows from the fact that the dielectric strength of a gas is proportional to its density.

(*c*). If the gas is in a closed system similar to condition (*b*) but the gas is saturated and an excess of liquefied gas is present in the system, the gas pressure will change with temperature according to the vapor pressure of the gas at the particular temperature. The dielectric strength of the gas will change in such a system nearly the same as the vapor pressure of the gas. Vapor pressure of CCl_2F_2 is shown in figure 6. It is obvious that such a system has much greater change in dielectric strength of the gas with change in temperature than do the systems (*a*) and (*b*).

Summary

1. The impulse and the 60 cycle crest breakdown strength of nitrogen are substantially the same when tested between spheres at less than radius spacing; the impulse and 60 cycle crest breakdown strength of CCl_2F_2 are likewise the same. Nitrogen at 175 pounds per square inch absolute pressure, CCl_2F_2 at 62 pounds pressure and 10-C transformer oil at atmospheric pressure break down at the same impulse voltage when tested between 6.25 centimeter spheres spaced at one centimeter. Under the same conditions the 60 cycle breakdown voltages of the three fluids are the same with nitrogen at 80 pounds absolute pressure, CCl_2F_2 at 25 pounds absolute pressure, and 10-C oil at atmospheric pressure.

2. The fact that there is a condition where the 60 cycle breakdown of a rod gap in CCl_2F_2 is over two times the impulse breakdown of the same gap under the same condition is disturbing to the orthodox theory surrounding the electrical behavior of spark gaps in gases.

The 60 cycle breakdown between rod gaps is substantially higher in nitrogen above 60 pounds per square inch absolute or in CCl_2F_2 above atmospheric pressure than in transformer oil. On the contrary, the impulse breakdown between rod gaps is considerably lower in nitrogen under 215 pounds per square inch absolute pressure and CCl_2F_2 below 85 pounds per square inch absolute pressure than in transformer oil.

3. The breakdown strength of solid insulations tested in nitrogen at 215 pounds per square inch absolute pressure and in CCl_2F_2 at 85 pounds per square inch absolute pressure as compared to its breakdown in transformer oil indicates that with but one exception the tests made in transformer oil showed higher strength than when made in the gases at the above pressures.

An Automatically Reclosing Breaker for Co-ordinating Distribution Systems

H. L. RAWLINS
ASSOCIATE AIEE

J. M. WALLACE
ASSOCIATE AIEE

Synopsis: The increasing spread of distribution systems in which fault protection is afforded by fuses has resulted in long outages and high maintenance costs. Excellent coordination is possible with modern fuses, but their inability to differentiate between a permanent and a temporary fault results in frequent outages and costly service trips.

A new automatically reclosing circuit breaker with pronounced inverse time current tripping characteristics makes possible an improved radial distribution system in which outage and maintenance are reduced to a minimum. The effectiveness of coordination is increased to a point where an outage is confined to the immediate neighborhood of a permanent fault. Service trips are no longer necessary unless there is a permanent fault condition to be removed from the system.

Extended Distribution Systems Require New Type of Protective Equipment

IN recent years there has been a large increase in the number of distribution systems having long lines and small loads scattered over considerable territory. Such systems represent an increase in the use and application of electricity as well as affording users the benefits and conveniences of a reliable source of power. The continued extension and successful operation of these systems depends upon a low initial cost and a low maintenance cost.

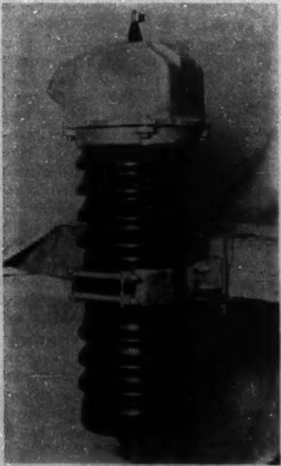

Figure 1. Single-pole automatically reclosing circuit breaker

The use of expensive lines and conventional apparatus for fault protection would result in low maintenance costs, but the installation cost could not be justified. Inexpensive lines with simple fuse protection for faults provide a low installation cost but result in high maintenance cost and unsatisfactory service. A high percentage of the maintenance cost of these extended systems is chargeable to the servicing required by faults. More than 80% of all faults are temporary and will not prevent the immediate restoration of service, so the elimination of service trips on such faults will materially reduce maintenance costs. The successful extension of such systems, therefore, depends upon the low installed cost of a device that will interrupt all faults and then restore service after all temporary faults.

The fault currents on these systems are relatively low and of such a value that distribution cutouts are used for sectionalizing, even to the use of five or more cutouts in series. The excellent coordination possible with modern fuses permits definite restriction of outages to the immediate neighborhood of a fault. On such systems, outages are of long duration and their restriction to limited areas greatly increases the quality of service. Therefore, a further requirement for a device to provide fault protection on such systems is its adaptability to an extensive coordination scheme. This will be accomplished if the device has a time current characteristic approximating that of modern fuses.

The necessarily inexpensive construction used on these systems, together with their length and exposure, has multiplied the number of faults to the point where simple fuses are inadequate for sectionalizing duty. Repeating fuses reduce the necessity for immediate service trips but require a periodic servicing and may not differentiate between a permanent and a temporary fault due to their short reclosing time. Close coordination is not dependable with repeating fuses, for a fuse is a thermal device and the heat stored in a protected fuse may result in its melting upon repeated operations of the fuse protecting it. It is seen, therefore, that an additional requirement is a time current characteristic which is not affected by repeated operations of the preceding protective device.

Since only a limited interrupting capacity is required, it is possible to make an inexpensive automatically reclosing oil circuit breaker to fulfill all of the requirements for operation on extended distribution systems. The requirements are:

1. Adequate interrupting ability.
2. Automatic reclosing to permit restoration of service after a temporary fault.
3. Pronounced inverse time current characteristic to permit close coordination on an extensive system.
4. Consistent time delay on tripping which is not affected by previous circuit conditions.
5. Reliable operation and low oil deterioration to reduce service trips to a minimum.
6. Low cost and a light weight to reduce the total installed cost to a minimum.

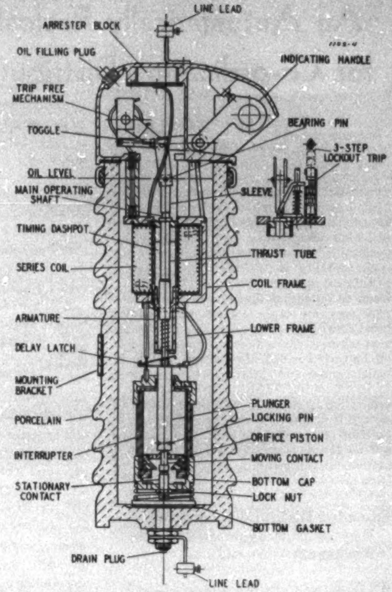
Figure 3. Indicating handle, oil gauge, and operation counter grouped under protecting hood

Figure 4. Sectional view of breaker with side view of lockout trip



7. Complete self protection in that no overload current (within the interrupting rating) or surge voltage shall damage the device.

From the application viewpoint the most important of these requirements is the inverse time current characteristic. The coordination possible with a breaker having the proper time characteristic greatly increases the scope of its application and makes possible the economical extension of low capacity distribution lines.

Construction and Operation of New Breaker

All of the above application requirements are fulfilled by the single pole automatically reclosing circuit breaker shown in figure 1. In addition, it has many other inherent features such as trip free closing; immediate manual reclosing after lockout; lockout on first interruption when manually reclosed against a fault; and multitap coil to permit ready change in rating. The interrupting chamber and all operating parts are easily removed in one unit as shown in figure 2. The indicating handle, oil gauge, and operation counter are grouped under an integral protecting hood, as shown in figure 3.

Figure 4 is a cross sectional view showing all principal elements of the breaker. The breaker is normally biased closed by the contact pressure springs, except during lockout. This differs from more conventional breakers in that, on tripping, the contacts are forced apart against spring pressure instead of being opened by accelerating springs. The energy required to operate the breaker is obtained from a series coil. The small size of coil used to operate the breaker and continuously carry overload currents just below the minimum tripping current is made possible by using an efficient type of interrupter that requires only a short travel. Wide separation of the contacts on lockout is obtained by releasing a spring that opens the breaker in the conventional manner and is reset, on closing, by means of the handle. Additional energy to interrupt heavier currents is obtained from the interrupter itself after the initial separation of the contacts.

Referring to figure 4, the armature when actuated by an overcurrent through the series coil moves upward and forces the entrapped oil from the timing dashpot. This action provides the inverse time characteristic on tripping. The shape of the time current curve is a function of dashpot size and port area together with the magnetic circuit and other factors. After a predetermined travel, the dashpot is opened, permitting the free armature to drive the moving contact open against the contact pressure springs. The moving contact opens rapidly for a short distance and then picks up the orifice piston which forces oil into the arc path resulting in interruption at the end of the first half cycle after the orifice piston starts to travel. On high currents the pressure developed within the interrupter will produce an additional driving force on the plunger thereby forcing oil into the arc path under a pressure proportional to the value of current being interrupted. The moving contact is free to move upward through the armature thus permitting overtravel on high current interruptions. The moving contact is prevented from reclosing at once by the delay latch which is not released until the armature again reaches its starting position. This results in a reclosing time of approximately five seconds. The time interval before reclosing permits the escape of gas from the top of the interrupter and entrance of fresh oil into the bottom. This flushing takes place through washer type valves that close instantly upon the appearance of pressure during interruption.

There is provided a simple, three step lockout trip which is notched up by the travel of the armature during each interruption. On the third interruption it breaks the toggle that holds the trip free mechanism in the closed position, thereby permitting the contacts to be driven to the extreme open position. The manual

Figure 5. Interruption of 1,120 amperes at 13,800 volts

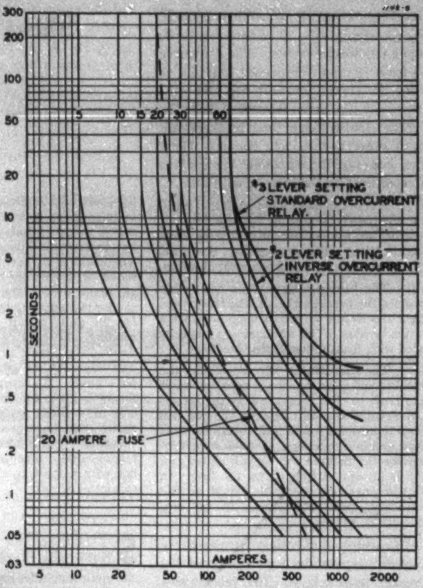

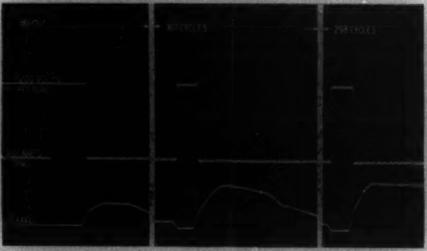

Figure 7. Three interruptions and lockout, 476 amperes at 7,200 volts

Note the travel ofthe contacts to the full open position after final interruption. (Portionsoffilmshowing breaker open between reclosures have been deleted from the original eight-foot film)

return of the indicating handle to the closed position will reset this toggle and the lockout trip and permit the breaker to close after the usual time delay. The lockout trip will be reset only to its second position from which it will lock out the breaker if there is a further interruption. If the fault has been removed from the line, the lockout trip will slowly reset to provide three step lockout on subsequent faults.

The series coil is made up of four separate windings. By connecting these windings in series, series-parallel, and parallel it is possible to obtain the six ratings from two coils, one coil furnishing the 5, 10, and 20 ampere ratings and the other coil furnishing the 15, 30, and 60 ampere ratings. To prevent damage to the coil from transient voltages, a suitable arrester is connected directly across its terminals.

Interruption and Lockout Tests

Repeated interrupting tests at both high and low currents on extremely fast circuits have demonstrated the high efficiency and low oil deterioration of the breaker. Indications are that the breaker can be in service many years before an oil change is required. The interrupting ability of the breaker is determined by the short-time current rating of the series coil rather than by any limitations in the interrupter. Figure 5 shows an oscillogram of a single interruption of 1,120 amperes at 13,800 volts. Figure 6 shows a single interruption of 106 amperes at 7,200 volts. Compare the travel record and note the additional travel of the contacts on the higher current interruption. Figure 7 shows three interruptions and lockout on 476 amperes at 7,200 volts. Note the tripping time, the reclosing time, and the travel of the contacts to the extreme open position after lockout.

Co-ordination Characteristics

The important attribute of this breaker is the time current characteristic. More time delay on tripping allows more time for coordination and therefore permits closer coordination between adjacent ratings. Consequently, as great a time delay as possible has been incorporated in this breaker particularly at the lower values of current just above the minimum tripping current. Since the different ratings are obtained by varying the number of turns on the series coil the curves will be parallel and identical in shape with only a shift in the current axis. Figure 8 shows the time current characteristics for the six ratings of 5, 10, 15, 20, 30, and 60 amperes. The time values have been obtained from oscillographic records of interrupting tests. Sufficient time delay has been provided so that all of these ratings can be coordinated in series. The possibility of coordination between these breakers and fuses is further demonstrated by superimposing a 20 ampere fuse curve upon the breaker curves. The fuse curve is for a 20 ampere universal fuse link as used in distribution cutouts and is a representative curve for such links.

The coordination of these breakers with each other is relatively simple. There are, however, three possible applications in coordinating the breaker with fuses.

(1). A fuse can be selected such that it will be completely protected by the breaker, that is, the breaker will operate three times and lockout without melting the fuse. This would be a rather infrequent application.

(2). The fuse can be used to completely protect the breaker, that is, the fuse would clear the circuit without a single operation of the breaker. This arrangement might be used with transformer protective links.

(3). The fuse can be selected so that the breaker will clear the circuit once to permit the fault to clear, and then on the second operation, if the fault persists, the fuse will blow due to the stored heat remaining in it from the first operation. On the second reclosure the breaker will remain closed and the fault will be isolated by the fuse. In this arrangement the fuse would be the outermost protective device in the sectionalizing scheme.

The shape of the time current curve further suggests the coordination of the breaker with relays. The relay curve shown in figure 7 is for a standard overcurrent relay of the moving disk type. By adjusting it to the proper lever setting and proper current ratio, it is possible to have the relay curve very close to that of the breaker. With the setting shown, the breaker will consistently protect the relay and thus prevent tripping an entire substation. The time delay between operations of the reclosing breaker is sufficient to allow the relay disk to return to its starting point, so the coordination will be the same for each operation. With reclosing fuses, a much larger margin between the fuse curve and the relay curve would be necessary due to the short reclosing time. Here the relay disk would not return to its original position and there would be cumulative turning of the disk and consequent operation of the relay.

A further advantage of this breaker for fault protection on low capacity systems lies in the economies offered by the use of simple gaps for lightning protection. On this type of system a temporary outage is not serious and, with the coordination afforded by these breakers, such an outage due to lightning is confined to a small area and is removed upon the first reclosure.

Conclusions

An automatically reclosing circuit breaker meeting all of the requirements for use on extended distribution systems has been developed and proven by repeated tests. A particularly important aspect of this breaker is the pronounced time delay on tripping that permits coordination of several breakers in series and coordination of the breakers with standard fuses of comparable ratings. The coordination possible with this breaker greatly increases the scope of its application and permits the economical extension of low capacity distribution systems with improved quality of service.

Short Circuits in Synchronous-Machine Armatures

R. A. GALBRAITH
ASSOCIATE AIEE

Synopsis: An approximate solution is obtained for the current in a short-circuited coil or group of coils in the armature of a synchronous machine operating under load. The solution is expressed as the sum of a series of harmonics whose terms are in geometric ratio. The results obtained are similar in form to those previously obtained for the short circuit of a complete phase winding, and they reduce to that for the single-phase short circuit in the limiting case when the coil group comprises a complete phase. An experimental check of the theory is given for the case of a short circuit of a single armature coil, and it is shown that close agreement is obtained between theory and test with respect to the fundamental component of current, though not with respect to the small higher harmonics of current.

SOLUTIONS for single-phase and three-phase short circuits of synchronous machines have been obtained by several authors, those of Park[1] and of Doherty and Nickle[4] being notable. These analyses, however, have considered only complete phase windings, and it is the purpose of this paper to extend the theory to treat short circuits of a single armature coil or group of coils. The solution obtained is applicable to machines operating under load, the effect of the load currents being obtained by an approximation that is sufficiently accurate for practical purposes.

As one coil or a group of coils is essentially a single phase, the analysis is similar in form to that of Doherty and Nickle for the single-phase short circuit. Following their procedure, a general expression is obtained for the magnetic flux linkages of armature and field windings. The constant-linkage theorem, which states that the magnetic flux linkages in any closed electric circuit are constant if the resistance is neglected, is applied to determine the initial currents when the short circuit occurs. From physical considerations, these currents are then separated into their sustained and transient components, and the proper decrement factors are applied to the latter.

Assumptions

For simplification, this analysis is applied to an ideal synchronous machine.[2] In such a machine, linear relationships exist between magnetic flux and currents in any part of the machine, so that the principle of superposition applies. The phase windings are identical and symmetrically placed about the armature, and there are only two field circuits, the main field winding in the direct axis and a short-circuited winding in the quadrature axis, both of which are symmetrical about their respective axes. Only fundamental harmonics of magnetomotive force and voltage appear in the phase windings.

In addition to the assumption regarding the ideal machine, other simplifications are made. The resistances of the group of short-circuited armature coils and of the field circuits are neglected in deter-

R. A. GALBRAITH is assistant professor of electrical engineering, University of Texas, Austin, Texas.

The material in this paper is part of a dissertation presented to the graduate school of Yale University in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

[1] For all numbered references, see list at end of paper.

mining initial currents in these windings but are taken into account in obtaining approximate values for the decrement factors. It is also assumed that the effect of the relatively large load resistance is to attenuate the unidirectional and even harmonics of induced current in the load circuit so quickly that these transient elements may be entirely neglected.

The solution is further simplified by making the assumption that, owing to the small mutual inductance between the phases and the coil group, the load currents are unaffected by the short circuit. The value of short-circuit current obtained under this assumption is regarded as the first approximation to the correct result. The effect of this current upon the load currents is then determined, and if the latter are changed an appreciable amount, the analysis is repeated, assuming that the load currents change by this amount. The second approximation is usually sufficiently accurate for all practical purposes, making further refinement unnecessary.

Analytical Development

Since the theorem of superposition is applicable to the ideal synchronous machine, the extension of Blondel's two-reaction method developed by Doherty and Nickle[3] is applied in appendix I to obtain expressions for the inductances of the field and armature circuits. Without loss of generality, the armature winding of which the short-circuited coils are a part is designated as phase *A*, and the angle between the axis of the coil group and that of phase *A* is β. Equations are then developed for the self and mutual inductances for the coil group, and it is found that these inductances may be conveniently expressed as functions of known design constants of the machine and the conventional inductances per phase.

Following the procedure that has been outlined, the inductance equations are used in appendix II to obtain the armature and field linkages of the machine. It is found that the results may be conveniently expressed in terms of the currents i_d and i_q defined by

$$i_d=i_a\cos\theta+i_b\cos(\theta-120°)+ i_c\cos(\theta-240°) \quad (1)$$

$$i_q=i_a\sin\theta+i_b\sin(\theta-120°)+ i_c\sin(\theta-240°) \quad (2)$$

The linkages in the short-circuited coil group are then

$$\psi_s=K_s\{(^3/_2)L_di_d+M_dI_d\}\cos(\theta-\beta)+ K_s\{(^3/_2)L_qi_q+M_qI_q\}\sin(\theta-\beta)+ \{L_{SD}\cos^2(\theta-\beta)+L_{SQ}\sin^2(\theta-\beta)\}\times (i_s-i_a) \quad (3)$$

where i_s is the short-circuit current in the coil group. Expressions for the inductances and for the constant K_s are given in appendix I. The corresponding field linkages are

$$\psi_D=M_di_d+K_sM_d(i_s-i_a)\cos(\theta-\beta)+L_dI_d \quad (4)$$

$$\psi_Q=M_qi_q+K_sM_q(i_s-i_a)\sin(\theta-\beta)+L_qI_q \quad (5)$$

These linkage equations will be used to obtain the solutions for the initial currents after the short circuit.

In conformity with the usual practice in the literature, the equations that follow are expressed in terms of reactances instead of inductances. The reactance corresponding to any inductance is the product of the latter and ω, where $\omega=2\pi f$, f being the rated frequency of the machine. Thus $X_{SD}'=\omega L_{SD}'$.

SOLUTION FOR CURRENTS

When the short circuit occurs, spontaneous unidirectional components of current appear in the coil group and the field circuit tending to sustain the linkages at their initial value. The voltages that support these transient currents are generated through the collapse of the magnetic fields existing at the instant of short circuit.

As the machine rotates, the transient unidirectional current in the field induces a transient fundamental component of current in the coils, and this in turn causes a second harmonic in the field. This "reflection" from field to coils and back again gives rise to a series of even harmonics in the field and a series of odd harmonics in the coils, all of which are proportional to the average induced field current and all of which decay at the rate determined by the field decrement factor σ_f. Similarly the transient unidirectional current in the short-circuited coils causes a series of even harmonics in the coils and a series of odd harmonics in the field that decay to zero according to the decrement factor of the coil group, σ_s.

The rotating magnetic field due to the average field current supported by exciter voltage causes fundamental and higher harmonics of sustained current to appear in the short-circuited coils and also causes a series of even harmonics in the field.

Owing to the relatively large resistance of the load the transient unidirectional and even harmonics of current induced in the phases by the short circuit will be damped out very quickly and may be neglected. Because of the small mutual inductance between the coil group and the phases, only the fundamental of the induced odd harmonics that also appear is of appreciable magnitude. This component, being due to the fundamental of the short-circuit current in the faulty coils and the transient element of the average field current, will have a sustained and a transient value. The latter decays according to the field decrement factor. Neglecting the small harmonics, therefore, the induced load current can be represented by a sustained and a transient fundamental component. These must be added to the load current existing before the short circuit to get the total phase currents. The corresponding currents i_d and i_q, defined by equations 1 and 2, will then have the form

$$i_d=i_{d1}+(i_{d0}-i_{d1})e^{-\sigma_f t} \quad (6)$$

$$i_q=i_{q1}+(i_{q0}-i_{q1})e^{-\sigma_f t} \quad (7)$$

where i_{d0} and i_{q0} are the initial values before the short-circuit and i_{d1} and i_{q1} are the final sustained values. Approximate expressions for i_{d1} and i_{q1} are given in equations 19 and 20.

First Approximation to Short-Circuit Current. Following the procedure previously outlined, the first approximation to the short-circuit current is obtained by assuming that the load currents are unchanged. When the constant-linkage theorem is applied, it is shown in appendix III that if the short circuit occurs at $\theta=\theta_0$, the initial current in the coil group is

$$i_s=i_a+i'+i'' \quad (8)$$

The components i' and i'' are

$$i'=\frac{-2e_{SD}}{X_{SD}'+\sqrt{X_{SD}'X_{SQ}'}}\{\cos(\theta-\beta)+ B\cos 3(\theta-\beta)+B^2\cos 5(\theta-\beta)+\ldots\ldots\} \frac{-2e_{SQ}}{X_{SQ}'+\sqrt{X_{SD}'X_{SQ}'}}\{\sin(\theta-\beta)+ B\sin 3(\theta-\beta)+B^2\sin 5(\theta-\beta)+\ldots\ldots\} \quad (9)$$

$$i''=\frac{e_{SD}\cos(\theta_0-\beta)+e_{SQ}\sin(\theta_0-\beta)}{\sqrt{X_{SD}'X_{SQ}'}}\times \{1+2B\cos 2(\theta-\beta)+2B^2\times \cos 4(\theta-\beta)+\ldots\ldots\} \quad (10)$$

where

$$e_{SD}=K_s\{(^3/_2)X_di_{d0}+X_{md}I_{d0}\} \quad (11)$$

and

$$e_{SQ}=K_s\{(^3/_2)X_qi_{q0}\} \quad (12)$$

are the direct and quadrature components of the voltage in the coil group prior to the short circuit, and

$$B=\frac{\sqrt{X_{SQ}'}-\sqrt{X_{SD}'}}{\sqrt{X_{SQ}'}+\sqrt{X_{SD}'}} \quad (13)$$

is a constant.

By the assumption made, i_a is unchanged, so that the additional current that is due to the short circuit is represented by the components i' and i''. The latter contains the d-c and even harmonics that arise to maintain the linkages at their initial value; therefore it is transient in character and decays to zero at the rate determined by σ_s. The other component, i', contains the odd harmonics and is proportional to the average field current.

As shown in appendix III, the average field current just after the short circuit occurs is

$$I_d(\text{average}) = G_0 I_{d0} \tag{14}$$

where G_0 is a constant defined by equation 60. Since the average sustained field current is I_{d0}, it is $1/G_0$ times as great as the initial value. The sustained value of i', therefore, is $1/G_0$ times as great as the initial value expressed in equation 9. The remaining portion $(1-1/G_0)i'$, is a transient and decays according to σ_f. The first approximation to the short-circuit current in the coil group is therefore

$$i_s = i_a + \frac{1}{G_0} i' + \left(1 - \frac{1}{G_0}\right) i' e^{-\sigma_f t} + i'' e^{-\sigma_s t} \tag{15}$$

The effect of the change in load currents being small, it will be found that this expression gives results that do not differ greatly from those obtained by the more accurate expression, equation 21.

The additional current introduced in the coil group by the short circuit is $(i_s - i_a)$, and for the reasons previously mentioned, its fundamental component is the only one that has appreciable effect upon the load currents. From equations 9 and 15, the sustained value of

$$(i_s - i_a)(\text{fundamental}) = I_1 \cos(\theta - \beta - \alpha_1) \tag{16}$$

where

$$I_1 = \frac{1}{G_0}\left[\left\{\frac{e_{SD}}{X_{SD}' + \sqrt{X_{SD}' X_{SQ}'}}\right\}^2 + \left\{\frac{e_{SQ}}{X_{SQ}' + \sqrt{X_{SD}' X_{SQ}'}}\right\}^2\right]^{1/2} \tag{17}$$

and

$$\alpha_1 = \tan^{-1}\left\{\left(\frac{e_{SQ}}{e_{SD}}\right)\frac{X_{SD}' + \sqrt{X_{SD}' X_{SQ}'}}{X_{SQ}' + \sqrt{X_{SD}' X_{SQ}'}}\right\} \tag{18}$$

Taking approximate account of the effect of this current, it is shown in appendix IV that the sustained values of i_d and i_q corresponding to equations 6 and 7 are

$$I_{d1} = -\frac{3}{2}\,\frac{x_q + X_L}{r^2 + (X_d + X_L)(X_q + X_L)}\left[X_{md} I_{d0} + K_S X_D \frac{I_1}{2}\cos\alpha_1 + \frac{r}{X_q + X_L} K_S X_Q \frac{I_1}{2}\sin\alpha_1\right] \tag{19}$$

$$i_{q1} = \frac{-r}{X_q + X_L}\, i_{d1} - \frac{3}{2(X_q + X_L)} K_S X_Q \frac{I_1}{2}\sin\alpha_1 \tag{20}$$

The corresponding expressions for i_{d0} and i_{q0} are obtained from those for i_{d1} and i_{q1} by putting $I_1 = 0$.

Second Approximation to Short-Circuit Current. The next step in the solution for the short-circuit currents is to assume that i_d and i_q have average values given by equations 6 and 7. Following the same procedure as before, the linkages of the coil group and the field circuits may be obtained and solved for the initial currents in the coil group and the field winding. Separated into its sustained and transient components and with the proper decrements applied, the second approximation to the short-circuit current in the coil group is

$$\begin{aligned}
i = {} & \frac{2}{3}\{i_{d1}\cos\theta + i_{q1}\sin\theta\} - \\
& \frac{1}{G_1}\Bigg[\frac{2\{e_{SD} - K_S(2/3)X_d'(i_{d0} - i_{d1})\}}{X_{SD}' + \sqrt{X_{SD}' X_{SQ}'}} \times \\
& \{\cos(\theta - \beta) + B\cos 3(\theta - \beta) + \ldots\} + \\
& \frac{2\{e_{SQ} - K_S(2/3)X_q'(i_{q0} - i_{q1})\}}{X_{SQ}' + \sqrt{X_{SD}' X_{SQ}'}}\{\sin(\theta - \beta) + \\
& B\sin 3(\theta - \beta) + B^2\sin 5(\theta - \beta) + \ldots\}\Bigg] + \\
& e^{-\sigma_f t}(2/3)\{(i_{d0} - i_{d1})\cos\theta + (i_{q0} - i_{q1})\sin\theta\} - \\
& \frac{1e^{-\sigma_f t}}{G_1}\left[\frac{\{(G_1 - 1)e_{SD} - K_S(2/3)X_d'(i_{d0} - i_{d1})\}\cos(\theta - \beta) + \{(G_1 - 1)e_{SQ} - K_S(2/3)X_q'(i_{q0} - i_{q1})\}\sin(\theta - \beta)}{(1/2)(X_{SD}' + X_{SQ}') + (1/2)(X_{SD}' - X_{SQ}')\cos 2(\theta - \beta)}\right] + \\
& e^{-\sigma_s t}\frac{\{e_{SD}\cos(\theta_0 - \beta) + e_{SQ}\sin(\theta_0 - \beta)\}}{\sqrt{X_{SD}' X_{SQ}'}} \times \\
& \{1 + 2B\cos 2(\theta - \beta) + 2B^2\cos 4(\theta - \beta) + \ldots\}
\end{aligned} \tag{21}$$

where

$$G_1 = \frac{X_{SD} + \sqrt{X_{SD}' X_{SQ}'}}{X_{SD}' + \sqrt{X_{SD}' X_{SQ}'}} \times \left[1 + \frac{2(X_d - X_d')(i_{d0} - i_{d1})}{3X_{md} I_{d0}} + \frac{X_{SD} - X_{SD}'}{X_{SD}' + \sqrt{X_{SD}' X_{SQ}'}} \cdot \frac{2X_d i_{d1}}{3X_{md} I_{d0}}\right] \tag{22}$$

The solution for the coil current for the case of short circuit at no load is obtained by letting $i_{d0} = i_{q0} = i_{d1} = i_{q1} = 0$ in equation 21. This is equivalent to making $e_{SQ} = 0$ and $e_{SD} = K_s X_{md} I_{d0}$.

Because of the relatively small mutual inductance between the coil group and the phase and field circuits $(i_{d0} - i_{d1})$, $(i_{q0} - i_{q1})$, and $(G_1 - 1)$ are ordinarily small. Therefore it is usually possible to neglect the terms involving $\varepsilon^{-\sigma_f t}$ when making calculations using equation 21. For the sake of completeness, however, they have been included.

One component of the sustained short-circuit current is equal to the sustained load current $(2/3)\{i_{d1}\cos\theta + i_{q1}\sin\theta\}$. The other component is the sum of two odd harmonic series whose terms, in ascending order, are in geometric ratio. The ratio, B, is given in equation 13.

The expression for the short circuit current of the group of coils is similar in form to that given by Doherty and Nickle[4] for the single phase short circuit and their discussion of the effects of the machine constants upon the form of the solution applies equally well here. In the limiting case when the coil group comprises a complete phase, the solution for the condition of no load is exactly the same as theirs.

Decrement Factors

Expressions for the decrement factors may be obtained by the approximate method used by Doherty and Nickle,[4] which they have discussed fully. It is then found that the decrement factor for the coil group is

$$\sigma_s = \frac{\omega r_s}{\sqrt{X_{SD}' X_{SQ}'}} \tag{23}$$

where r_s is the resistance of the shorted coils, and that for the field is

$$\sigma_f = \frac{X_{SD} + \sqrt{X_{SD}' X_{SQ}'}}{X_{SD}' + \sqrt{X_{SD}' X_{SQ}'}} \cdot \frac{R_d}{L_d} \tag{24}$$

when R_d is the total resistance of the field circuit.

Experimental Confirmation of Theoretical Results

To verify the theory, experimental measurements were made of the short-circuit current in a single coil of a 125-horsepower, 440-volt, 60-cycle, 900-rpm, three-phase, synchronous motor. This machine had a full-pitch armature winding, no amortisseur on the rotor, and was a specially built laboratory machine with the leads to the armature coils brought out to a terminal board, making each coil accessible for measurements. The measured values of the reactances and resistances of the machine are given in table I.

Table I. Measured Reactances* and Resistances of Test Machine

$X_d =$ 1.520 ohms $X_D =$ 1.050 ohms
$X_d' =$ 0.445 ohm $X_D' =$ 0.266 ohm
$X_q = X_q' =$ 1.205 ohms $X_Q = X_Q' =$ 0.970 ohm

$X_s =$ 0.237 ohm
$X_{md} =$ 37.3 ohms
$r_a =$ 0.048 ohm at 25 C (line to neutral)
$R_d =$ 23.5 ohms at 25 C

* Measured by static test method.

Using the equations that have been developed, it is found that for a single armature coil of the machine,

$K_s = 0.0434$
$X_{SD} = X_{SQ} = X_{SQ}' = 0.0126$ ohm
$X_{SD}' = 0.01109$ ohm

The short-circuit current was measured by taking the voltage drop across a 0.000243-ohm, non-inductive shunt in series with the coil. The wave form of the current was obtained from an oscillogram of this voltage, and the magnitudes of the sustained harmonic components were measured with a vacuum-tube harmonic analyzer.

The coil used in the test was in the center of phase A, so that $\beta = 0$. The current was calculated analytically and checked experimentally for short circuits occurring under two different operating conditions, one when the machine was loaded, and one at no load. Both tests were made at reduced voltage to eliminate the effect of saturation as far as possible.

For the short circuit under load, the machine was operating with a pure resistive load of 2.45 ohms per phase and a field current of 0.992 ampere. The short circuit occurred at $\theta_0 = 215°$. The calculated current for the short-circuited coil was

$$\begin{aligned} i_s = {} & -164.0 \cos(\theta - 17.28°) - 5.13 \times \\ & \cos(3\theta - 23.16°) - 0.161 \times \\ & \cos(5\theta - 23.16°) - \ldots - e^{-0.0133\omega t}[4.80 \times \\ & \cos(\theta + 19.85°) + 0.116 \times \\ & \cos(3\theta + 13.38°) + \ldots] - e^{-0.1067\omega t}[163.3 + \\ & 10.27 \cos 2\theta + 0.324 \cos 4\theta + \ldots] \end{aligned}$$

where $215° < \theta$ and $\omega t = (\theta - \theta_0)$ in radians. In table II the magnitudes of the harmonics of the calculated sustained current are compared with the actual values as measured with a harmonic analyzer.

The short-circuit at no load occurred at $\theta_0 = 180°$ and the field current was 0.988 ampere. The calculated current is

$$\begin{aligned} i_s = {} & -185.5 \cos\theta - 5.85 \cos 3\theta - 0.184 \times \\ & \cos 5\theta - \ldots \\ & -e^{-0.1067\omega t}\{191.5 + 12.06 \cos 2\theta + 0.38 \times \\ & \cos 4\theta + \ldots] \end{aligned}$$

where $180° < \theta$ and $\omega t = (\theta - \theta_0)$ in radians. The magnitude of the sustained harmonics of the calculated and measured currents are compared in table II.

Considering only the fundamental components of sustained current, the data in table II show that the calculated and measured values agree very closely. The analytical and experimental results for the higher harmonics, however, do not agree. This is probably due in large part to the fact that the higher harmonics of mutual linkages between the coil and the other machine circuits were neglected in the analysis. While the voltages due to higher harmonics of flux are ordinarily small in the complete phase due to the effects of fractional pitch and distributed windings, they may be much more important in one or two coils. To neglect these harmonics of flux, therefore, may introduce considerable error in the higher harmonics of current in the short-circuited coils. As they have little effect on the fundamental voltage, however, they may be disregarded in determining the fundamental component of current.

Table II. Comparisons of Peak Values* of Harmonics of Sustained Current in a Single Coil

	Fundamental	Third	Fifth
Machine loaded			
Calculated	164.0	5.13	0.161
Measured	165.5	29.1	6.69
No load			
Calculated	185.5	5.85	0.184
Measured	190.7	30.85	3.49

* All values are given in amperes.

Oscillograms were made of the short-circuit current, and these were compared with a graphical plot of the calculated current. The agreement between the calculated and test results was fairly good, both during the transient period and after the transient components had died out. The effect of the larger values of the harmonics in the actual current was noticeable, however, the actual waves being slightly more peaked than those which were calculated.

Had the test machine been operated at higher flux densities, the effect of saturation would probably have been noticeable. As pointed out by Doherty and Nickle, this would not prevent the use of the results of the theoretical analysis, as the effect of saturation may be taken into account by proper shading of the machine constants.

Appendix I

Inductance Equations

Expressions for the inductances of the field and armature circuits may be obtained by application of the extension of Blondel's method previously mentioned. With the assumptions that have been made, only the fundamental component of magnetomotive force need be considered in obtaining the mutual linkages due to any machine circuit. The procedure is to resolve this space sinusoid into two components, one in the direct axis and one in the quadrature axis, determine the corresponding fundamental linkages due to each component acting separately, and combine these linkages to get the resultant. The fundamental linkages in any other circuit of the machine per unit current in the exciting circuit are equal to the mutual inductance between the two. That portion that is due to the space fundamental of air gap flux is the inductance of armature reaction, and the remainder, which is due to flux in the slots and end windings, is leakage inductance.

SELF-INDUCTANCE OF ARMATURE REACTION OF A COMPLETE PHASE WINDING

Let the flux density per unit magnetomotive force at the armature surface be represented by the even harmonics series[8]

$$P = P_0 + P_2 \cos 2\lambda + P_4 \cos 4\lambda + \ldots \qquad (25)$$

The fundamental component of the linkages with the complete phase A winding of the air-gap flux due to the fundamental component of magnetomotive force of phase A may be expressed as

$$\psi_{aa} = i_a\{L_{AD} \cos^2\theta + L_{AQ} \sin^2\theta\} \qquad (26)$$

where

$$L_{AD} = 3.2Dl(yN_cK_dK_p)^2\{P_0 + (1/2)P_2\} \qquad (27)$$

$$L_{AQ} = 3.2Dl(yN_cK_dK_p)^2\{P_0 - (1/2)P_2\} \qquad (28)$$

are the static inductances of armature reaction for one phase.

MUTUAL INDUCTANCES BETWEEN COIL GROUP AND PHASE AND FIELD WINDINGS

If the space fundamental of magnetomotive force for the coil group is considered, it may easily be shown that the linkages of armature reaction in phase A due to the current in the coil group are

$$\psi_{as} = i_sK_s\{L_{AD} \cos(\theta - \beta) \cos\theta + L_{AQ} \times \sin(\theta - \beta) \sin\theta\} \qquad (29)$$

where

$$K_s = \frac{sK_{ds}}{pyK_d} \qquad (30)$$

and s is the number of coils in the group, y the slots per phase per pole, p the number of poles, K_d the phase belt distribution factor, and K_{ds} the distribution factor for the s coils; that is, sK_{ds} is the ratio of the fundamental of magnetomotive force for the coil group to that for a single coil. The corresponding linkages in phase B are obtained by replacing $\cos\theta$ and $\sin\theta$ by $\cos(\theta - 120°)$ and $\sin(\theta - 120°)$ respectively, and those for phase C may be obtained by using $(\theta - 240°)$ instead of $(\theta - 120°)$. The linkages per unit current in these expressions are equal to the mutual inductances of armature reaction between the phase windings and the coil group. The corresponding mutual leakage linkages will have the same form except that, being independent of rotor position, they will be the same for direct and quadrature axes. These mutual leakage inductances are $K_sL_l \cos\beta$, $K_s2L_{lm} \times \cos(\beta - 120°)$, and $K_s2L_{lm} \cos(\beta - 240°)$ for phases A, B, and C respectively. Adding these components to those due to armature reaction, it is found that the mutual inductance between the coil group and phase A is

$$L_{as} = K_s\{L_D \cos(\theta - \beta) \cos\theta + L_Q \times \sin(\theta - \beta) \sin\theta\} \qquad (31)$$

The corresponding expression for the mutual inductance between the coil group and phase B is

$$L_{bs}=K_s\{(L_D-L_0)\cos(\theta-\beta)\cos(\theta-120°)+(L_Q-L_0)\sin(\theta-\beta)\sin(\theta-120°)\} \quad (32)$$

and that for phase C is similar to equation 32 with $(\theta-240°)$ instead of $(\theta-120°)$.

The procedure followed in the preceding paragraph may be used to obtain the mutual inductances between the coil group and the field windings. These inductances are then found to be

$$M_{sd}=K_sM_d\cos(\theta-\beta) \quad (33)$$

$$M_{sq}=K_sM_q\sin(\theta-\beta) \quad (34)$$

It should be noted that all of the mutual inductances for the coil group are expressed as the product of the constant K_s and the inductances of the machine per phase.

SELF INDUCTANCE OF A COIL GROUP

Although space harmonics of magnetomotive force cannot appear in the complete phase winding of an ideal machine, they must be considered in obtaining an expression for the self inductance of a coil group. In the work that follows, therefore, the complete magnetomotive force of the coil group will be considered.

As the inductance of a coil group is a function of the self and mutual inductances for the individual coils in the group, the first step in this analysis will be to develop an expression for the self inductance of a single coil. The next step will be to obtain a general expression for the mutual inductance between two coils. These self and mutual inductances may then be combined to obtain the total self inductance of the coil group.

Assuming that the current i_s in a single coil of N_c turns is distributed in a line at the armature surface and that the iron has infinite permeability, the magnetomotive force distribution of the coil over the coil span ρ is a square-topped wave of magnitude

$$A_1=(1-\rho/p\pi)(0.4\pi N_ci_s) \quad (35)$$

If the relation between the flux density and magnetomotive force is expressed by equation 25, the linkages, with the coil, of the air-gap flux due to this magnetomotive force may be shown to be

$$\psi_{ss}=[(p-\rho/\pi)\{\pi^2/8(pyK_dK_p)^2\}]\times\{(\rho/2\pi)(L_{AD}+L_{AQ})+(1/\pi)\times(L_{AD}-L_{AQ})\sin\rho\cos 2(\theta-\beta)\} \quad (36)$$

when the small higher harmonics are neglected.

Since the path of the leakage flux in the slots and end windings is practically the same for a single coil and a complete phase and since there are $1/py$ as many turns for the single coil as for the phase winding, the ratio of the leakage linkages for the coil to those for the phase is approximately $1/(py)^2$. As indicated by equations 26 and 36 this is much smaller than the corresponding ratio for the linkages due to air-gap flux. The leakage component is, therefore, only a small percentage of the total linkages of the coil. Since $2L_{lm}$ is also very small in comparison to $(^1/_2)(L_{AD}+L_{AQ})$, the assumption will be made that the total linkages of the coil can be expressed in a form similar to equation 36 with

$$(^1/_2)(L_D+L_Q)-L_0=(^1/_2)(L_{AD}+L_{AQ})+2L_{lm}$$

substituted for $(^1/_2)(L_{AD}+L_{AQ})$. Although this assumption may introduce considerable error in the leakage linkages added, it will make only a small discrepancy in the total linkages, and the equation may be put in a much more convenient form for calculation. The total self inductance of a single coil is then

$$L_{ss}=L_{SD}\cos^2(\theta-\beta)+L_{SQ}\sin^2(\theta-\beta) \quad (37)$$

where

$$L_{SD}=[(p-\rho/\pi)\{\pi^2/8(pyK_dK_p)^2\}]\times[(\rho/\pi)\{(^1/_2)(L_D+L_Q)-L_0\}+(1/\pi)(L_D-L_Q)\sin\rho] \quad (38)$$

$$L_{SQ}=[(p-\rho/\pi)\{\pi^2/8(pyK_dK_p)^2\}]\times[(\rho/\pi)\{(^1/_2)(L_D+L_Q)-L_0\}-(1/\pi)(L_D-L_Q)\sin\rho] \quad (39)$$

The magnetomotive force distribution of the single coil over the armature outside the coil span will be a square-topped wave of magnitude

$$A_2=-(\rho/p\pi)(0.4\pi N_ci_s) \quad (40)$$

Using equations 27 and 28 and making the same assumptions regarding leakage linkages that were made in deriving equation 37, it may be shown that the mutual inductance between two coils separated a small angle Δ is approximately

$$L_{ms}=\{(p-\rho/\pi)(\pi^2/8)/(pyK_dK_p)^2\}\times[\{\rho/\pi-\rho\Delta/(p\pi-\rho)\}\{(^1/_2)(L_D+L_Q)-L_0\}+(1/\pi)\cos\Delta\sin(\rho-\Delta)\times\{(L_D-L_Q)\cos 2(\theta-\beta)\}] \quad (41)$$

The total self inductance of a group of coils may be obtained from the relationship

$$L_{ss}=L_{11}+L_{22}+L_{33}+\ldots+2(L_{12}+L_{13}+L_{23}+\ldots) \quad (42)$$

where L_{11}, L_{22}, . . . are the self inductances of each coil given by equation 37 and L_{12}, L_{13}, . . . are the mutual inductances between coils 1 and 2, 1 and 3, etc., as given by equation 41. It is apparent that the total self inductances of the coil group can be put in the form of equation 37 if L_{SD} and L_{SQ} are given the proper values. Equation 37, therefore, is a general expression for the total self inductance of a group of armature coils whether the group consists of one, two, or more coils.

TRANSIENT INDUCTANCES

The transient inductances L_{SD}' and L_{SQ}' are defined by

$$L_{SD}'=L_{SD}-K_s^2(M_d^2/L_d) \quad (43)$$

$$L_{SQ}'=L_{SQ}-K_s^2(M_q^2/L_q) \quad (44)$$

The inductances L_d', L_q', L_D', and L_Q' correspond to the transient reactances X_d', X_q', X_D', and X_Q' as ordinarily defined in the literature.

Appendix II

Linkage and Voltage Equations

The armature and field linkages for an ideal synchronous machine under normal conditions have been given by Park.[1,2] Following his analysis, it may be shown that if

$$\psi_d=(^3/_2)(L_d+L)i_d+M_dI_d \quad (45)$$

$$\psi_q=(^3/_2)(L_q+L)i_q+M_qi_q \quad (46)$$

then the following voltage equations may be obtained:

$$-\frac{d\psi_d}{dt}-\psi_q\frac{d\theta}{dt}=\frac{2}{3}ri_d \quad (47)$$

$$-\frac{d\psi_q}{dt}+\psi_d\frac{d\theta}{dt}=\frac{2}{3}ri_q \quad (48)$$

where r is the combined resistance of one phase of the machine and load.

When the machine contains another circuit of a group of short-circuited coils, the linkage equations must be modified to include the effect of the additional current in the faulty coils. This may be done by making use of the expressions for the mutual inductances between the coil group and the phase and field windings.

It is convenient to consider the magnetomotive force of the portion of the phase A winding that is outside the faulty coils as the difference between that due to a current i_a in the complete phase winding and that due to the coil group carrying the same current i_a. Similarly, the linkages in this portion of the phase A winding due to other currents may be obtained by subtracting the linkages in the faulty coils from those in the complete phase.

When the inductance equations developed in appendix I are used, the modified forms of equations 45 and 46 become

$$\psi_d=(^3/_2)(L_d+L)i_d+K_sL_D(i_s-i_a)\times\cos(\theta-\beta)+M_dI_d \quad (49)$$

$$\psi_q=(^3/_2)(L_q+L)i_q+K_sL_Q(i_s-i_a)\times\sin(\theta-\beta)+M_qI_q \quad (50)$$

It may then be shown that, to a close approximation, the voltage equations 47 and 48 are applicable to the short-circuited machine when ψ_d and ψ_q have the values given in equations 49 and 50.

Appendix III

Short-Circuit Currents Assuming Load Currents Constant

At the instant of short circuit, $\theta=\theta_0$, $i_d=i_{d0}$, $i_q=i_{q0}$, $I_d=I_{d0}$, and $I_q=0$. Applying the constant linkage theorem, the linkages in the coil group and the field windings are

$$K_s\{(^3/_2)L_di_d+M_dI_d\}\cos(\theta-\beta)+K_s\{(^3/_2)L_qi_q+M_qI_q\}\sin(\theta-\beta)+\{L_{SD}\cos^2(\theta-\beta)+L_{SQ}\sin^2(\theta-\beta)\}(i_s-i_a)=K_s\{(^3/_2)L_di_{d0}+M_dI_{d0}\}\cos(\theta_0-\beta)+K_s\{(^3/_2)L_qi_{q0}\}\sin(\theta_0-\beta) \quad (51)$$

$$M_di_d+K_sM_d(i_s-i_a)\cos(\theta-\beta)+L_dI_d=M_di_{d0}+L_dI_{d0} \quad (52)$$

$$M_qi_q+K_s(i_s-i_a)\sin(\theta-\beta)+L_qI_q=0 \quad (53)$$

In accordance with the method of analysis that has been outlined, the first approximation to the solution is obtained by assuming that $i_d=i_{d0}$ and $i_q=i_{q0}$ remain constant. Then a simultaneous solution of equations 51, 52, and 53 gives

$$(i_s-i_a)=\frac{e_{SD}\{\cos(\theta_0-\beta)-\cos(\theta-\beta)\}+e_{SQ}\{\sin(\theta_0-\beta)-\sin(\theta-\beta)\}}{(^1/_2)(X_{SD}'+X_{SQ}')+(^1/_2)(X_{SD}'-X_{SQ}')\cos 2(\theta-\beta)} \tag{54}$$

$$I_d=I_{d0}-\frac{X_{SD}-X_{SD}'}{K_sX_{md}}(i_s-i_a)\cos(\theta-\beta) \tag{55}$$

where e_{SD} and e_{SQ} are defined by equations 11 and 12. These may also be expressed as

$$(i_s-i_a)=i'+i'' \tag{56}$$

$$I_d=I_d'+I_d'' \tag{57}$$

where i' and i'' are given by equations 9 and 10 and I_d' and I_d'' are

$$I_d'=I_{d0}+\frac{X_{SD}-X_{SD}'}{K_sX_{md}}\,\frac{e_{SD}}{X_{SD}'+\sqrt{X_{SD}'X_{SQ}'}}+\frac{X_{SD}-X_{SD}'}{K_sX_{md}}\left[\frac{e_{SD}(1-B)^2}{2\sqrt{X_{SD}'X_{SQ}'}}\{\cos 2(\theta-\beta)+B\cos 4(\theta-\beta)+\ldots\}+\frac{e_{SQ}(1-B^2)}{2\sqrt{X_{SD}'X_{SQ}'}}\times\{\sin 2(\theta-\beta)+B\sin 4(\theta-\beta)+\ldots\}\right] \tag{58}$$

$$I_d''=\frac{(X_{SD}-X_{SD}')(1+B)}{2K_sX_{md}\sqrt{X_{SD}'X_{SQ}'}}\{e_{SD}\cos(\theta_0-\beta)+e_{SQ}\sin(\theta_0-\beta)\}[\cos(\theta-\beta)+B\cos 3(\theta_0-\beta)+\ldots] \tag{59}$$

The average field current is

$$I_d(\text{average})=I_{d0}+\frac{X_{SD}-X_{SD}'}{K_sX_{md}}\,\frac{e_{SD}}{X_{SD}'+\sqrt{X_{SD}'X_{SQ}'}}=G_0I_{d0} \tag{60}$$

where G_0 is the value of G_1 obtained from equation 22 by setting $i_{d1}=i_{d0}$.

The component of field current, I_d'', contains the odd harmonics and is due to the unidirectional component and even harmonics of the current (i_s-i_a) to which it is directly proportional. It therefore decays to zero according to the decrement factor σ_s.

The current I_d', containing the unidirectional component and even harmonics, must have an average sustained value I_{d0} since it is supported entirely by the exciter voltage. Its sustained value is therefore $(1/G_0)i_d'$. The remainder $(1-1/G_0)I_d'$, is transient in character and, being proportional to the average field current, decays at a rate fixed by σ_f.

Separated into sustained and transient components and with the decrement factors applied, the field current at any instant after the short circuit is

$$I_d=(1/G_0)I_d'+(1-1/G_0)I_d'e^{-\sigma_f t}+I_d''e^{-\sigma_s t} \tag{61}$$

Appendix IV

Short-Circuit Currents Assuming Change in Load Currents

A second approximation to the solution for the short-circuit current is obtained by assuming that i_d and i_q have average values given by equations 6 and 7. It will first be necessary, however, to develop expressions for the currents i_{d1} and i_{q1}.

The currents i_{d1} and i_{q1} may be obtained by use of the voltage equations given in appendix II. Considering only average values, $d\psi_d/dt=d\psi_q/dt=0$. The average value of $(i_s-i_a)\cos(\theta-\beta)$ is $(^1/_2)I_1\cos\alpha_1$ and that of $(i_s-i_a)\sin(\theta-\beta)$ is $(^1/_2)I_1\sin\alpha_1$, where I_1 and α_1 are defined by equations 17 and 18. Likewise, the average value of I_d is I_{d0} and the average of $I_q=0$. Then from equations 47, 48, 49, and 50,

$$(^3/_2)(X_q+X_L)i_{q1}+(^1/_2)K_sX_QI_1\sin\alpha_1+(^3/_2)ri_{d1}=0 \tag{62}$$

$$(^3/_2)(X_d+X_L)i_{d1}+(^1/_2)K_sX_DI_1\cos\alpha_1-(^3/_2)ri_{q1}=-X_{md}I_{d0} \tag{63}$$

These may be solved simultaneously to obtain the currents i_{d1} and i_{q1}. The results are given in equations 19 and 20.

With currents i_d and i_q given by equations 6 and 7, the linkage equations for the short-circuited coils and field windings may be obtained. Following the same procedure as before, these may be solved for the initial currents. When the short-circuit current is separated into its sustained and transient components and the proper decrements are applied, the second approximation to the solution is that given by equation 21.

Nomenclature

i_a, i_b, i_c = currents in phases A, B, and C

i_s = current in short-circuited coil group

I_d = current in main field winding

I_q = current in field winding in quadrature axis

K_d, K_p = distribution and pitch factors for armature phase winding

K_{ds} = distribution factor for the group of s coils as discussed following equation 30

$K_s=(sK_{ds}/pyK_d)$ is a constant

L_D, L_Q = total static inductances, single phase, in the direct and quadrature axes, respectively. These correspond to the commonly used reactances, X_D and X_Q

L_d, L_q = total three phase, line to neutral inductances in the direct and quadrature axes corresponding to the synchronous reactances X_d and X_q

$L_0=(L_l-2L_{lm})$ = zero sequence inductance corresponding to X_0

L_l, L_{lm} = self and mutual leakage inductances per phase

L_{SD}, L_{SQ} = inductances of coil group in the direct and quadrature axes. See appendix I

L = load inductance per phase corresponding to X_L

M_q = maximum mutual inductance per phase between quadrature axis field winding and armature

M_d = maximum mutual inductance per phase between main field and armature

s = number of coils in short-circuited coils

X_d, X_q, X_d', X_q' = usual three phase, line to neutral, synchronous and transient reactances for ,the direct and quadrature axes

$X_{md}=\omega M_d$

X_D, X_Q, X_D' X_Q', = usual static single phase and transient reactances in the direct and quadrature axes

X_{SD}, X_{SQ} = reactances corresponding to L_{SD}, L_{SQ}

$X_L=\omega L$ = reactance of load per phase

β = angular displacement, in electrical radians, of the axis of the group of s short-circuited coils from that of phase A

ρ = coil pitch in electrical radians

θ = angular displacement of direct axis from that of phase A, measured in electrical radians

σ_f = decrement factor of main field, defined by equation 23

σ_s = decrement factor of short-circuited coils, defined by equation 24

Transient Overspeeding of Induction Motors

RAYMOND W. AGER
ASSOCIATE AIEE

Synopsis: A transient swing above synchronous speed has been observed when a certain standard squirrel cage induction motor was started without load. This paper presents an explanation of the phenomenon based on the frequency modulation of the power supply caused by the rapid variation of the power taken from the line. Mathematical relations are developed and applied to the operating conditions of this motor. The agreement of the mathematical and test curves indicates that the explanation is basically correct although some secondary effects, not considered, may be present.

A TRUE induction motor cannot, of itself, operate at or above synchronous speed. The torque developed by this type of motor passes through zero at synchronous speed. It should, therefore, never be able to send the motor above that speed. Yet, in making some acceleration tests, a certain motor was consistently found to go above synchronous speed for a few cycles each time it was started.

This motor was from a standard line of squirrel cage induction motors. It had a cast aluminum rotor with deep, narrow slots. There were no salient-pole structures on the rotor, and, further, the rotor bars were skewed so that there was no tendency for the rotor to lock into synchronism. After the motor was up to speed and had settled down, the slip at no load became constant at less than 0.1 per cent.

The tests in which this behavior was observed were similar to those described in a previous paper.[1] A bakelite disc having 500 divisions accurately engraved around the periphery was mounted on the motor shaft. This disc was illuminated by light pulses from a stroboscopic lamp flashing 60 times per second, and the disc's position was photographically recorded at each flash. The motor was reversed on the line and readings were taken as the motor speed dropped from full speed in one direction to zero and then came back up to full speed in the opposite direction. Velocities were calculated by taking position differences, and accelerations were calculated by taking velocity differences. Since the friction forces were very small the entire torque of the motor was used in producing accelerations. The accelerations observed were converted to torques and plotted against speed in figure 1. Figure 2 shows a section of the velocity versus time curve for the same test. In this test the motor was operated at rated voltage. Due to the high torques developed and the low inertia of the rotor, the motor dropped from full speed in one direction to zero and returned to full speed in the opposite direction in a little over one-half second.

The curve of figure 2 shows that the motor passed through synchronous speed about 35.5 cycles after the test was started, and that it rose almost two per cent above synchronous speed on the first over-swing. A second over-swing was recorded and a third one indicated. Reference to the torque curve of figure 1 shows that the torque developed was practically equal to full-load torque as the motor passed through synchronous speed the first time.

The reason for this peculiar behavior was first qualitatively described as follows. The input to the motor had both power and lagging components. The power input to the motor was approximately proportional to the torque developed. The curve of figure 1 would indicate that during the first part of the test the power input was relatively constant. After passing the maximum torque at about 85% of synchronous speed the power taken from the lines dropped very rapidly. The lagging component of the line current, however, certainly did not vary in the same way. A more gradual change of this component would be expected. The power component would reverse if the motor changed from motor to generator action. Such reversal would not occur in the magnetizing component. From full load to no load the lagging component should be nearly constant and therefore cause constant *IR* and *IX* drops. Since it is the rapid variation of these impedance drops which is important and not their magnitudes the effects of the lagging component may be neglected. The power was supplied from a transformer bank connected to a 4,000 volt system. The bank had an appreciable reactance. Neglecting the resistance of the bank and the lagging component of the motor current, the vector diagram would be as indicated in figure 3. In this diagram E_1 represents the transformer primary voltage vector which may be taken as constant in magnitude and rotating at a constant velocity ω_1. E_2 is the motor-voltage vector and *IX* is the reactance drop in the transformer due to the power component of the motor current. As long as the power component is constant the vector E_2 must rotate at the same speed as the vector E_1, although lagging behind it. If the power component decreases the impedance drop must decrease and the vector E_2 must catch up with vector E_1. Therefore during this transient period the vector must rotate at a velocity ω_2 greater than that corresponding to the normal line frequency. With a frequency greater than 60 cycles impressed on the motor terminals, even if only for a few cycles, the motor may attain a speed greater than the 60 cycle synchronous speed if very lightly loaded.

A more quantitative analysis following the above ideas has indicated that this reasoning is correct. The motor on which the tests were made is no longer available and accurate measurements of its constants had not been made. Approximate values of some of these constants had been determined and the others may be estimated accurately enough for present purposes. All values used are thought to be within 3% of the correct values except

Paper 41-150, recommended by the AIEE committee on electrical machinery, and presented at the AIEE Pacific Coast convention, Yellowstone National Park, August 27–29, 1941. Manuscript submitted May 8, 1941; made available for preprinting July 16, 1941.

Raymond W. Ager is of the school of electrical engineering, Cornell University, Ithaca, N. Y.

The data used in this paper were obtained by C. N. Williamson, a former student of the University of California, now with the U. S. Navy engineering department.

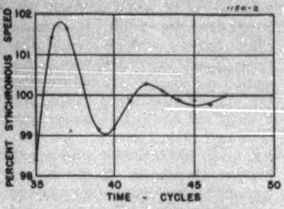

Figure 2. Section of velocity-versus-time curve for same test as figure 1

the full load slip. The full load slip was not determined but the motor manufacturer was consulted before assigning the value used.

Near synchronous speed the torque developed is proportional to the slip, and this torque will all be used in accelerating the rotor if the friction forces are negligible.

$$T = K_1 S = \frac{WR^2}{g} \times \frac{d\omega}{dt} \tag{1}$$

Where S is the slip and ω is the angular velocity of the rotor in radians per second. The full load torque of the motor was 45 pound-feet, and the full load slip was about 2.0 per cent. Therefore the constant K_1 was 45/0.020 or 2,250. The inertia of the rotor, coupling, and disc was 4.0 pound-feet-squared.

From figure 3

$$\omega_2 = \omega_1 - \frac{d\alpha}{dt} \tag{2}$$

The line frequency was 60 cycles per second so that $\omega_1 = 2\pi 60 = 377$. Equation 2 is on a 2-pole basis while equation 1 is for a general p-pole machine. Converting equation 1 to the 2-pole basis it becomes

$$T' = \frac{2K_1}{p} S = \frac{4WR^2}{p^2 g} \frac{d\omega'}{dt} \tag{3}$$

The slip which must be used in these relations depends upon the angular velocity of the rotor and the frequency applied to the motor terminals, and is not the apparent slip based on the nominal line frequency. Therefore

$$S = \frac{\omega_2 - \omega'}{\omega_2} \tag{4}$$

From this

$$\omega_2 = \frac{\omega'}{1-S} \tag{5}$$

Combining (2) and (5)

$$\frac{\omega'}{1-S} = \omega_1 - \frac{d\alpha}{dt} \tag{6}$$

But α is a function of the slip. In the region of interest where the slip is small the lagging component of motor current is nearly constant while the power component is directly proportional to the slip. The angle α therefore varies directly with the slip in this region.

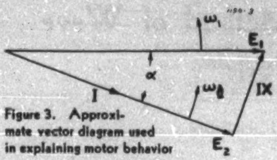

Figure 3. Approximate vector diagram used in explaining motor behavior

$$\alpha = K_2 S \tag{7}$$

The reactance which must be used in computing α is not just the transformer and lead reactance. The motor reactance must be included in this total and will usually be the largest item. For full load the reactance drop was estimated to be 20% of E_1. The angle α was therefore 11.5° or 0.20 radian for 2% slip, and the constant K_2 equal to 10.

Combining equations 6 and 7

$$\omega' = (1-S)\left(\omega_1 - K_2 \frac{dS}{dt}\right) \tag{8}$$

This value of ω' may be substituted in equation 3 giving

$$\frac{2K_1 S}{p} = \frac{4WR^2}{p^2 g} \frac{d}{dt} (1-S)\left(\omega_1 - K_2 \frac{dS}{dt}\right) \tag{9}$$

Differentiating after multiplying by $\frac{p^2 g}{4WR^2}$

$$\frac{K_1 pg}{2WR^2} S = (1-S)\left(-K_2 \frac{d^2S}{dt^2}\right) - \left(\omega_1 - K_2 \frac{dS}{dt}\right)\left(\frac{dS}{dt}\right) \tag{10}$$

Rearranging and dividing by K_2

$$(1-S)\frac{d^2S}{dt^2} + \left(\frac{\omega_1}{K_2} - \frac{dS}{dt}\right)\frac{dS}{dt} + \frac{K_1 pg}{2K_2 WR^2} S = 0 \tag{11}$$

Since the slip is very small in the region of interest the term $(1-S)$ is nearly equal to 1. Also the term $\left(\frac{\omega_1}{K_2} - \frac{dS}{dt}\right)$ is not very different from $\frac{\omega_1}{K_2}$. In figure 2, $\frac{dS}{dt}$ has a value of about 1.8 as the motor passes through synchronism the first time. The tests were made on a 60 cycle supply so that $\frac{\omega_1}{K_2} = 37.7$. Making these approximations, equation 11 becomes

$$\frac{d^2S}{dt^2} + \frac{\omega_1}{K_2}\frac{dS}{dt} + \frac{K_1 pg}{2K_2 WR^2} S = 0 \tag{12}$$

The roots of this equation are

$$D = -\frac{\omega_1}{2K_2} + \sqrt{\frac{\omega_1^2}{4K_2^2} - \frac{K_1 pg}{2K_2 WR^2}} \tag{13}$$

Substituting the numerical values corresponding to the tests in this equation

$$D = -18.8 + \sqrt{355 - 3{,}622}$$
$$= (-18.8 + j57.2)(-18.8 - j57.2) \tag{14}$$

By choosing zero time as the first time the motor passes through synchronous speed or zero slip, and further making the slopes of the two curves the same at this point, the slip equation becomes

$$S = -0.0315\epsilon^{-18.8t} \sin 57.2t \tag{15}$$

This is a damped oscillation having a frequency of 9.1 cycles per second. The frequency of the damped oscillation shown in figure 2 is about 10 cycles per second. The damping is nearly the same in the two cases. A plot of equation 15 is shown in figure 4. The test curve of figure 2 is replotted for comparison. Negative values of slip have been plotted above the axis and the ordinate scaled in terms of synchronous speed so that the curve will appear the same as figure 2. The discrepancies between the test results and equation 15 are due to several causes. First the determination of the constants of the motor were not as accurate as desired. Second the setting up and solution of the differential equation involved approximations. Third the motor was changing speed so rapidly that one might expect that the functions K_1 and K_2, called constants, might not be strictly constant, and their numerical values under these transient conditions might be different from values determined by steady state tests.

Equation 13 indicates that oscillations will be present when the quantity under the radical is negative. This condition exists when

$$\frac{K_1 K_2 p}{WR^2} > \frac{\omega_1^2}{2g} \tag{16}$$

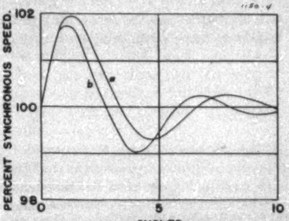

Figure 4

A Cathode-Ray Method of Wave Analysis

VINCENT O. JOHNSON
ASSOCIATE AIEE

Synopsis: Complex periodic functions, when transformed into a corresponding voltage wave, may be analyzed with the use of a cathode ray oscillograph. The complex wave is represented upon the fluorescent screen of the cathode ray tube by a vertical displacement at the same time that a sinusoidal horizontal oscillation exists. If the frequency of the sinusoidal oscillation bears an integral relation to the fundamental frequency of the complex wave, a Lissajous figure is viewed on the screen. The areas of these Lissajous figures are directly related to the coefficients of the Fourier series of the complex wave. The area is determined by measuring a photograph of the figure using a polar planimeter. The method is based on the theory developed by Mr. L. W. Chubb in connection with the Chubb Polar Analyzer.[4] Advantages of the method are that it is quick and convenient, only standard laboratory equipment is necessary, and with special equipment, it promises to make possible the analysis of ultrahigh frequency waves.

PERIODIC waves, such as the vibration of mechanical bodies or the variation of current and voltage in electric circuits, are often complex. In electric circuits, sinusoidally varying functions usually give the most satisfactory operation. Calculations are much easier, values may be expressed graphically in vector diagrams, and vector equations may be used. The same is true of mechanical vibration. Hence, in order to handle complex waves conveniently, it is desirable that they be separated into their sinusoidal components. It is the purpose of this paper to describe and explain a new method of wave analysis using a cathode ray oscillograph. The underlying theory is not new, but the method is thought to be faster and the results more complete than other methods of wave analysis using ordinary laboratory equipment. It is hoped that this method will prove useful in other laboratories.

Application of Lissajous Figures to Wave Analysis

The electron beam in a cathode ray tube is deflected by electrostatic forces. If the beam be deflected in one direction by an alternating voltage, and at the same time by another voltage in a direction at right angles to the first, the resulting position of the beam at any instant of time is a function of both voltages. If one frequency is an even multiple of the other, the resulting pattern upon the screen is a Lissajous figure.

In order to begin a study of Lissajous figures, a simple Lissajous figure is shown in figure 1. The two functions to be compounded are $f(\theta)=A_1 \sin \theta$, and $g(\theta)=A_2 \sin (\theta+\alpha)$. The Lissajous figure is an ellipse with a maximum vertical dimension of $2A_2$ and a maximum horizontal dimension of $2A_1$. If $\alpha=0$, the ellipse becomes a single straight line; if $\alpha=90°$, one axis of the ellipse will be vertical and equal to $2A_2$, and the other axis will be horizontal and equal to $2A_1$; if $\alpha=90°$ and $A_1=A_2$, the Lissajous figure becomes a circle. More complex Lissajous figures are obtained if either or both functions are complex. In this case the fundamental frequencies of the functions must be the same or bear an integral ratio to each other.

The Fourier series for a complex function may be expressed as follows:

$$f(\theta)=A_0+C_1 \sin (\theta+\theta_1)+C_2 \sin 2(\theta+\theta_2)+ \ldots +C_n \sin n(\theta+\theta_n)+ \ldots \quad (1)$$

where θ is a function of time equal to $2\pi ft$. However, due to the difficulty of using the harmonics in their various phase positions, each harmonic is usually resolved into two quadrature components thus:

$$f(\theta)=A_0+A_1 \sin \theta+B_1 \cos \theta+A_2 \sin 2\theta+B_2 \times \cos 2\theta+ \ldots +A_n \sin n\theta+B_n \cos n\theta+ \ldots \quad (2)$$

As a result, wherever complex periodic waves are encountered they are usually resolved into their harmonic components in order to permit a simpler mathematical treatment. The process of harmonic analysis, then, reduces merely to a problem of evaluating the coefficients A_0, A_1, B_1, etc., in the above series. This can be done in a great number of ways.

Experiments have been conducted in the laboratories of the A. & M. College of Texas using a low voltage cathode ray oscillograph for wave analysis. The complex wave is applied to the horizontal plates which give the cathode beam a vertical displacement. This pair of plates will be referred to hereafter as the horizontal plates, and the other pair of plates as the vertical plates. Ordinarily

Paper 41-156, recommended by the AIEE committee on instruments and measurements, and presented at the AIEE South West District meeting, St. Louis, Mo., October 8–10, 1941. Manuscript submitted June 19, 1941; made available for preprinting August 15, 1941.

VINCENT O. JOHNSON is with engineering laboratories and standards, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

1. For all numbered references, see list at end of paper.

For K_1 and K_2 may be substituted their values in terms of full-load torque, slip, and angular phase shift.

$$\frac{T\alpha p}{WR^2S^2} > \frac{\omega_1^2}{2g} \quad (17)$$

This relation indicates that overspeeding may be reduced by increasing the WR^2 of a machine. Large machines have large values of WR^2 but also produce large torques. The inertia constant usually increases more rapidly than the torque, as the machine size is increased, so that these larger motors should show less tendency to over speed. The most important factor is the full-load slip since it occurs in the function as a squared term. Motors with low full-load slip should have much greater tendencies to overspeed than high-slip motors. Operation at reduced voltage would decrease this tendency by changing the relation between the torque, slip, and angle.

Various acceleration methods have been considered as a means of determining the speed-torque curves of induction motors. The above analysis indicates that precautions must be taken to avoid conditions similar to those found in these tests if accurate results are to be obtained. However the errors involved are appreciable only near synchronous speed where the frequency change represents a large percentage of the rotor frequency. Where acceleration methods are used to determine only the low-speed part of the curve, errors due to this frequency modulation should not be important.

the vertical plates receive a saw-tooth shaped voltage wave, which produces a linear horizontal sweep and allows visual observation of the shape of the complex wave. For wave analysis, the vertical plates are connected to a generator which will produce a nearly pure sine wave.

Since equation 2 is an expression representing a complex wave $f(\theta)$, let it represent the complex wave that is applied to the horizontal plates of the oscillograph. Also let $g(\theta)=-K\cos k(\theta+\alpha_k)$ be the sinusoidal wave applied to the vertical plates. The function $g(\theta)$ has a frequency k times the frequency of the fundamental of $f(\theta)$, so if k is an integer, a Lissajous figure will appear upon the oscillograph screen. The amplitude of $g(\theta)$ is K, and the angle α_k in the expression indicates the phase angle between $g(\theta)$ and the cosine term of the kth harmonic of $f(\theta)$.

Referring again to figure 1 and the discussion of plotting Lissajous figures, it is evident that the shape of the Lissajous figure depends upon the phase angle $k\alpha_k$. There is an infinite number of shapes that may be assumed as $k\alpha_k$ may assume an infinite number of values between 0 and 2π. If the frequency of $g(\theta)$ is not exactly a multiple of the frequency of $f(\theta)$, that is, if the two waves are not synchronized, the figure will gradually change through a complete cycle of shapes as the phase angle changes from 0 to 2π.

The area S_k of one of these figures may be calculated from the expressions of the two functions $f(\theta)$ and $g(\theta)$, and is as follows:

$$S_k=kK\pi(A_k\cos k\alpha_k+B_k\sin k\alpha_k) \qquad (3)$$

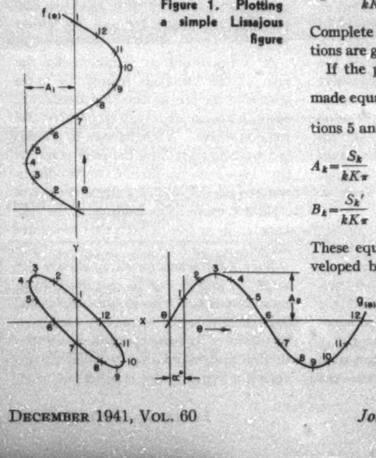

Figure 1. Plotting a simple Lissajous figure

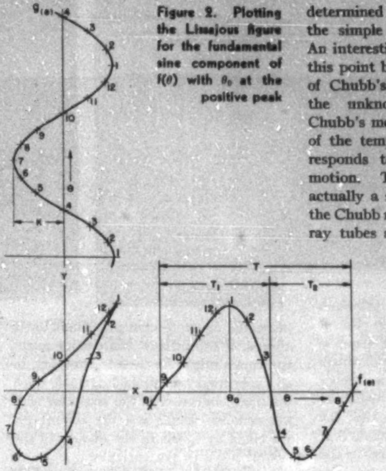

Figure 2. Plotting the Lissajous figure for the fundamental sine component of $f(\theta)$ with θ_0 at the positive peak

It will be noticed that this expression contains only two coefficients of the series for $f(\theta)$. However, it is necessary to be able to solve for one of the coefficients independently. This may be done if another expression can be derived that will contain the same two coefficients. If the phase angle α_k were allowed to change to a new value, say β_k, the area of the figure would change to a new value S_k'. This area may be expressed similarly as

$$S_k'=kK\pi(A_k\cos k\beta_k+B_k\sin k\beta_k) \qquad (4)$$

If equations 3 and 4 are combined, the resulting expressions for A_k and B_k are as follows:

$$A_k=\frac{S_k\sin k\beta_k-S_k'\sin k\alpha_k}{kK\pi\sin k(\beta_k-\alpha_k)} \qquad (5)$$

$$B_k=\frac{S_k'\cos k\alpha_k-S_k\cos k\beta_k}{kK\pi\sin k(\beta_k-\alpha_k)} \qquad (6)$$

Complete derivations of the above equations are given in the appendices.

If the phase angles $k\alpha_k$ and $k\beta_k$ were made equal to 0 and $\frac{\pi}{2}$ respectively, equations 5 and 6 would reduce to

$$A_k=\frac{S_k}{kK\pi} \qquad (7)$$

$$B_k=\frac{S_k'}{kK\pi} \qquad (8)$$

These equations correspond to those developed by L. W. Chubb in connection with the Chubb polar analyzer.[4] However, the fact that it is difficult to accurately adjust the frequency and phase angle of the sine wave generator to a predetermined value precludes the use of the simple expressions in (7) and (8). An interesting analogy may be drawn at this point between this method and that of Chubb's. The vertical deflection of the unknown wave corresponds to Chubb's mechanical deflection by means of the template, and the oscillator corresponds to Chubb's simple harmonic motion. The cathode ray method is actually a simplification in apparatus of the Chubb method, making use of cathode ray tubes and oscillators to replace the Chubb mechanical apparatus. Like the Chubb method, this method will not apply to a determination of the constant term A_0 in a Fourier series. The constant term is relatively unimportant, and if it exists in a circuit, it may be determined by means of a direct current instrument.

It is interesting to note that the expressions 5 and 6 are both in terms of some area divided by π. The graphical method of analysis introduced by C. Runge[2] makes use of a theoretical area obtained by multiplying each ordinate by a function of the corresponding angle. The Lissajous figure automatically produces this same area as an actual figure that may be measured, with the exception that the area is multiplied by K the amplitude of $g(\theta)$, and k the order of the harmonic. Hence both K and k appear in the denominator of expressions 5 and 6.

Discussion of Experimental Procedures

In experimental analysis by means of the cathode ray method, several serious problems have been encountered; (1) the area of the Lissajous figure must be determined easily and accurately, (2) the sine wave source must be of a variable frequency and have very low harmonic content, (3) the frequency must be adjustable to synchronize with the fundamental of the complex wave, (4) the phase angle between the sine wave and the complex wave must be readily determined, and (5) results must be obtained in suitable units.

The Lissajous figure remains stationary on the screen only as long as the two waves are properly synchronized. With a little practice it may be possible to estimate the net area of a figure on the screen. A better practice, however, is to photograph the figure and later measure the area with an ordinary polar planimeter.

Figure 3 (left). Transformer exciting current wave

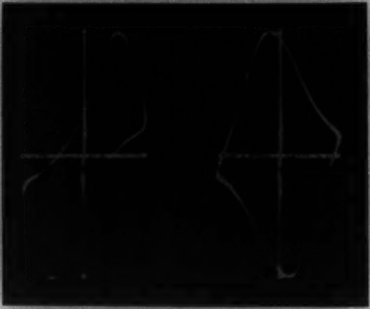

Figure 4 (right). A pair of Lissajous figures for determining the fundamental harmonic

The camera used is important, although an expensive one is not necessary. Better results will be obtained if the room is slightly darkened, but complete darkness is more of a handicap than a help. Since speed is more important than depth of focus, a fast lens is desirable. Also, the size of the image on the film demands that the camera be focused at distances in the vicinity of one or two feet. Once the camera is focused, however, it should not be changed during the process of analyzing a wave, as a change of focus would change the scale of units upon the film.

The sine wave source may be either a mechanical generator or an oscillator. The mechanical generator, of course, would be adaptable only at lower frequencies. In the 60 cycle range, the seventh harmonic is 420 cycles, and a generator producing from 60 to 420 cycles is a rare and expensive piece of equipment and may still develop a high percentage of harmonics. The most desirable characteristic of a mechanical generator would be the accuracy with which synchronism and phase relations could be worked out by mechanical gearing. In general a good quality variable frequency oscillator is more convenient to handle and more easily adjustable.

A number of different types of oscillators may be used. The only requirements are that the oscillator have a nearly constant amplitude over the proper frequency range and that the harmonic content be very small. The power required to maintain voltage across the plates of the tube is very small, so the power rating of the oscillator is relatively unimportant. However, if the output voltage is low, the oscillograph must have an amplifier to produce a figure of the desired size upon the screen.

The frequency of the oscillator must coincide exactly with that of the complex wave if a Lissajous figure is to remain stationary, and frequency drift of either the oscillator or the complex wave will cause the figure to change. There are a number of automatic synchronizing methods which might be used.[5] However, in all cases tried the method depends upon the interconnection of the oscillator with the complex wave, and the advantages are offset by a loss in the quality of the output wave of the oscillator. For this reason manual control of the frequency is desirable and a good frequency control is an important feature of the oscillator.

When the frequencies are synchronized so that the Lissajous figure remains stationary, there are a number of different shapes that the figure can assume. These depend upon the phase angle between the two waves. It is important to be able to determine this phase angle since it enters into the expression for the coefficients of the Fourier series, equations 5 and 6. In figure 2 a complex wave $f(\theta)$ has been plotted on the horizontal axis and a sine wave $g(\theta)$ has been plotted on the vertical axis. The Fourier series for $f(\theta)$ depends upon the location of a reference point where all the sine terms of the series are zero and all the cosine terms have a positive maximum value. Call this point θ_0. In many methods of analysis, the point where the complex wave crosses the axis is chosen for θ_0. For the cathode ray method of analysis, the maximum positive peak of $f(\theta)$ is thought to be a more suitable point for θ_0. The general expression for $g(\theta)$ in figure 2 is $g(\theta)=-K \cos k(\theta+\alpha_k)$. Since θ_0 is a value of θ such that $\sin(\theta_0)=0$ and $\cos(\theta_0)=+1$, θ_0 is some multiple of 2π. Hence, $g(\theta)$ for $\theta=\theta_0$ reduces to

$$g(\theta_0)=-K \cos k\alpha_k \qquad (9)$$

In figure 2, the Lissajous figure has been plotted for the case when $\alpha_k=0$, and $g(\theta_0)=-K$. It will be noted that the Lissajous figure has a peak in the upper right corner a distance $-K$ from the Y axis. If α_k has a value other than zero, $g(\theta_0)$ will be reduced in magnitude and the peak will have moved a distance $(K-K \cos k\alpha_k)$ to the left. The peak can always be located on the oscillogram and $g(\theta_0)$ may be measured directly. Then the angle $k\alpha_k$ is, from equation 11,

$$k\alpha_k = \cos^{-1}(g(\theta_0)/K) \qquad (10)$$

From equation 10, $k\alpha_k$ may be either positive or negative since the cosine is the same for either case, but in writing the sine of $k\alpha_k$, it is important to know whether $k\alpha_k$ is positive or negative. It is positive if $g(\theta)$ has already passed its negative maximum at the time $f(\theta)$ reaches its peak value. The best way to determine this when viewing the figure on the oscillograph screen is to adjust the frequency of the sine wave generator to a value slightly greater than that of the harmonic and stop the figure by synchronizing the two frequencies after the peak has left the upper right corner moving to the left. If the peak is stopped before it reaches the midpoint, the angle will be between 0° and 90°, while if it is stopped between the midpoint and the upper left corner, the angle will be between 90° and 180°. It is good practice to make $k\alpha_k$ about 45° and $k\beta_k$ about 135°.

It is important in planimetering the area of the Lissajous figures, to move always in the proper direction around the loops, for some areas may be positive and some negative. A simple way to do this is always to start from the peak point on the Lissajous figure and move downward to the left, thus tracing through one complete cycle. The reading on the planimeter is or can be corrected to square inches.

Now if the scales for all figures are the same, A_k and B_k can be calculated from equations 5 and 6 in inches. However, it is usually better to convert each area by means of its scale constant to a hypothetical unit, which may be called square volts if a voltage wave is being analyzed,

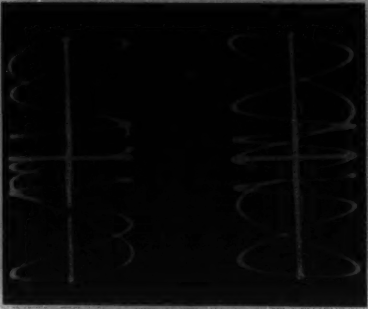

Figure 5. A pair of Lissajous figures for determining the seventh harmonic

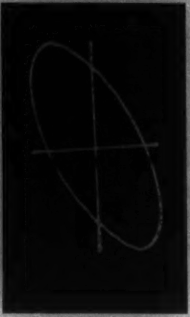

Figure 6. Calibration picture

or square amperes for a current wave. Then K (assumed constant) can be converted to the correct units, and the value of A_k is derived in those units. If K is not constant, equations 5 and 6 must be altered as follows:

$$A_k = \frac{S_k/K \sin k\beta_k - S_k'/K' \sin k\alpha_k}{k\pi \sin k(\beta_k - \alpha_k)} \tag{11}$$

$$B_k = \frac{S_k'/K' \sin k\alpha_k - S_k/K \cos k\beta_k}{k\pi \sin k(\beta_k - \alpha_k)} \tag{12}$$

The scale constant may be determined by taking a picture of a pure sine wave of known amplitude at the same time the other pictures are being taken. In fact, it is a good practice to take two or three calibration pictures during an experiment. Obviously, a change in amplification on the oscillograph or focus of the camera will alter the scale constant. If the scale constant varies slightly for unavoidable reasons, either an average constant must be used or individual constants must be assigned to each picture.

Experimental Results

In order to determine to some extent how practical the cathode ray method of wave analysis is, an exciting current wave for a potential transformer was analyzed. Figure 3 shows an oscillogram of the wave that was analyzed. The results of the cathode ray method were compared with results using another method of analysis. The other method was the graphical method of C. Runge using 72 points.[2] A comparison of results is shown in table I. The analysis was only carried as far as the seventh harmonic as the graphical method becomes very inaccurate for higher harmonics and correspondingly small magnitudes. It is thought that the two methods possess about the same degree of accuracy for low order harmonics up to the third, but for higher harmonics the cathode ray method is thought to be more accurate. The areas of the Lissajous figures for higher harmonics may be rather accurately determined because they are proportional to the order of the harmonic k times the magnitude of the corresponding coefficients.

Table I. Comparison of Results in an Experimental Analysis of a Transformer Exciting Current

	Cathode-Ray Method		Runge Method	
Harmonic	Magnitude Amperes	Phase Angle Degrees	Magnitude Amperes	Phase Angle Degrees
First	0.318	0	0.327	0
Third	0.1120	44.2	0.1135	50.0
Fifth	0.0267	54.5	0.0248	59.0
Seventh	0.00794	7.7	0.00725	12.6

Figures 4 and 5 show examples of some of the Lissajous figures that were used in the experimental analysis. The pictures were taken using a 35 mm. camera with an f-4.5 lens. Exposures were made at $^1/_{25}$ of a second. This was found to give a very good trace on the film when the intensity of the cathode ray was adjusted to a reasonable brightness. Since the light emitted from a cathode ray oscillograph screen is very small, a camera with a fast lens is a distinct advantage. Another desirable feature in this application is a short focus, since the size of the figures on the screen is hardly more than two inches high. The zero axes of the Lissajous figures were obtained by exposing the film once with the exciting current wave shorted out and once with the sine wave shorted out in addition to the exposure for the figure itself. Figure 6 is an example of one of the calibration pictures that were taken. It is a Lissajous figure similar to those in figure 4 except that both waves are sinusoidal.

Figure 7 shows the equipment as it was assembled for the experimental analysis. The cathode ray oscillograph had a 5 inch screen and the size of the figure could be adjusted through step up amplifiers on both the horizontal and vertical plates. The oscillator was a beat frequency type having a frequency range from 20 to 17,000 cycles and a practically constant amplitude over that range. Just in front of the oscillator and to the left is a small tuning condenser which was used in parallel with the main tuning condenser on the oscillator to give a finer adjustment of frequency.

Conclusion

It is important to note that only standard laboratory equipment is necessary for the cathode ray analysis. The method is much faster and less tedious than the graphical method, because most of the calculation is dispensed with. Harmonics that do not exist, or are negligible, are apparent at once from the areas of the Lissajous figures without further calcu-

Figure 7. Apparatus used for the experimental analysis

lation. The other harmonics may be quickly calculated and converted to the correct units.

But much more important than any other advantage is the fact that the cathode ray oscillograph will respond effectively to much higher frequencies than any other type of oscillograph. The vibrator elements in most mechanical oscillographs have a natural frequency of 5,000 cycles per second undamped; so it is evident that any frequency in this range would be somewhat magnified and the results would be erratic. The cathode ray oscillograph may be used in the radio frequency range. Thus, high frequency waves may be analyzed with the same simplicity and completeness as are the power frequency waves.

With the possibility of completely analyzing higher frequency waves, the study of mechanical vibration may be accelerated and improved. A device that would couple the mechanical system to an electrical circuit and reproduce the mechanical oscillations as electrical functions would make possible the analysis of mechanical vibration with a cathode ray oscillograph.

The frequency range of cathode ray oscillographs has been still further increased with the invention of a new microwave oscillograph devised for the centimeter range of wave lengths, where ordinary oscillographs are not adaptable.[8] These high frequency waves are distorted in the ordinary cathode ray oscillograph because the finite time required for an electron to pass across a deflecting field is of the same order of magnitude as the time required for one cycle of the wave. Also, if the two deflection fields are spaced along the direction of the beam, the time lag between the two fields is an appreciable part of a cycle. In the microwave oscillograph, the deflection fields are made small and brought very close together. All dimensions of the tube are likewise reduced, and the image is thrown upon an especially fine grain fluorescent screen. The image itself is so small that it must be observed and photographed by means of a microscope. This new instrument should make ultra-high frequency wave analysis possible, with very little change from the method described in this paper.

Appendix I

Areas of Lissajous Figures

The general expression for the sinusoidal function is

$$g(\theta) = -K \cos k(\theta+\alpha_k) \tag{13}$$

and

$$\begin{aligned} dg(\theta) &= kK \sin k(\theta+\alpha_k)d\theta \\ &= kK(\cos k\alpha_k \sin k\theta + \sin k\alpha_k \cos k\theta)d\theta \end{aligned} \tag{14}$$

The area of the Lissajous figure is

$$S_k = \int_0^{2\pi} f(\theta)dg(\theta) \tag{15}$$

The complex function $f(\theta)$, given in equation 2, may be changed to the following form:

$$f(\theta) = A_0 + \sum_{n=1}^{\infty} A_n \sin n\theta + \sum_{n=1}^{\infty} B_n \cos n\theta \tag{16}$$

The integration may be carried out for each part of $f(\theta)$ independently as follows:

$$\int_0^{2\pi} A_0 kK \sin k(\theta+\alpha_k)d\theta = 0$$

$$\int_0^{2\pi} (A_n \sin n\theta)(kK \cos k\alpha_k \sin k\theta)d\theta = 0 \qquad \text{if } n \neq k$$

$$\int_0^{2\pi} (A_n \sin n\theta)(kK \sin k\alpha_k \cos k\theta)d\theta = 0 \qquad \text{for all } n$$

$$\int_0^{2\pi} (B_n \cos n\theta)(kK \cos k\alpha_k \sin k\theta)d\theta = 0 \qquad \text{for all } n$$

and

$$\int_0^{2\pi} (B_n \cos n\theta)(kK \sin k\alpha_k \cos k\theta)d\theta = 0 \qquad \text{if } n \neq k$$

If $n = k$

$$\begin{aligned} \int_0^{2\pi} (A_n \sin n\theta)(kK \cos k\alpha_k \sin k\theta)d\theta &= \\ A_k kK \cos k\alpha_k \int_0^{2\pi} \sin^2 k\theta d\theta &= \\ (A_k kK \cos k\alpha_k)\pi & \end{aligned}$$

and

$$\begin{aligned} \int_0^{2\pi} (B_n \cos n\theta)(kK \sin k\alpha_k \cos k\theta)d\theta &= \\ B_k kK \sin k\alpha_k \int_0^{2\pi} \cos^2 k\theta d\theta &= \\ (B_k kK \sin k\alpha_k)\pi & \end{aligned}$$

Only two terms remain in the expression for the area S_k,

$$\begin{aligned} S_k &= A_k kK\pi \cos k\alpha_k + B_k kK\pi \sin k\alpha_k \\ &= kK\pi(A_k \cos k\alpha_k + B_k \sin k\alpha_k) \end{aligned} \tag{17}$$

Since it is known that α_k may assume a new value β_k, the expression for S_k' may be written immediately,

$$S_k' = kK\pi(A_k \cos k\beta_k + B_k \sin k\beta_k) \tag{18}$$

Appendix II

Derivation of General Expression for the Coefficients

Equations 17 and 18 may be changed to the following form:

$$A_k \cos k\alpha_k + B_k \sin k\alpha_k = \frac{S_k}{kK\pi} \tag{19}$$

$$A_k \cos k\beta_k + B_k \sin k\beta_k = \frac{S_k'}{kK\pi} \tag{20}$$

These equations may be solved by determinants for the coefficients A_k and B_k.

$$\begin{aligned} A_k &= \frac{\dfrac{1}{kK\pi}\begin{vmatrix} S_k, & \sin k\alpha_k \\ S_k', & \sin k\beta_k \end{vmatrix}}{\begin{vmatrix} \cos k\alpha_k, & \sin k\alpha_k \\ \cos k\beta_k, & \sin k\beta_k \end{vmatrix}} \\ &= \frac{\dfrac{1}{kK\pi}(S_k \sin k\beta_k - S_k' \sin k\alpha_k)}{\cos k\alpha_k \sin k\beta_k - \cos k\beta_k \sin k\alpha_k} \\ &= \frac{S_k \sin k\beta_k - S_k' \sin k\alpha_k}{kK\pi \sin k(\beta_k - \alpha_k)} \end{aligned}$$

$$\begin{aligned} B_k &= \frac{\dfrac{1}{kK\pi}\begin{vmatrix} \cos k\alpha_k, & S_k \\ \cos k\beta_k, & S_k' \end{vmatrix}}{\begin{vmatrix} \cos k\alpha_k, & \sin k\alpha_k \\ \cos k\beta_k, & \sin k\beta_k \end{vmatrix}} \\ &= \frac{\dfrac{1}{kK\pi}(S_k' \cos k\alpha_k - S_k \cos k\beta_k)}{\cos k\alpha_k \sin k\beta_k - \cos k\beta_k \sin k\alpha_k} \\ &= \frac{S_k' \cos k\alpha_k - S_k \cos k\beta_k}{kK\pi \sin k(\beta_k - \alpha_k)} \end{aligned}$$

The Apparent-Impedance Method of Calculating Single-Phase-Motor Performance

WAYNE J. MORRILL
MEMBER AIEE

Synopsis: In the past several years there have been offered a number of calculation methods to be used in connection with predetermining the performance of single-phase induction motors. While such methods are usually based upon either the cross field or the revolving field theory, they differ from each other according to individual preferences.

In the present paper there is proposed a method which seems to be convenient and simple, and which, because of symmetry, involves a minimum of charts in carrying out the necessary calculations. The method is proposed because it has been used in one design department for a number of years and found to be very satisfactory as a practical method.

In the calculation of performance of single-phase motors by the revolving-field theory, there appear repeatedly certain quantities which have been defined as apparent impedances. The actual determination of an apparent impedance when the characteristic impedances of the motor are known involves a considerable amount of labor and the use of complex quantities. This labor has caused some engineers to avoid a straightforward use of the revolving-field theory and to substitute artificial steps, or actually to use entirely different methods. In a case such as this it is often convenient to consider whether the labor of calculation could be avoided by the use of a suitable chart wherein the calculational work is done once and for all and, for a specific calculation, it is merely necessary to read the values from the chart. It is the principal purpose of this paper to indicate how such charts may be constructed for the determination of apparent impedance and to show how the use of such charts can be made to simplify induction-motor performance calculations.

Per-Unit Apparent-Impedance Charts

The values of the apparent impedances of a single-phase motor were given in equations 54 to 57, inclusive, of my 1929 paper[1] on the revolving-field theory. These values are indicated below in equations 1 to 4.

$$R_f=\frac{X_m^2\dfrac{R_2}{s}}{\left(\dfrac{R_2}{s}\right)^2+(X_2+X_m)^2} \tag{1}$$

$$X_f=\frac{X_m\left[\left(\dfrac{R_2}{s}\right)^2+X_2(X_2+X_m)\right]}{\left(\dfrac{R_2}{s}\right)^2+(X_2+X_m)^2} \tag{2}$$

$$R_b=\frac{X_m^2\left(\dfrac{R_2}{2-s}\right)}{\left(\dfrac{R_2}{2-s}\right)^2+(X_2+X_m)^2} \tag{3}$$

$$X_b=\frac{X_m\left[\left(\dfrac{R_2}{2-s}\right)^2+X_2(X_2+X_m)\right]}{\left(\dfrac{R_2}{2-s}\right)^2+(X_2+X_m)^2} \tag{4}$$

The right-hand members of each of the above four equations contain three independent variables, if R_2/s and $R_2/(2-s)$ be each considered as a single variable. Functions involving three independent variables are usually considered too complicated to chart since they involve families of curves. However, if the apparent impedances and each of the independent variables of the preceding equations be expressed as per unit of one of the independent variables, it is possible to reduce the number of independent variables by one. This can be done if both sides of the four above equations be divided by X_m and both the numerator and denominator of each of the right-hand members be divided by X_m^2. The resulting equations are given in 5 to 8 below:

$$\frac{R_f}{X_m}=\frac{\dfrac{R^2}{X_m s}}{\left(\dfrac{R_2}{X_m s}\right)^2+\left(\dfrac{X_2}{X_m}+1\right)^2}=\text{per unit forward field apparent resistance} \tag{5}$$

$$\frac{X_f}{X_m}=\frac{\left(\dfrac{R_2}{X_m s}\right)^2+\dfrac{X_2}{X_m}\left(\dfrac{X_2}{X_m}+1\right)}{\left(\dfrac{R_2}{X_m s}\right)^2+\left(\dfrac{X_2}{X_m}+1\right)^2}=\text{per unit forward field apparent reactance} \tag{6}$$

$$\frac{R_b}{X_m}=\frac{\dfrac{R_2}{X_m(2-s)}}{\left(\dfrac{R_2}{X_m(2-s)}\right)^2+\left(\dfrac{X_2}{X_m}+1\right)^2}=\text{per unit backward-field apparent resistance} \tag{7}$$

$$\frac{X_b}{X_m}=\frac{\left(\dfrac{R_2}{X_m(2-s)}\right)^2+\dfrac{X_2}{X_m}\left(\dfrac{X_2}{X_m}+1\right)}{\left(\dfrac{R_2}{X_m(2-s)}\right)^2+\left(\dfrac{X_2}{X_m}+1\right)^2}=\text{per unit backward-field apparent reactance} \tag{8}$$

In equations 5 to 8 the independent variables will have the following definitions:

$\dfrac{R_2}{X_m s}$ = per unit secondary resistance at slip s

$\dfrac{R_2}{X_m(2-s)}$ = per unit secondary resistance at slip $2-s$

$\dfrac{X_2}{X_m}$ = per unit secondary reactance

On the basis of the above definitions of the independent variables, there are only two independent variables in the right-hand members of equations 5 to 8. It therefore becomes possible to plot each of equations 5 to 8 in the form of a family of curves. Since the only difference between the expressions for per unit apparent forward field resistance and reactance and the similar expressions for the backward field is the use of R_2/s in place of $R_2/(2-s)$, the curves for the forward and backward field apparent impedances will be identical and only two families of curves need be drawn.

In figures 1 and 2 there are shown curves of per unit apparent resistance and per unit apparent reactance plotted for definite values of per unit secondary reactance and as a function of the reciprocal of the per unit secondary resistance for slips of s or $2-s$. The reciprocal of the per unit secondary resistance has been chosen as the independent variable because the resulting curves spread out in such a fashion as to make them more easily and more accurately read.

In order to make use of the charts and to obtain an actual value of apparent resistance or reactance, it is first necessary to obtain the per unit secondary reactance, X_2/X_m, to learn which of the curves

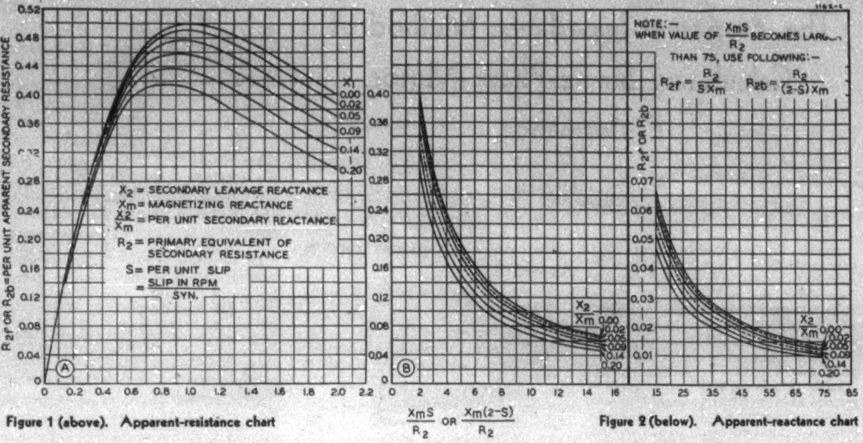

Figure 1 (above). Apparent-resistance chart

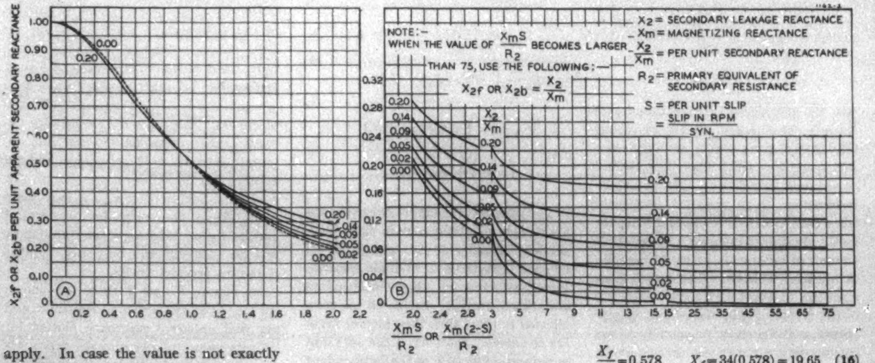
Figure 2 (below). Apparent-reactance chart



apply. In case the value is not exactly the same as that of a curve, it is, of course, necessary to interpolate between two adjacent curves.

Once the proper curve has been selected, the corresponding value of per unit apparent resistance or reactance may be read as the ordinate corresponding to the proper value of $X_m s/R_2$ or $X_m(2-s) \div R_2$. The actual apparent resistance or reactance is obtained as the product of the per unit apparent resistance or reactance by X_m, the magnetizing reactance.

As an example of actual use of these curves, consider the case of a single-phase motor having the following constants:

$$R_2 = 2 \tag{9}$$

$$X_2 = 1.7 \tag{10}$$

$$X_m = 34 \tag{11}$$

If this motor is operating at a slip of 0.05, the per unit forward and backward field secondary reactances will be

$$\frac{X_2}{X_m} = \frac{1.7}{34} = 0.05 \tag{12}$$

and the reciprocal of the per unit forward and backward field secondary resistances will be

$$\frac{X_m s}{R_2} = \frac{34(0.05)}{2} = 0.85 \tag{13}$$

$$\frac{X_m(2-s)}{R_2} = \frac{34(1.95)}{2} = 33.2 \tag{14}$$

Using these values and figures 1 and 2, the per unit apparent impedances and the corresponding actual impedance values are given below:

$$\frac{R_f}{X_m} = 0.475 \qquad R_f = 34(0.475) = 16.18 \tag{15}$$

$$\frac{X_f}{X_m} = 0.578 \qquad X_f = 34(0.578) = 19.65 \tag{16}$$

$$\frac{R_b}{X_m} = 0.0273 \qquad R_b = 34(0.0273) = 0.928 \tag{17}$$

$$\frac{X_b}{X_m} = 0.0482 \qquad X_b = 34(0.0482) = 1.638 \tag{18}$$

Calculation of Single-Phase-Motor Performance

In the calculation of motor performance it is usually desirable to proceed from a relatively simple idealized conception and to introduce phenomena of secondary importance by modifying the results obtained from the idealized concept. For example: The equivalent circuit for the single-phase motor which was given in figure 1 of my 1929 paper (figure 3 of the present paper), and which has appeared many times in publications by other authors, makes no provision for repre-

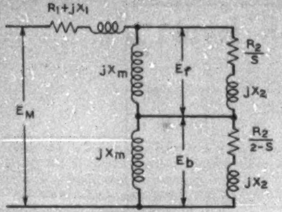


Figure 3. Single-phase-motor equivalent circuit

senting the core-loss current. Such current could be shown as flowing through a high resistance which is connected in parallel with the magnetizing reactance of each forward and backward field. In actual practice it is usually found that the effect of the core-loss current on the motor performance is relatively small since the current itself is usually very small and since its time-phase relation is at 90 degrees with respect to the magnetizing current, which latter is usually relatively large. For this reason, it has usually been found desirable to consider the core loss as if it were the result of a high resistance in parallel with the entire motor and to neglect the effect of the flow of the core-loss current through the primary impedance of the motor. When this approach is employed, the core loss may be introduced as an input which is added to the input determined from the idealized equivalent circuit.

There are two other losses which must be accounted for in making an exact single-phase motor calculation and these are the rotational iron loss and the mechanical friction, sometimes called friction and windage. The rotational iron loss is indistinguishable from friction in its effect upon motor performance since the loss appears as a retarding torque tending mechanically to slow down the motor. The torque of rotational core loss differs from the torque of friction in that, in addition to being a function of speed, it is also a function of the currents in the stator and the rotor and, while an exact expression for the torque would be complicated, it and the corresponding power loss may be approximately represented as proportional to the second power of the stator current.

If it be presumed that the rotational iron loss and the mechanical friction are both known, and that the two rotational losses be classed as friction and represented by the symbol W_f, the effect of this combined rotational loss is properly accounted for if W_f be subtracted from the electrical output as determined from the idealized circuit.

A Novel Reclosing Relay

P. O. BOBO
MEMBER AIEE

Synopsis: This paper describes a reclosing relay for oil circuit-breaker control which is new in design, new in function, and new in operation. It was designed and built with additional features to meet certain reclosing requirements which cannot be obtained by use of standard reclosing relays. These reclosing requirements, brought about by complete automatization of high-voltage oil circuit-breakers in transmission networks and on lines containing automatic sectionalizing air-break switches, are herein described. Also several schemes of time-sequence-coordination are given for the operation of oil circuit-breakers with automatic line sectionalizing air-break switches. Of special interest is a scheme for materially reducing fuse outages, which utilizes the described reclosing relay for coordinating the operations of a breaker with fuse operations on the line served by the breaker.

BECAUSE of the greater exposure and higher potential stresses of the transmission system over those of the generation and distribution systems, most interruptions to electric service are caused by failures in the transmission process. Although transmission lines can be built almost interruption proof by utilizing modern design, the fact remains that the greater number of lines were built several years past when such quality lines, if at all possible, were so only at a prohibitive cost. Thus the major problem is simply an economical balance between what can be done to reduce the number of interruptions and what can be done to minimize or remove the adverse effects of those which do occur. It is a question whether to rebuild the older lines or accept the interruptions as inevitable and minimize their adverse effects upon service.

It is not the author's purpose to answer this question since each power company must work out its own problems. The author does wish, however, to discuss that side of the question regarding means for minimizing the adverse effects of service interruptions due to faults on the transmission system.

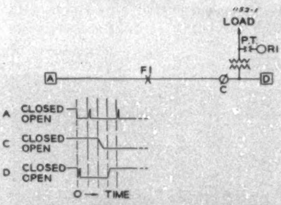

Figure 1. Operation-sequence diagram of line breakers and one automatic sectionalizing air-break switch with low side potential control for opening only

Service interruptions seldom result from failure of the conductor, but are caused by short circuits resulting from lightning. Accompanying voltage disturbances, however, can be practically nullified by the use of high speed relays, a fact which is repeatedly demonstrated on the Oklahoma Gas & Electric Company system. Large industrial motor loads now ride through all disturbances, whereas before installation of such relays these loads were occasionally lost. Moreover, since installing them permanent faults are a rarity and insulator replacements are few because the power is interrupted before burning action effects permanent damage.

Breaker-Reclosing Equipment, Transmission System

Although fast clearing of faults minimizes the voltage disturbance to remaining parts of system and greatly reduces the possibility of permanent line damage, it still interrupts service to consumers served from or through the faulted section. Through the modern practice of equipping breakers with automatic reclosing relays, the duration of such an interruption is greatly minimized. But when the breaker is located within a transmission network, its reclosing requirements necessitate the use of a reclosing relay having greater utility than the standard makes now available. The latter relays are generally designed for use on distribution feeders or radial transmission lines where the only requirements are to perform upon a breaker a certain number of closures at definite time intervals, and to lock out the breaker from further closures if the final closure is unsuccessful because of a permanent fault.

Paper 41-152, recommended by the AIEE committee on protective devices, and presented at the AIEE South West District meeting, St. Louis, Mo., October 8–10, 1941. Manuscript submitted July 8, 1941; made available for preprinting August 19, 1941.

P. O. Bobo is assistant protective engineer with Oklahoma Gas and Electric Company, Oklahoma City, Okla.

---

value of slip is very small. The time required for a single calculation should not exceed five to ten minutes and, where a number of calculations are done in parallel, even this time can usually be bettered.

Apparent impedance charts are not confined to the calculation of single-phase motors, but they may also be applied to polyphase motors, shaded pole motors, shading coils of relays, and other electrical devices. A calculation form for polyphase motors is too obvious and simple to present here, but in a similar way to that which has been used for the straight single-phase motor, it is possible to lay out a calculation form for an unbalanced two-phase motor such as the capacitor motor. An example of a calculation form of this type is shown in figure 6.

Advantages

The advantage of the apparent impedance method as herein outlined for the calculation of induction motor performance lies in the symmetry and naturalness of the approach. This symmetry is particularly indicated by the fact that the curves for the forward and backward field impedances are identical and the further fact that these impedances may not only be used in a simple fashion to obtain the input current, but the same quantities are also used in equally simple fashion in expressions for torque and output.

It is felt that the use of the apparent impedance charts not only eliminates considerable labor, but also a great deal of the possibility of error, for with the use of the charts, the calculational operations are reduced to arithmetic and complex quantities need not be considered.

A further advantage of the method lies in the assistance which it gives to a visualization of how the motor characteristics vary as the constants are changed. The separate points of a calculation are tied together mentally through the continuity of the curves.

In the determination of motor constants from test, the apparent impedance charts are used in reverse because apparent impedances at definite speeds are known and it is desired to find the true impedances.

Such relays cannot be used in transmission networks because they are either unidirectional in operation, which requires extended resetting times, or they cannot be adapted to the conditions desired without use of extra equipment.

Need for a Reclosing Relay for Functioning Under Variable Line Conditions

A reclosing relay for transmission network use must be capable of distinguishing between energized and de-energized line conditions. Also, it must be adaptable for use in conjunction with synchronism-check relays for closing breakers on in-phase conditions. For example, it may be desirable to limit to one terminal the re-energization of a transmission line following tripouts, with closure of the remaining terminal breaker permitted only after successful re-energization of the line. The first requires closures on "de-energized line" only, and the second requires closures on "energized line" only which may also require synchronism-check.

For use in unattended and semi-attended substations a reclosing relay must be capable of one or more subsequent reclosures in addition to the immediate or delayed initial reclosure, since operating experience shows that out of the total tripouts about 85% are successfully re-energized by an immediate breaker reclosure, 10% by a second reclosure, 1% by a third reclosure, and 4% result in permanent faults. The percentage of successful immediate reclosures on circuits equipped with modern high speed fault clearing relays is above average and the percentage of permanent faults is far below average.

Need for a Fast Accurate-Timing Reclosing Relay

Transmission lines are customarily divided into several parts by airbreak switches so that any one section, on becoming faulty, can be removed and service restored to the remaining parts. Most airbreak switches are, as yet, manually operated but with service requirements becoming more exacting, automatization of certain airbreak switches affords an inexpensive means of speeding service restoration to loads tapped on transmission lines.

Airbreak switches are generally incapable of interrupting fault currents. They are designed to be opened under normal service conditions. Therefore, under fault conditions they must be opened after the line is de-energized and the time of opening must be coordinated with the time of re-energization of the circuit by the terminal breakers of the line. To accomplish this time coordination between the automatic sectionalizing switches and line breakers and yet restore service in minimum time, requires the use of a fast accurate breaker-control relay. Short time intervals between breaker reclosures are essential in order to minimize the time gaps between operations of the breakers and sectionalizing switches.

The extent to which an airbreak switch need be automatized depends upon service requirements of the load or loads protected and the quality of the transmission line serving the loads. Several schemes of time-sequence-coordination are given below as examples, in which the operations of airbreak switches are controlled from potential indications only.

Figure 1 shows a single airbreak switch *C* automatized for opening only. No high tension potential device is required for airbreak switch control, the potential indication to control relay *R*1 being received from low side of power transformer as indicated. This scheme is applicable for protecting a load tapped between a long and a short section of line where few permanent faults are expected in the short section and practically all are expected in the long section. Since the airbreak switch is automatized only for opening, it is desirable that opening not take place until after some assurance of a permanent fault. For this reason at least two attempts are made to re-energize the line before the airbreak switch opens.

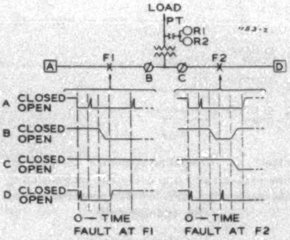

Figure 2. Operation-sequence diagram of line breakers and two automatic sectionalizing air-break switches with low side potential control

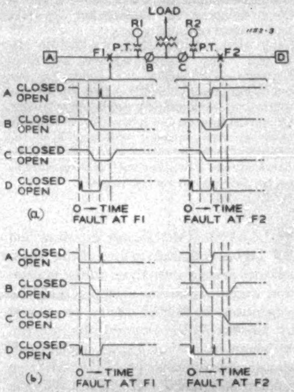
Figure 2 shows two airbreak switches controlled by relays *R*1 and *R*2, which also receive potential indications from the low side of power transformers. This scheme assures service to a load should a permanent fault occur on either side of the load.

Figure 3*a* shows two airbreak switches automatized for both opening and closing operations. This requires the use of potential devices connected to the line side of each airbreak switch for control. Since these switches will reclose automatically with line re-energized, less assurance is required that a fault be permanent before the switches automatically open. For this reason only one attempt at re-energizing the line is made before opening takes place. Switches *B* and *C* are identically equipped and controlled. They open simultaneously a definite time after initial attempt to re-energize line. After switches *B* and *C* open, breakers *A* and *D* close simultaneously; breaker *A*, closing on the fault, will reopen, and breaker *D* will remain closed. The line being re-energized to switch *C* will cause this switch to close and re-establish service.



Figures 3a and 3b. Operation-sequence diagram of line breakers and two automatic sectionalizing air-break switches with high side potential control

Figure 3*b* shows two airbreak switches with equipment identical to that of the switches in figure 3*a*, but having different timing control. These switches are automatized so that only one switch is open at any given time. This scheme affords a faster means of service restoration than the scheme of figure 3*a* for faults in the *F*1 section, and slightly longer time for faults in the *F*2 section.

Need for a Quick-Resetting Reclosing Relay

To prevent possible hazards to service within a transmission system, a reclosing relay is needed with quick resetting action following any successful reclosure. However, some time should elapse after a reclosure before permitting the device to reset quickly, as assurance that the reclosure was successful and that no permanent fault exists on the line. This time interval should be greater than the re-opening time of breaker under an existing fault condition, and its length is limited only by the permissible duty on the breaker. In no case, however, should the resetting time be extended until the device has traversed its complete reclosing cycle.

In the case of a breaker equipped with a unidirectional reclosing relay which trips on a transient fault, closes automatically and again trips on a second transient fault, the feeder customers would needlessly be without service until a subsequent reclosure point is reached. Even though this outage is momentary, important motor loads may be dropped, whereas with a quick resetting reclosing relay service would be immediately re-established upon the second tripout. In addition, if a transient tripout occurs during the timing interval between the final reclosure point and the lock-out position of a standard unidirectional reclosing relay, it will lock out without reclosing the breaker. Obviously such hazards can be serious, especially in a transmission system with isolated unattended or semi-attended substations, since it is possible for lines to be out of service or loop circuits to be open for lengthy periods when such unidirectional relays are so employed.

Likewise, on lines containing automatic sectionalizing airbreak switches and whose terminal breakers are controlled by unidirectional relays, subsequent tripouts as described above may cause these sectionalizing switches to open unnecessarily (due to loss of potential) and thereby seriously hazard service. Under these conditions the time coordination between the operations of the breakers and switches becomes disrupted.

Description of the Reclosing Relay

In view of the foregoing and the fact that automatic substations and motor operated sectionalizing switches have increased in number on the Oklahoma Gas and Electric Company system, the author designed an accurate timing, adjustable resetting, automatic reclosing relay for universal breaker application in the company's transmission system. It consists of an assembly of eleven standard telephone type relays mounted in a standard glass covered case as shown pictorially in figure 4 and schematically in figure 5. It contains no fabricated parts other than a terminal board and a mounting plate for the relays. Its principal features are:

Timer

The device contains no motor-driven gears, drum, or camshaft for interval timing. Timing is obtained by a vibrating reed relay acting in conjunction with slow-operate relays to pulse a stepping switch at intervals adjustable between 1 and 15 seconds. The vibrating reed relay *VR*, figures 4 and 5, on energization pulls-up and energizes slow-release relay *SR*, which seals in and de-energizes the *VR* relay; de-energization releases the reed which vibrates to rest, thus energizing (through break contacts) slow-operate relay *SO2*. Relay *SO2* in turn energizes slow-operate relay *SO3* to move the stepping switch one step by energizing the operating coil *SS*. Relay *SO3* de-energizes relay *SR* which causes repetition of the timing cycle for further movements of the stepping unit. The stepping switch has 10 steps which make possible a maximum time duration of $2^{1}/_{2}$ minutes for this reclosing relay. As many as 3 breaker reclosures can be made by it, and they can be accurately spaced from 3 seconds to $1^{1}/_{4}$ minutes apart.

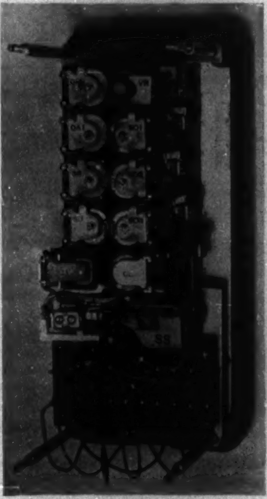


Figure 4. The reclosing relay, an assembly of 11 telephone-type relays

Variable Conditions of Breaker Closure

The recloser contains a built-in "line potential checking relay" (*QAL*) which affords choice of breaker closures on "de-energized line only," "energized line only," or "energized and/or de-energized line." By means of an external terminal connection the device can be interlocked with a synchronism-check relay for closures on "energized line in-phase only" or "de-energized line and/or energized line in-phase."

Variable Conditions of Timer Movement

By this term is meant the conditions under which the stepping switch is advanced following the initial reclosure. For most applications the "conditions of timer movement" and the "conditions of breaker closure" should be the same in order that the timer not move the stepping switch past subsequent reclosure points to the "lockout position" while the conditions of breaker reclosure are incorrect. On the other hand, when the time coordination between operations of breakers and sectionalizing switches is close it is necessary that the reclosing relays serving both terminals of the line advance together regardless of breaker closing conditions.

Quick Reset

The most salient feature of the reclosing relay is its ability to reset following successful reclosures. Reset takes place immediately after the breaker has remained closed a definite time as assurance that the fault was not permanent. Retripping of the breaker before this time expires will cause the relay to progress toward subsequent reclosing points without resetting. This definite time limit is adjustable in impulse intervals of the stepping switch independently after each reclosure. The reset feature may be omitted from any reclosure, as is sometimes desired, to limit the possible rupturing duty that may be imposed upon a breaker with limited rating.

Antipump on All Reclosures

The relay is inherently anti-pump (electrically trip free) on all reclosures, that is, for each reclosure the closing circuit to the breaker is opened immediately upon closure and cannot be re-energized until a subsequent reclosing point is reached, and only then providing the breaker is open and closing conditions satisfy the settings made on the terminal board later described. This feature is obtained by energizing the closing relay *CL* through

contacts of the set-up relay *SU* (figures 4 and 5), which is initiated from points of the stepping switch just preceding the points of closure, and is held energized by its own contacts until dropped by the control relay *QAb* on closure of the breaker.

Setting the Relay

The pulsing intervals of the stepping unit are adjustable between 1 and 15 seconds by screws which vary the reed amplitude of the vibrating reed relay (*VR*). All other settings are made electrically by inserting plug type jumpers in proper jacks on the terminal board, figures 4 and 5. The points of the stepping switch are terminated in a row of jacks numbered 2 to 10 on the board. The number 1 jack represents the zero point or normal position of the stepping switch —being controlled by slow-operate relay *SO*1, which is operated by an off-normal contact "*SS*-on" on the stepping unit.

Directly below this row of jacks is a row of 3 binding posts, *SU*, *CL*, and *R*, from which by use of jumper connections to the row of jacks time settings are made for: (1) initiation of the set-up relay *SU*, (2) energization of the closing relay *CL*, which closes the breaker, (3) resetting of the relay. Reset is accomplished instantaneously by energization of relay *QA*1 which seals in and maintains energized the reset coil *SSR* of the stepping switch until the unit has fully reset and relay *SO*1 is de-energized by the opening of "off-normal" contact "*SS*-on." Note that resetting cannot take place unless relay *QAb* is de-energized as indication that breaker is closed.

The conditions of breaker reclosure are set by placing jumpers from binding post "*X*" to jack "*DL*" for "dead-line" closing conditions, to jack "*HDL*" for "hot and/or dead-line" (non-restricted) conditions, and to jack "*HL*" for "hot-line" conditions. Jacks *DL* and *HL* are controlled by a break and a make contact respectively of line checking relay *QAL*. If synchronism-check is desired, the external terminal stud "22" is connected in series with the contacts of the synchronism-check relay to the positive bus; otherwise this terminal stud is connected directly to the positive bus. These connections to point "*X*" establish the conditions for which the set-up relay *SU* is energized.

The conditions of timer movement are set by placing jumpers from binding post "*T*" to the same jacks as those for the conditions of closure. Such connections to point "*T*" control the conditions for which the timer relays *SR*, *VR*, and *SO*2 are energized.

Immediate or delayed initial reclosure is chosen by inserting jumper from jack "*IR*" to jack "*I*" for "immediate" reclosure, or from jack "*IR*" to jack "*D*" for "delayed" reclosure. Connection to jack "*I*" permits immediate energization of operating coil *SS* of stepping switch, and connection to jack "*D*" interposes one impulse cycle of timing relays before energization of coil *SS*.

Other Features

As can be seen from schematic connection diagram figure 5, only one breaker auxiliary switch (152*b*) is required for operation, or in many cases the reclosing relay may be controlled directly from the breaker alarm or indicating light circuits instead, since the only requirement is energization of relay *QAb* when breaker is open.

The auxiliary relay *CL* which energizes the breaker closing circuit is equipped with a vacuum contact for the high-current capacity required in energizing breaker closing contactors. Its coil is slow releasing in order to permit ample time for the breaker to latch closed without any necessary critical adjustment of the breaker auxiliary switch.

The reclosing relay can be made for operating voltages from 24 to 250 volts d-c, or a-c with a rectifier unit.

A mechanical pointer fastened to the shaft of the stepping switch indicates when the relay is locked out by pointing to line marked "*LO*" on front of stepping unit.

The relay will automatically reset upon manual closing of breaker after lockout, provided breaker remains closed for one impulse interval of timer, otherwise it will remain in the lock-out position.

For remote supervisory indication and for other external functions of control associated with reclosing of breakers, two auxiliary "off-normal" contacts (*SS*-on) are brought out to terminal studs 13, 14, and 21. In attended stations where the relay is located away from control board, remote off-normal supervision indicates relay operations to the attendant. An important control function using an off-normal contact involving fuse operations is described below.

Method of Reducing Fuse Outages

To lessen the outages caused by transient faults on multibranch-fuse circuits served through a common breaker, the Oklahoma Gas and Electric Company is using a unique automatic scheme which permits instantaneous initial tripping of the breaker for a fault at any point on the circuit. Service is immediately restored by the breaker reclosing equipment. The instantaneous opening of the breaker interrupts transient short-circuits before the branch fuses have time to blow. Service can then be restored to the fused branch immediately, instead of waiting until a fuse can be replaced. Of course, service to the entire circuit is momentarily interrupted, but it is doubtful whether such an interruption is more serious than the voltage disturbance caused by a longer clearing time of a fuse.

In order to protect customers on unfaulted branches when a permanent fault occurs, a reclosing relay fulfilling the following requirements is needed. It must remove the instantaneous tripping relays from service prior to the immediate reclosure of the breaker so as to permit coordination between breaker time-delay relays and sectionalizing fuses, and it should hold these instantaneous relays removed from service until it has reset and again is capable of an immediate reclosure, otherwise more than a transient outage may result needlessly to all customers.

The reclosing relay herein described with its auxiliary "off-normal" contact on the stepping switch fulfills all requirements. This "off-normal" contact (figure 5, terminal studs 13 and 21) is connected in series with the instantaneous tripping relay contacts and opens this circuit upon movement of the stepping switch off-normal just before closure of the breaker. The circuit remains open until the relay is fully reset.

The reset feature of the reclosing relay for this service is as useful in preventing fuse outages as the scheme itself.

Operating Experience

The accompanying table is an analysis of operations from January 1939 through June 1941 of the line breakers which are equipped with the reclosing relay.

	Number	Per Cent
I. Breakers serving lines equipped with automatic sectionalizing air-break switches:		
Line terminals equipped	7	
Line faults	123	100
Normal service restored, initial reclosure	101	82
Normal service restored, second reclosure	7	6
Normal service restored, third reclosure	6	5
Relay lockouts	9	7
Reset feature, beneficial	12	10
Permanent faults	12	100
Line correctly sectionalized	8	67
Line sectionalizing failures	4	33
II. Breakers serving 66 kv-loop-circuit lines:		
Line terminals equipped	6	
Line faults	304	100
Normal service restored, initial reclosure	298	98
Normal service restored, second reclosure	3	1
Normal service restored, third reclosure	0	0
Relay lockouts	3	1
Reset feature, beneficial	40	13
III. Breakers serving multi-branch-fuse circuits:		
Line terminals equipped	1	
Line faults	46	100
Normal service restored, immediate reclosure	45	98
Normal service restored, second reclosure	1	2
Normal service restored, third reclosure	0	0
Relay lockouts	0	0
Reset feature, beneficial	3	6

Under (I) above, three of the successful sectionalizing operations were accomplished within 8 seconds by equipment utilizing the scheme of figure 3*b*. The four "line sectionalizing failures" were in no case due to improper functioning of the reclosing relays. One was caused by a blown fuse in an airbreak, switch mechanism; one was caused by the nature of the fault—open conductor, grounded on one end and in clear on the other; one was caused by the failure of a breaker to latch closed; the fourth was caused by manual interference with the automatic reclosing relay.

The most important result shown by the analysis is the fact that the reset feature of the relay was beneficial in restoring service for 55 of the total 471 fault operations, that is, for approximately 12% of the faults, which faults occurred following a successful reclosure and within the total cycle of time for which the relays were set, the quick resetting action of the relay, in addition to speeding restoration of service, prevented the following possible service hazards. (Previously described under "Need for Quick Resetting Reclosing Relay.)

1. Disruption of time-sequence coordination between operations of automatic sectionalizing airbreak switches and line terminal breakers.

2. Longer than transient outages to important loads.

3. Loop circuits remaining open for lengthy periods.

4. Lockouts of reclosing relays without closing the breakers.

Conclusions

The relay meets the following requirements which are essential to successful operation of oil circuit breakers in an extensive transmission network:

1. Variable conditions of closure
2. Variable conditions of timing
3. Fast and accurate timing between closures
4. Anti-pump characteristics
5. Auxiliary off-normal contacts for external control and indications
6. Operation on either alternating or direct current
7. Quick resetting following successful reclosures

It is through the fulfillment of above requirements that the reclosing relay permits a transmission system to render maximum continuity of service. Interruptions caused by transient faults are minimized; hazards caused by untimely tripouts are eliminated; coordination between breakers and automatic sectionalizing switches is made faster and more effective; and fuse outages on certain circuits are greatly reduced. All of this has been definitely proved by 14 installations of the relay in the Oklahoma Gas & Electric Company's system over a period of $2^1/_2$ years beginning January 1939. Experience also has shown that the relay is dependable and virtually trouble free—a tribute to the versatile and highly developed relays originally created for automatic telephone systems.

Formulas for the Inductance of Rectangular Tubular Conductors

THOMAS JAMES HIGGINS
ASSOCIATE AIEE

THE formula for the inductance per unit length of two parallel conductors of rectangular cross section, obtained by using the formal expressions for the geometric mean distance of a rectangle to itself and the geometric mean distance between two rectangles with sides parallel, is exceedingly cumbersome. More than a score of logarithms and arc tangents must be evaluated when computing the inductance for a given conductor spacing and cross section. To circumvent such lengthy calculations when computing the reactance of like parallel rectangular strap conductors, Dwight[1, 2] has published curves, each plotted for a certain conductor spacing and cross section, from which the reactance can be obtained. Unless, however, the conductor spacing and the ratio of conductor thickness to breadth coincides with those values for which the curves are plotted, interpolation is necessary. Recently Roth[3] has expressed the inductance of such lines in the form of a rapidly converging series, the parameters of which are the spacing and dimensions of the conductors. Usually, a few terms of this series suffice to yield a value of inductance sufficiently accurate for all design purposes.

As regards rectangular tubular conductors, the only analytical literature is a paper by Dwight and Wang[4] giving formulas for *thin square* tubular conductors. These are derived on the assumption that the conductor walls are so thin that the sides can be considered as but line segments. The geometric mean distances for such segments are then used to calculate the inductance. Such a procedure is equivalent to asserting that the current flows solely on the surface of the conductors. It follows, then, that the values of inductance computed on this basis will be *less* than the actual values. Consequently, while these formulas suffice for many calculations on square tubular conductors, if accuracy is a desideratum of design this minimization of thickness restricts the range of application of these formulas to *very thin square* tubular conductors. Recognizing this restriction and noting, further, that commercial conductors have rounded corners, Dwight and Wang give formulas, empirically deduced, from which corrections for thickness and for rounded corners can be calculated.

The inductance of rectangular tubular conductors of appreciable thickness (and not necessarily square) can be obtained from equations given by the author[5] for the case of a line composed of two parallel conductors, the cross sections of which are geometrically similar but dimensionally different hollow rectangles. However, as these equations are implicit rather than explicit, they are ill suited to numerical computation. Yet, in light of the increasing use of rectangular tubular conductors for main bus bars, electric furnace installations, and other heavy current duties (especially feeders for batteries of welders), it is most desirable to have formulas with which one can calculate quickly the inductance for any conductor spacing or cross section. *Such formulas are derived in this paper*, it being assumed that the conductors are nonmagnetic, square cornered, of such length that end effects are negligible, and carry currents uniformly distributed over the cross sections of the individual conductors.

Although obtained through a procedure involving rather intricate analysis, the formulas themselves are simple in nature. With them a designer can calculate rapidly the inductance of a single-phase circuit composed of solid or tubular rectangular conductors; or of a three, six, or twelve-phase circuit composed of solid or tubular rectangular conductors, the axes of which lie in a plane.

I. The Formal Solution

With reference to figure 1, we seek A_1 which satisfies the differential equations

$$\nabla^2 A_1 = 4\pi w \text{ over } C_1 \qquad (1)$$

$$\nabla^2 A_1 = -4\pi w \text{ over } C_4 \qquad (2)$$

$$\nabla^2 A_1 = 0 \text{ over the remainder of the right half-plane} \qquad (3)$$

and the boundary conditions

$$A_1 = 0 \text{ at infinity} \qquad (4)$$

$$A_1 = 0 \text{ on the line } x = 0 \qquad (5)$$

$$\frac{\partial A_1}{\partial y} = 0 \text{ on the line } y = 0 \qquad (6)$$

The boundary conditions are obtained as follows: (4) from knowledge that the vector potential vanishes at infinity except for an arbitrary constant, taken here as zero; (5) from observation that the line $x = 0$ and the left-hand portion of the circle of infinite radius constitute, in the limit, a line of induction, whence, lines of induction being lines of constant vector potential, the vector potential is zero as on the circle at infinity; (6) from noting that the horizontal component of induction density vanishes on the line $y = 0$, or $B_x = \partial A_1/\partial y = 0$.

For the problem at hand, A_1 is an even function of y, an odd function of x. Accordingly, A_1 is expressed by the double Fourier integral

$$A_1 = (4/\pi^2) \times \int_0^\infty \int_0^\infty \int_0^\infty \int_0^\infty A_1(X, Y) \sin Mx \times \cos Ny \cos NY \sin MX dX dY dN dM \qquad (7)$$

the same satisfying (5) and (6) unconditionally, and (1), (2), and (3) providing $A_1(X, Y)$ or an integral containing $A_1(X, Y)$ is appropriately determined. Thus, if the double Fourier integral expressing the current density at any point in the conductors,

$$w = (4/\pi^2) \int_0^\infty \int_0^\infty \int_0^\infty \int_0^\infty w(x, y) \times \sin Mx \cos Ny \cos NY \times \sin MX\, dX dY dN dM$$

$$= (4/\pi^2) \int_0^\infty \int_0^\infty \int_0^h \int_{d-e}^{d+e} w \sin Mx \times \cos Ny \cos NY \sin Mx\, dX dY dN dM$$

$$= (8w/\pi^2) \int_0^\infty \int_0^\infty \frac{1}{MN} \sin Mx \cos Ny \times \sin Nh \sin Md \sin Me\, dN dM \qquad (8)$$

is substituted in the right-hand member of

$$4(M^2+N^2)/\pi^2 \times \int_0^\infty \int_0^\infty \int_0^\infty \int_0^\infty A_1(X, Y) \sin Mx \times \cos Ny \cos NY \sin Mx\, dX dY dN dM = 4\pi w \qquad (9)$$

obtained by substituting (7) in (1), we

Paper 41-168, recommended by the AIEE committee on basic sciences, and presented at the AIEE Southern District meeting, New Orleans, La., December 3–5, 1941. Manuscript submitted July 23, 1941; made available for preprinting October 6, 1941.

THOMAS JAMES HIGGINS is assistant professor of electrical engineering, Tulane University of Louisiana, New Orleans, La.

This paper is based upon a thesis submitted by Professor Higgins to the faculty of Purdue University in June 1941 in partial fulfillment of the requirements for the degree of doctor of philosophy.

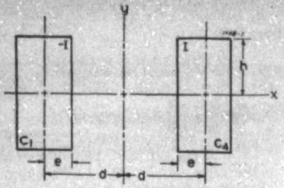

Figure 1

have, on comparing the two members of the resulting equation

$$\int_0^\infty \int_0^\infty A_1(X,Y) \cos NY \sin MX \times dXdY = 8\pi w \frac{\sin Nh \sin Md \sin Me}{MN(M^2+N^2)} \quad (10)$$

Finally, substituting (10) in (7), we have for A_1

$$A_1 = (32w/\pi) \int_0^\infty \frac{\sin Md \sin Me \sin Mx}{M} \times \int_0^\infty \frac{\sin Nh \cos Ny}{N(M^2+N^2)} dNdM \quad (11)$$

For the current distribution of figure 2 we have, analogously,

$$A_2 = (-32w/\pi) \int_0^\infty \frac{\sin Md \sin ME \sin Mx}{M} \times \int_0^\infty \frac{\sin NH \cos Ny}{N(M^2+N^2)} dNdM \quad (12)$$

Superimposing the current distributions of figures 1 and 2 results in that of figure 3. The corresponding vector potential is

$$A = A_1 + A_2 \quad (13)$$

The total electromagnetic field energy W is, by symmetry, four times that associated with the current flowing through the shaded portions of figure 3. Thus, from the usual expression, $W = {}^1/_2 \int AwdS$, we have

$$W = 2\int_0^h \int_{d-e}^{d+e} Awdxdy - 2\int_0^H \int_{d-E}^{d+E} Awdxdy \quad (14)$$

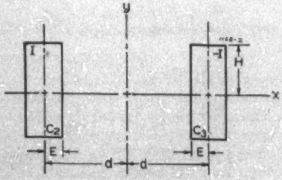

Figure 2

Substituting (11) and (12) in (13), and, in turn, (13) in (14), we have

$$W = (64w^2/\pi) \times \int_0^h \int_{d-e}^{d+e} \int_0^\infty \frac{\sin Md \sin Me \sin Mx}{M} \times \int_0^\infty \frac{\sin Nh \cos Ny}{N(M^2+N^2)} dNdMdxdy -$$
$$(64w^2/\pi) \times \int_0^h \int_{d-e}^{d+e} \int_0^\infty \frac{\sin Md \sin ME \sin Mx}{M} \times \int_0^\infty \frac{\sin NH \cos Ny}{N(M^2+N^2)} dNdMdxdy -$$
$$(64w^2/\pi) \times \int_0^H \int_{d-E}^{d+E} \int_0^\infty \frac{\sin Md \sin Me \sin Mx}{M} \times \int_0^\infty \frac{\sin Nh \cos Ny}{N(M^2+N^2)} dNdMdxdy +$$
$$(64w^2/\pi) \times \int_0^H \int_{d-E}^{d+E} \int_0^\infty \frac{\sin Md \sin ME \sin Mx}{M} \times \int_0^\infty \frac{\sin NH \cos Ny}{N(M^2+N^2)} dNdMdxdy \quad (15)$$

These integrals are such that the order of integration can be varied as desired. Accordingly, integrating first with respect to x and then with respect to y, we have after collecting terms

$$W = (128w^2/\pi) \int_0^\infty \frac{\sin^2 Md \sin^2 Me}{M^2} \times \int_0^\infty \frac{\sin^2 Nh}{N^2(M^2+N^2)} dNdM +$$
$$(128w^2/\pi) \int_0^\infty \frac{\sin^2 Md \sin^2 ME}{M^2} \times \int_0^\infty \frac{\sin^2 NH}{N^2(M^2+N^2)} dNdM -$$
$$(256w^2/\pi) \times \int_0^\infty \frac{\sin^2 Md \sin ME \sin Me}{M^2} \times \int_0^\infty \frac{\sin NH \sin Nh}{N^2(M^2+N^2)} dNdM \quad (16)$$

Now[8]

$$\int_0^\infty \frac{\sin NH \sin Nh}{N^2(M^2+N^2)} dN = \frac{\pi}{2M^3}(MH - \epsilon^{-Mh} \sinh MH) \quad (17)$$

Substituting appropriately in (16), we have

$$W = 64w^2 \int_0^\infty \frac{\sin^2 Md \sin^2 Me}{M^5} \times (Mh - \epsilon^{-Mh} \sinh Mh)dM +$$
$$64w^2 \int_0^\infty \frac{\sin^2 Md \sin^2 ME}{M^5} \times (MH - \epsilon^{-MH} \sinh MH)dM -$$
$$128w^2 \int_0^\infty \frac{\sin^2 Md \sin ME \sin Me}{M^5} \times (MH - \epsilon^{-Mh} \sinh MH)dM \quad (18)$$

The third integral in (18) can be written as the sum of two integrals, such that W is expressed as the sum of four like integrals. Doing so, we have

$$W = 64w^2 \int_0^\infty \frac{\sin^2 Md \sin^2 Me}{M^5} \times (Mh - \epsilon^{-Mh} \sinh Mh)dM +$$
$$64w^2 \int_0^\infty \frac{\sin^2 Md \sin^2 ME}{M^5} \times (MH - \epsilon^{-MH} \sinh MH)dM -$$
$$128w^2 \int_0^\infty \frac{\sin^2 Md \sin ME \sin Me}{M^5} \times \left[\frac{M(h+H)}{2} - \epsilon^{-\frac{M(h+H)}{2}} \sinh \frac{M(h+H)}{2}\right]dM +$$
$$128w^2 \int_0^\infty \frac{\sin^2 Md \sin ME \sin Me}{M^5} \times \left[\frac{M(h-H)}{2} - \epsilon^{-\frac{M(h-H)}{2}} \sinh \frac{M(h-H)}{2}\right]dM \quad (19)$$

Each integral of (19) is of the form

$$\frac{y}{2} f_1(x_1, x_2, x_3, x_4) - {}^1/_2 f_2(x_1, x_2, x_3, x_4, y) \quad (20)$$

As shown in the appendix

$$f_1 = \int_0^\infty \frac{1}{M^4} \sin Mx_1 \sin Mx_2 \sin Mx_3 \times \sin Mx_4 \, dM = \frac{\pi}{3!2^4} \sum_{t=1}^{8} (-1)^p |k_t^3| \quad (21)$$

k_t designating any one of the eight possible terms to be formed from

$$(x_1 \pm x_2 \pm x_3 \pm x_4)$$

by arbitrary selection of the plus and minus signs, while p is the number of minus signs in k_t.

For f_2 we have

$$f_2 = 2\int_0^\infty \frac{1}{M^5} \sin Mx_1 \sin Mx_2 \sin Mx_3 \times \sin Mx_4 \epsilon^{-\frac{My}{2}} \sinh \frac{My}{2} dM = \frac{1}{192} \sum_{t=1}^{8} (-1)^p F(k_t, y) \quad (22)$$

where k_t and p have the same significance as in (21), and

$$F(k_t, y)=(k_t^4-6y^2k_t^2+y^4)\log(k_t^2+y^2)^{1/2}+4yk_t(k_t^2-y^2)\tan^{-1}(k_t/y)-k^4\log|k_t| \quad (23)$$

The fifth column of table I contains the values of k_t used in evaluating the first two integrals in (19), while those for the second two integrals of (19) are in the sixth column.

Defining new variables, $r=2e$, $R=2E$, $s=2h$, $S=2H$, $D=2d$, and $t=e-E=h-H$, evaluating each integral of (19) by means of (21) and (22), and collecting terms, we have for the terms of (19) taken in order

$$W=w^2\{W(r, s)+W(R, S)-2[W(R+t, S+t)-W(t, S+t)]+2[W(R+t, t)-W(t, t)]\} \quad (24)$$

where $W(r, s)$ is defined by

$$W(r, s)={}^1/_6[2F(D, s)-F(D+r, s)-F(D-r, s)+2F(r, s)-2F(0, s)+4\pi r^2s(3D-r)] \quad (25)$$

Collecting the terms of (24), we have

$$W=w^2[W(r, s)+W(R, S)+2W(t, S+t)+2W(R+t, t)-2W(R+t, S+t)-2W(t, t)] \quad (26)$$

The energy W being known in terms of the dimensions and spacings of the conductors, the inductance can be obtained at once from the usual formula, $W={}^1/_2LI^2$. Hence

$L=2W/w^2(rs-RS)^2$ abhenries per centimeter of line length (27)

If $R=S=0$ we have solid conductors, and (27) becomes

$L=2W(r, s)/(wrs)^2$ abhenries per centimeter of line length (28)

The 60-cycle reactance per thousand feet of conductor is obtained by multiplying L by 5.74×10^{-8}.

II. Series Expressions for L

We turn now to finding series expansions which enable one to calculate quickly each of the terms of (26). Expanding (25) in powers of r, we obtain

$$W(r, s)=\frac{1}{6}\left[2F(r, s)-2F(0, s)+4\pi r^2s(3D-r)-r^2\frac{\partial^2F(D, s)}{\partial D^2}-\frac{r^4}{2\cdot 3!}\frac{\partial^4F(D, s)}{\partial D^4}-\frac{r^6}{3\cdot 5!}\frac{\partial^6F(D, s)}{\partial D^6}-\ldots\right] \quad (29)$$

The details of the expansion and expressions for the various derivatives, in terms of the dimensions and spacing of the conductors, are given in the appendix. Substituting appropriately in (29) and collecting terms, we have

$$W(r, s)=2r^2\left\{s^2\left[\frac{7}{12}+\frac{1}{2}\log\frac{D^2+s^2}{r^2+s^2}\right]-\left[\frac{D^2}{2}+\frac{r^2}{12}\right]\log\frac{D^2+s^2}{D^2}+\frac{s^4}{12r^2}\log\frac{s^2+r^2}{s^2}+\frac{r^2}{12}\log\frac{r^2+s^2}{r^2}+2sD\tan^{-1}(s/D)-\frac{2}{3}rs\tan^{-1}(s/r)-\frac{2s^3}{3r}\tan^{-1}(r/s)-\frac{r^4}{180}\left[\frac{1}{D^2}-\frac{D^2-s^2}{(D^2+s^2)^2}\right]-\frac{r^6}{1,680}\times\left[\frac{1}{D^4}-\frac{(D^2-s^2)^2-4D^2s^2}{(D^2+s^2)^4}\right]-\frac{r^8}{7,560}\times\left[\frac{1}{D^6}-\frac{(D^2-s^2)^3-12s^2D^2(D^2-s^2)}{(D^2+s^2)^6}\right]-\ldots\right\} \quad (30)$$

If r$<s$, (30) can be put in a more convenient form. Utilizing the power series for $\log(1+x)$ and $\tan^{-1}x$, we have after expanding appropriately in (30) and collecting terms

$$W(r, s)=2r^2\left\{\frac{s^2}{2}\log\frac{D^2+s^2}{s^2}-\frac{D^2}{2}\log\frac{D^2+s^2}{D^2}+2sD\tan^{-1}(s/D)-\pi rs/3+r^2\left[\frac{25}{75}-\frac{1}{12}\log\frac{r^2(D^2+s^2)}{s^2D^2}\right]-\frac{r^4}{180}\left[\frac{1}{D^2}-\frac{D^2-s^2}{(D^2+s^2)^2}-\frac{1}{s^2}\right]-\frac{r^6}{1,680}\times\left[\frac{1}{D^4}-\frac{(D^2-s^2)^2-4D^2s^2}{(D^2+s^2)^4}+\frac{1}{s^4}\right]-\ldots\right\} \quad (31)$$

If $r<s$ and, in addition, $D>s$, we can expand (31) still further obtaining

$$W(r, s)=2r^2s^2\left\{\log\frac{D}{s}+\frac{r^2}{s^2}\times\left[\frac{25}{72}-\frac{1}{12}\log\frac{r^2(D^2+s^2)}{s^2D^2}\right]+\frac{3}{2}-\frac{\pi r}{3s}+\frac{1}{12}\frac{s^2}{D^2}-\frac{1}{60}\frac{s^4}{D^4}+\frac{1}{168}\frac{s^6}{D^6}-\ldots-\frac{1}{180}\frac{r^4}{s^4}\times\left[\frac{s^2}{D^2}-\frac{s^2D^2-s^4}{(D^2+s^2)^2}-1\right]-\ldots\right\}$$

$$=2r^2s^2\left\{\log\frac{1}{m}+n^2\times\left[\frac{25}{72}-\frac{1}{12}\log n^2(1+m^2)\right]+\frac{3}{2}-\frac{\pi r}{3s}+\frac{m^2}{12}-\frac{m^4}{60}+\frac{m^6}{168}-\ldots-\frac{n^4}{180}\times\left[m^2-\frac{m^2-m^4}{(1+m^2)^2}-1\right[-\ldots\right\} \quad (32)$$

where $m=s/D$ and $n=r/s$.

If, however, $r<s$ and $s>D$, we have from (31)

$$W(r, s)=2r^2s^2\left\{\pi m+\left(\log m-\frac{3}{2}\right)m^2-\frac{m^4}{12}+\frac{m^6}{60}-\frac{m^8}{168}+\ldots-\frac{\pi n}{3}+n^2\times\left[\frac{25}{72}-\frac{1}{12}\log n^2\left(1+\frac{1}{m^2}\right)\right]-\frac{n^4}{180}\times\left[\frac{1}{m^2}-\frac{m^2-1}{(m^2+1)^2}-1\right]-\ldots\right\} \quad (33)$$

where now $m=D/s$ and $n=r/s$.

If $r>s$, we have from (30)

$$W(r, s)=2r^2s^2\left\{\frac{1}{2}\log\frac{D^2+s^2}{r^2}-\frac{D^2}{2s^2}\log\frac{D^2+s^2}{D^2}+\frac{2D}{s}\tan^{-1}(s/D)-\frac{r^2}{12s^2}\log\frac{D^2+s^2}{D^2}-\frac{\pi s}{3r}-\frac{s^2}{6r^2}\left[\log\frac{s}{r}-\frac{25}{12}\right]+\frac{1}{180}\frac{s^4}{r^4}-\frac{1}{1,680}\frac{s^6}{r^6}+\ldots-\frac{1}{180}\frac{r^4}{s^2}\times\left[\frac{1}{D^2}-\frac{D^2-r^2}{(D^2+r^2)^2}\right]-\ldots\right\} \quad (34)$$

If $r>s$ and, in addition, $D>r$, we have from (34)

$$W(r, s)=2r^2s^2\left\{\log\frac{D}{r}-\frac{1}{12n^2}\log(1+m^2)-\frac{n^2}{6}\log n+\frac{3}{2}-\frac{\pi n}{3}+\frac{25n^2}{72}+\frac{n^4}{180}-\frac{n^6}{1,680}+\ldots+\frac{m^2}{12}-\frac{m^4}{60}+\frac{m^6}{168}-\ldots-\frac{1}{180n^4}\left[m^2-\frac{s^2(D^2-r^2)}{(D^2+r^2)^2}\right]-\ldots\right\} \quad (35)$$

where $m=s/D$ and $n=s/r$.

If $r=s$, we obtain from (30)

$$W(r, s)=2r^4\left\{\frac{1}{2}\log\frac{D^2+r^2}{r^2}-\left[\frac{D^2}{2r^2}+\frac{1}{12}\right]\log\frac{D^2+r^2}{D^2}+\frac{2D}{r}\tan^{-1}(r/D)-1.579393-\frac{r^2}{180}\left[\frac{1}{D^2}-\frac{D^2-r^2}{(D^2+r^2)^2}\right]-\frac{r^4}{1,680}\left[\frac{1}{D^4}-\frac{(D^2-r^2)^2-4D^2r^2}{(D^2+r^2)^4}\right]-\ldots\right\} \quad (36)$$

If $r=s$ and, in addition, $D>r$, we have from (36)

$$W(r, s)=2r^4\left\{0.805087-\log m+\frac{m^4}{40}-\frac{11}{504}m^6+\frac{13}{720}m^8-\ldots-\frac{m^2}{180}\left[1-\frac{1-m^2}{(1+m^2)^2}\right]-\frac{m^4}{1,680}\times\left[1-\frac{(1-m^2)^2-4m^2}{(1+m^2)^4}\right]-\ldots\right\} \quad (37)$$

where $m=r/D$.

III. Identification of the Terms of (24)

As (28) can be written in the form

$$L=4\log(D_{14}/D_{11})=2W(r,s)/(wrs)^2 \qquad (38)$$

where D_{14} is the geometric mean distance between C_1 and C_4, while D_{11} is the geometric mean distance of C_1 or C_4 to itself, these latter can be expressed as functions of the terms of (25). Our expressions are somewhat simplified if we introduce the new function

$$G(k_t,y)=F(k_t,y)-2\pi y|k_t|(k_t^2-y^2) \qquad (39)$$

Comparison of $W(r, s)$ with expressions for $\log D_{14}$ and $\log D_{11}$ given elsewhere[6] reveals that

$$12r^2s^2\log D_{14}=2G(D,s)-G(D+r,s)-G(D-r,s)-25r^2s^2 \qquad (40)$$

$$12r^2s^2\log D_{11}=-2G(r,s)+2G(0,s)+4\pi rs^3-25r^2s^2 \qquad (41)$$

Similarly, from $W(R, S)$ we have

$$12R^2S^2\log D_{23}=2G(D,S)-G(D+R,S)-G(D-R,S)-25R^2S^2 \qquad (42)$$

$$12R^2S^2\log D_{22}=-2G(R,S)+2G(0,S)+4\pi RS^3-25R^2S^2 \qquad (43)$$

Like (28) written in the form of (38), we have[5] for (27)

$$L=\frac{4}{(rs-RS)^2}(r^2s^2\log D_{14}+R^2S^2\log D_{23}+2rsRS\log D_{12}-r^2s^2\log D_{11}-R^2S^2\times\log D_{22}-2rsRS\log D_{13}) \qquad (44)$$

Substituting (26) in (27) and comparing the resulting expression with (44), it follows that the as yet unidentified members of (26) must equal

$$-4rsRS\log D_{13}+4rsRS\log D_{12} \qquad (45)$$

Obviously, of the unidentified terms of (26), those containing D comprise the first component of (45), those not containing D comprise the second component of (45). We have, then,

$$12rsRS\log D_{13}=G(D+t,S+t)-25rsRS\; G(D-t,S+t)-G(D+R+t,S+t)-G(D-R-t,S+t)-G(D+t,t)-G(D-t,t)+G(D+R+t,t)+G(D-R-t,t) \qquad (46)$$

$$12rsRS\log D_{12}=2G(t,S+t)-2G(R+t,S+t)+4\pi R(S+t)^2-2G(t,t)+2G(R+t,t)-4\pi Rt^2-25rsRS \qquad (47)$$

where $(D-R-t)>0$.

It is evident that (40) to (47) inclusive are of particular value: with them one can calculate the inductance or reactance of any arrangement of like solid or tubular busbars, the axes of which lie in a plane. For as detailed in most texts on transmission theory, if there are n conductors constituting a polyphase circuit, the reactance of an individual wire (for example, wire a) is given by

$$x_a=0.2794\sum_{j=1}^{n}(I_j/I_a)\log(1/D_{ja}) \text{ ohms per mile at sixty cycles}$$

where

$$\sum_{j=1}^{n}I_j=0$$

Or again, if n conductors constitute a single-phase circuit, the inductance is given by

$$L=\sum_{j=1}^{n}\sum_{k=1}^{n}(-2/I^2)I_jI_k\log D_{jk} \text{ abhenries per centimeter of line}$$

IV. An Illustrative Problem

As an illustration of the rapidity of convergence of the formulas developed in section III, we now calculate the reactance of a line composed of square tubular conductors. We use the dimensional data of a like problem to be found in the previously mentioned paper of Dwight and Wang,[4] and thus simultaneously determine the magnitude of the minimization in the basic formula presented therein, the same being due to neglecting the thickness of the conductors when deriving this formula, and the accuracy of the formula given for correcting for the effect of thickness. The data follow:

$r=s=2.5$ inches; $t=0.5$ inch; $D=10$ inches;
$f=60$ cycles per second;
$X=0.0443$ ohm per thousand feet of conductor;
$L=3.85$ abhenries per centimeter of conductor (calculated from X).

For the data given, we have from (26)

$$W/w^2=W(2.5,2.5)+W(1.5,1.5)+2W(0.5,2)+2W(2,0.5)-2W(2,2)-2W(0.5,0.5) \qquad (48)$$

Thus, to determine W/w^2 each of the terms of (48) must be calculated. From (37) we have for the terms taken in order:

$$W(2.5,2.5)=78.125(0.805087+1.386294+0.0000977-0.0000589)=171.203$$

$$W(2,2)=32(0.805087+1.609438+0.000040-\ldots-0.000025)=77.264$$

$$W(1.5,1.5)=10.125(0.805087+1.897120+0.000012-\ldots-0.000008)=27.359$$

$$W(0.5,0.5)=0.125(0.805087+2.995732+0.000000-\ldots-0.000000)=0.475$$

From (32) we have

$$W(0.5,2)=2(1.609438+0.035875+1.500000-0.261799+0.003333-0.000027+\ldots+0.000022+\ldots)=5.774$$

From (35) we have

$$W(2,0.5)=2(1.609438-0.003329+0.014441+1.500000-0.261800+0.021703+0.000022-\ldots+0.000283-\ldots-0.000026)=5.761$$

The computation necessary to obtain each of these values of $W(x, y)$ was performed on an automatic calculating machine. As a check on both the computation and the series expansions, each value of $W(x, y)$ was then computed independently from (30). Agreement of the first five digits was interpreted as verification of the expansion and the first computations.

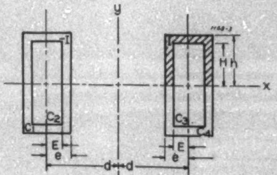

Figure 3

Substituting in (48) as indicated, we obtain

$$W/w^2=171.203+27.359+11.547+11.522-154.528-0.950=66.153$$

From (27) we have for the inductance

$L=66.153/(6.25-2.25)^2=4.135$ abhenries per centimeter of conductor

Multiplying L by $120\pi/10^9$ we obtain the reactance,

$X=496.1\pi/10^9$ ohm per centimeter of conductor

Converting to more suitable units, we have

$X=496.1\pi\times2.54\times12\times10^3/10^9$
$=0.0475$ ohm per thousand feet of conductor

Comparing this with the uncorrected value given by Dwight and Wang—namely, 0.0443 ohm per thousand feet of conductor, uncorrected—we find that our value is 0.0032 ohm per thousand feet larger; or, the difference due to neglecting the thickness of the conductor is, in this case, 6.7 per cent. If the conductor were larger with correspondingly thicker walls, the per cent difference would probably be greater.

For this problem Dwight and Wang obtain from their correction formula 0.0026 ohm per thousand feet increase due to thickness. Accordingly, adding this value to the original value yields 0.0469 ohm per thousand feet of conductor. The difference is now but 0.0006 ohm per thousand feet of conductor. Accordingly, in view of this close agreement one might conjecture that in calculating the reactance of *identical*, *square* tubular conductors for purposes other than wherein extreme accuracy is required, that so far as time of computation is concerned the simpler formulas of Dwight and Wang can be used to the advantage of those given in this paper. If, however, the conductors are other than *both* square and identical the formulas of this paper must be used perforce.

A glance at the individual values of $W(x, y)$ will reveal the extreme rapidity with which they converge. As only three decimal places were used in calculating W/w^2 from (48), it would have been necessary to have computed only the first two terms in each of $W(2.5, 2.5)$, $W(1.5, 1.5)$, $W(2, 2)$, and $W(0.5, 0.5)$. Likewise, several terms could have been omitted in $W(2, 0.5)$ and $W(0.5, 2)$.

Appendix

I. Determination of the Integrals f_1 and f_2

We can transform f_2 as follows:

$$2=\int_0^\infty \frac{\sin Mx_1 \sin Mx_2 \sin Mx_3 \sin Mx_4}{M^5}\times \epsilon^{\frac{-My}{2}} \sinh \frac{My}{2}\, dM$$

$$=\int_0^\infty \frac{\sin Mx_1 \sin Mx_2 \sin Mx_3 \sin Mx_4}{M^5}\times (1-\epsilon^{-My})\, dM$$

$$=\int_0^y \int_0^\infty \frac{\sin Mx_1 \sin Mx_2 \times \sin Mx_3 \sin Mx_4}{M^4}\epsilon^{-My}\, dM dy$$

Substituting the value of the infinite integral,[7] we have

$$f_2=\int_0^y \frac{1}{3!2^3}\sum_{i=1}^{8}(-1)^p\left[(k_i^3-3y^2k_i)\times \tan^{-1}\frac{k_i}{y}-(3yk_i^2-y^3)\log(k_i^2+y^2)^{1/2}\right]dy$$

Table I. Values of K_i for Evaluating Equation 19

x_1	x_2	x_3	x_4	k_i: $x_1=x_2=d$, $x_3=x_4=e$	k_i: $x_1=x_2=d$, $x_3=e$; $x_4=E$
+	+	+	+	$2d+2e$	$2d+e+E$
+	+	−	−	$2d-2e$	$2d-e-E$
+	+	+	−	$2d$	$2d+e-E$
+	+	−	+	$2d$	$2d-e+E$
+	−	+	+	$2e$	$e+E$
+	−	−	−	$-2e$	$-(e+E)$
+	−	+	−	0	$e-E$
+	−	−	+	0	$-(e-E)$

k_i designating any one of the eight possible terms formed from the member $(x_1 \pm x_2 \pm x_3 \pm x_4)$ by arbitrary selection of the plus and minus signs, while p is the number of minus signs in k_i. Integrating and collecting terms, we obtain

$$f_2=\frac{1}{4!2^3}\sum_{i=1}^{8}(-1)^p\left[(k_i^4-6yk_i^2+y^4)\times \log(k_i^2+y^2)^{1/2}+4yk_i(k_i^2-y^2)\tan^{-1}\frac{k_i}{y}-k_i^4\log|k_i|\right]$$

$$=\frac{1}{192}\sum_{i=1}^{8}(-1)^p F(k_i, y)$$

where $F(k_i, y)$ stands for the expression within the brackets.

Noting that

$$f_1=\int_0^\infty \frac{\sin Mx_1 \sin Mx_2 \sin Mx_3 \sin Mx_4}{M^4}dM$$

$$=\lim_{y\to 0_+}\int_0^\infty \epsilon^{-My}\times \frac{\sin Mx_1 \sin Mx_2 \sin Mx_3 \sin Mx_4}{M^4}dM$$

we obtain on substituting for the infinite integral

$$f_1=\lim_{y\to 0_+}\frac{1}{3!2^3}\sum_{i=1}^{8}(-1)^p\left[(k_i^3-3y^2k_i)\times \tan^{-1}\frac{k_i}{y}-(3yk_i^2-y^3)\log(k_i^2+y^2)^{1/2}\right]$$

$$=\frac{1}{3!2^3}\sum_{i=1}^{8}(-1)^p\frac{\pi}{2}|k_i^3|$$

II. Expansion of W(r, s) in a Power Series

By definition

$$W(r, s)=1/8[2F(D, s)-F(D+r, s)-F(D-r, s)+2F(r, s)-2F(0, s)+4\pi r^2 s(3D-r)]$$

Now

$$K(x, s)=2F(D, s)-F(D+r, s)-F(D-r, s)$$

considered as a function of x alone, can be expanded in a power series about the point $x=D$. Accordingly, by Taylor's theorem we have

$$K(x, s)=-r^2\frac{\partial^2(FD, s)}{\partial D^2}-\frac{r^4}{2\cdot 3!}\frac{\partial^4 F(D,s)}{\partial D^4}-\frac{r^6}{3\cdot 5!}\frac{\partial^6 F(D, s)}{\partial D^6}-\dots$$

where

$$F(D, s)=1/2(D^4-6D^2s^2+s^4)\log(D^2+s^2)-D^4\log D+4(sD^3-Ds^3)\tan^{-1}\frac{D}{s}$$

$$\frac{\partial F(D, s)}{\partial D}=(2D^3-6D^2s^2)\log(D^2+s^2)-4D^3\times \log D+4(sD^2-s^3)\tan^{-1}\frac{D}{s}-3Ds^2$$

$$\frac{\partial^2 F(D, s)}{\partial D^2}=6(D^2-s^2)\log(D^2+s^2)-12D^2\times \log D+24Ds\tan^{-1}\frac{D}{s}-7s^2$$

$$\frac{\partial^3 F(D, s)}{\partial D^3}=12D\log(D^2+s^2)-24D\log D+24s\tan^{-1}\frac{D}{s}$$

$$\frac{\partial^4 F(D, s)}{\partial D^4}=12\log(D^2+s^2)-24\log D$$

$$\frac{\partial^5 F(D, s)}{\partial D^5}=-\frac{24s^2}{D(D^2+s^2)}$$

$$\frac{\partial^6 F(D, s)}{\partial D^6}=24\left[\frac{1}{D^2}-\frac{D^2-s^2}{(D^2+s^2)^2}\right]$$

$$\frac{\partial^7 F(D, s)}{\partial D^7}=48\left[-\frac{1}{D^3}-\frac{-D^3+3Ds^2}{(D^2+s^2)^3}\right]$$

$$\frac{\partial^8 F(D, s)}{\partial D^8}=144\left[\frac{1}{D^4}-\frac{(D^2-s^2)^2-4s^2D^2}{(D^2+s^2)^4}\right]$$

$$\frac{\partial^9 F(D, s)}{\partial D^9}=576\left[-\frac{1}{D^5}-\frac{-D^5+10D^3s^2-5Ds^4}{(D^2+s^2)^5}\right]$$

$$\frac{\partial^{10} F(D,s)}{\partial D^{10}}=2{,}880\left[\frac{1}{D^6}-\frac{(D^2-s^2)^3-12s^2D^2(D^2-s^2)}{(D^2+s^2)^6}\right]$$

Stability Limitations of Long-Distance A-C Power-Transmission Systems

EDITH CLARKE
MEMBER AIEE

S. B. CRARY
MEMBER AIEE

Synopsis: Conventional methods of transmission are analyzed and discussed both for existing transmission distances up to about 300 miles and for greater distances up to a full wave length; also eight different methods that have been proposed for increasing the loading per circuit or distance to which a-c power can be transmitted are discussed. Of these methods, series compensation of the line reactance appears to be the most favorable for straightaway distances up to about 600 to 700 miles at 60 cycles. The problem is analyzed mathematically and with the aid of an a-c network analyzer. Curves are included which give the power limits and reactive kilovolt-ampere requirements for a large number of parameters, including the effect of distance, voltage, conductor size, series and shunt compensation, terminal impedances, and stability margin. This analysis indicates that the limitation of the transmission of a-c power greater straightaway distances than has been accomplished heretofore is primarily that of the cost of the line, the stability limitation can be overcome by a comparatively small increase in cost.

Introduction

TECHNICAL and economic developments in recent years have resulted in an increased and renewed interest in the problems associated with the electrical transmission of large blocks of power over long distances. Although this subject has been treated extensively in the literature, there appears to be a need at the present time for a brief review of the many ideas that have been presented and a further analysis of some of the fundamental considerations of the problem. The extensive use of a-c network analyzers by operating companies for studying their transmission problems and the availability of such means have made it comparatively easy to obtain data for both the existing and theoretical systems. With this information, more general conclusions can be drawn than were previously possible.

This paper is devoted essentially to the technical aspects of the problem of long-distance a-c power transmission. No attempt is made to determine the economic feasibility of such projects, as they necessarily depend upon many widely differing conditions and factors, which can be properly evaluated only for the particular case under consideration.

I. Existing Transmission—100 to 300 Miles

Existing a-c power transmission in the United States and Canada for distances of from 100 to 300 miles is accomplished by overhead transmission lines at 60 cycles with the exception of a few lines which operate at 25 cycles and a few at 50 cycles. All high-voltage overhead lines of conventional design have inductances and capacitances per unit length which fall within a narrow range. Accordingly, the surge impedance and velocity of propagation of these lines are practically the same, i.e. about 400 ohms and almost 186,000 miles per second (appendix *A*). Furthermore most transmission lines of 100 miles or more are operated at full load near unity power factor. Transmission line resistance losses and reactive kilovolt-ampere requirements increase rapidly when the receiving end power factor is changed appreciably from unity. Full load, therefore, in existing lines of 100 miles or more in length corresponds approximately to the surge impedance loading, by which is meant a load of approximately unity power factor of about 400 ohms equivalent impedance to neutral.

If there were no other important limitations such as stability, transmission lines would be expected to have a rated loading of an order of magnitude determined only by their surge impedance and circuit voltage, independent of frequency and length. Furthermore, since all high-voltage overhead transmission lines have practically the same surge impedance, their loading should vary only with, and directly with, the square of the line voltage. A check[1] of the major long-distance transmission lines in the United States and Canada indicates that this is essentially correct and that only five of these lines over 100 miles long are rated as high as 25 per cent above their unity power factor or approximate surge impedance loading. It is of interest to note that these five heaviest loaded lines are all single-circuit lines and are connected to systems which can tolerate the complete loss of the line and its associated generating capacity. Lines operated in parallel are usually more conservatively rated for normal conditions, so that they will attain this heavy loading only under unusual or emergency conditions. Table I, column 2, gives the approximate unity power factor rating, based on a surge impedance of 400 ohms, for different circuit voltages; and column 3 gives, what is termed in this discussion, the maximum practical rating. Column 2 in kilowatts is numerically equal to 2.5 $(kv)^2$ and column 3 is 1.25 times column 2, $(kv)^2$ being the square of the line-to-line voltage in kilovolts. Occasionally a line will be operated above the value given in column 3, under emergency or temporary conditions before additional line capacity is added or other changes are made. Lines operated with these extreme loadings require unusually large reactive kilovolt-ampere capacity, supplied by generators or synchronous condensers.

Table I. Approximate Transmission Loadings Per Circuit of Conventional Overhead A-C Lines of Moderate Length

Column 1 Receiver Voltage—Kv	Column 2 Unity Power Factor Rating* $Kw = 2.5(Kv)^2$	Column 3 Maximum Practical Rating $Kw = 1.25^{**} \times 2.5(Kv)^2$
550	755,000	945,000
495	615,000	765,000
440	485,000	605,000
385	370,000	465,000
330	270,000	340,000
275	190,000	240,000
220	120,000	150,000
154	60,000	75,000
132	44,000	54,000
110	30,000	38,000
66	11,000	14,000

*Based on surge impedance of 400 ohms.

**This factor is indicated by experience of the major existing lines of balanced design (100 to 300 miles).

Since even the longest existing transmission lines of almost 300 miles are being loaded as heavily as lines of 100 miles in length, it is apparent that the reactive kilovolt-ampere and kilowatt losses, and not necessarily stability, have been the important limitation of the loading. If there were no stability limitations,

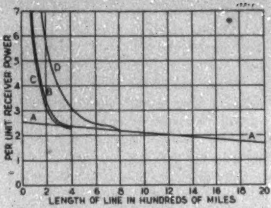

Figure 1. Receiver power with conventional 60-cycle transmission line terminated in dead impedance load

Line constants: $x = 0.8$ ohm per mile
$r = 0.08$ ohm per mile
$b = 5.2 \times 10^{-6}$ mhos per mile

Base kw = $(\text{kv})^2$

Curve *A*—Receiver power with surge impedance load

Curve *B*—Maximum receiver power without overvoltage along the line for impedance loads with impedance angle equal to that of surge impedance of line

Curve *C*—Maximum receiver power without overvoltage along the line for pure resistance loads

Curve *D*—Maximum receiver power without overvoltage along the line for impedance loads resulting in receiving end voltage equal to sending end voltage

economic transmission would dictate heavier loadings per circuit as the distance increases. Up to the present, efforts have been made to bring the transient stability limits due to faults and other disturbances to a point where the loadings of table I (either column) can be obtained with reliability on the circuits remaining in service after the disturbance. This has been accomplished in many systems by means of quick switching, good relaying, intermediate switching stations, almost lightning-proof lines, and good system design. In systems with quick switching and good relaying, where stability limits of the order of column 3 of table I cannot be obtained following a disturbance, experience indicates that the primary reason is the inability of the rotating equipment to provide the emergency reactive kilovolt-amperes required to maintain the bus voltages at the values necessary for the transmission of such loads. This is not necessarily the primary limitation for greater distances.

Conclusions for Existing Lines

1. Existing lines (100 to 300 miles) are operated at maximum loadings as high as 25 per cent above their surge impedance loading. Lines approaching 300 miles in length have loadings equal to or above previously built shorter lines.

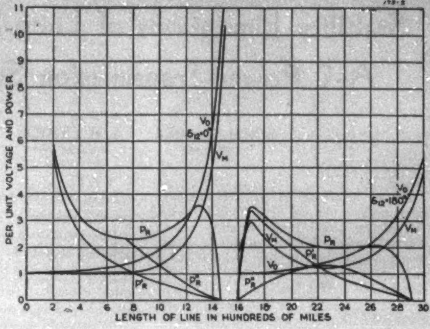

Figure 2. Steady-state stability power limits of conventional 60-cycle transmission lines with zero terminal impedances

Base kw = $(\text{kv})^2$
$E_1 = E_2$
$x = 0.8$ ohm per mile
$r = 0.08$ ohm per mile
$b = 5.2 \times 10^{-6}$ mhos per mile

2. For practical purposes, other conditions remaining the same, the power which can be transmitted over conventional lines varies directly as the square of the circuit voltage.

3. The desirability of using 330 kv as a transmission line voltage for moderate distances will depend to a considerable extent upon whether it is desirable or necessary to transmit 240,000 to 340,000 kw per circuit.

4. With modern equipment and system design practices, line reactive kilovolt-ampere requirements and losses rather than stability have been the important limitations for the transmission of power over conventional 60-cycle lines up to 300 miles in length.

II. Conventional Lines Longer Than 300 Miles

It has been realized for some time that stability will impose more severe limitations as transmission distances are increased. Transmission of a-c power in existing systems with conventional types of load requires that the transmission system develop sufficient synchronizing torque to keep the connected synchronous machines in synchronism. This condition has been termed a live-load requirement in contrast with a dead or impedance load. As transmission distances are increased, the importance of the type of load becomes greater. It is possible to transmit any distance, without overvoltage along the line, a dead load corresponding to the surge impedance load, similar to that used in communication circuits, the limitation of delivered power being determined by the circuit resistance losses. This is not true for live loads, or synchronous-synchronous interconnections, which have a stability limitation.

Curve *A* of figure 1 shows the power that can be delivered over conventional 60-cycle lines of different lengths having the same circuit constants when the receiving end is terminated by an impedance load equal to the surge impedance of the line. The ordinate of figure 1 is plotted in per unit receiver power, with each unit numerically equal to the square of the sending end line-to-line circuit voltage in kilovolts. The abscissa is hundreds of miles of transmission line. The gradual decrease in receiver power with increase in length of line in curve *A* is due to the line resistance losses which

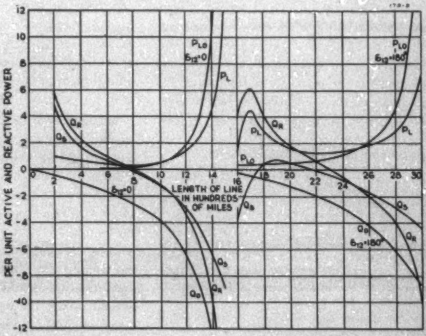

Figure 3. Reactive power and power loss of conventional 60-cycle transmission lines at steady-state stability limit and at no load

Base kva = base kw = $(\text{kv})^2$
$E_1 = E_2 = 1.0$
$x = 0.8$ ohm per mile
$r = 0.08$ ohm per mile
$b = 5.2 \times 10^{-6}$ mhos per mile

could be reduced by using lower resistance conductors. Curve *B* shows the receiver power corresponding to impedance loads which are fractions of the surge impedance. The load power factor is the same as that for the surge impedance load, but the magnitudes of the load impedances are such as to give maximum receiver power at any length of line without overvoltage along the line. For lines longer than approximately 400 miles in length, curves *A* and *B* coincide. Curve *C* is for the optimum pure resistance load without overvoltage along the line. This curve differs slightly from curve *B* because of the small capacitive components in the load impedances of curve *B*. Curve *C* crosses curve *A* between 300 and 400 miles of line. Curve *D* shows maximum receiver power for the case of impedance loads with sufficient capacitance to produce a receiving end voltage equal to the sending end voltage without overvoltage along the line. At slightly less than one-fourth wave length, overvoltages appear along the line at maximum power. (Without resistance, overvoltages under maximum load would not occur for lengths of line smaller than one-fourth wave length.) To reduce these overvoltages to rated voltage, the terminal voltages were reduced, but maintained equal. Curve *D* crosses curve *A* at slightly over one-fourth wave length of line. From these results, it is evident that for distances above approximately one-fourth wave length the maximum power that can be transmitted to an impedance load without overvoltages along the line corresponds to the surge impedance load. Curve *D* of figure 1 and the curves of the other figures in the paper were obtained on the a-c network analyzer.

Figure 2 shows P_R the maximum receiver power that can be transmitted with stability over conventional 60-cycle lines of various lengths between two synchronous systems of zero impedances. The line constants are the same as those of figure 1 and equal voltages are maintained at the sending and receiving ends of the line. Also in figure 2 are shown V_M and V_O the maximum voltages obtained along the line under maximum and no-load conditions, respectively, when the sending and receiving end voltages are equal and of rated magnitude. In the region of multiples of a one-half wave length very high voltages are obtained along the line for the condition of rated sending and receiving end voltages. P_R'' corresponds to the maximum receiver power with the terminal voltages maintained equal, but reduced below rated voltage so that voltages along the line do not exceed rated voltage. P_R' corresponds to the maximum receiver power with terminal voltages maintained equal at a value such that normal voltage is not exceeded at no load.

Figure 3 shows the sending and receiving end reactive kilovolt-ampere requirements corresponding to the power transfer shown in figure 2. Q_S and Q_R are per unit reactive power at the sending and receiving ends of the line, respectively, Q_O is the approximate per unit reactive power at both sending and receiving ends of the line at no load. Reactive power is plotted as positive or negative corresponding to over- or underexcited terminal synchronous systems, respectively. In figure 3 are also plotted P_L and P_{LO} the line losses at maximum load and at no load, respectively.

For distances less than one-half wave length, the stable operating range is in the first quadrant of the angular displacement δ_{12} between the sending and receiving end voltages; while between a half and a full wave length, the stable operating range is in the third quadrant. The no-load conditions were therefore taken as $\delta_{12}=0$ for distances less than one-half wave length, and $\delta_{12}=180$ degrees for distances between one-half and one wave length.

It is of interest to note that no power can be transmitted between two synchronous systems of zero impedances at the terminals of a half wave length line (see appendix *A*), but theoretically power can be transmitted with stability beyond a one-half wave length. It can be shown that for a given distance there is an optimum voltage ratio between the receiving and sending end voltages to obtain maximum power without overvoltage along the line. However, the voltage along the line becomes very sensitive or critical to terminal changes for extreme lengths of line so that operation without overvoltage is difficult.

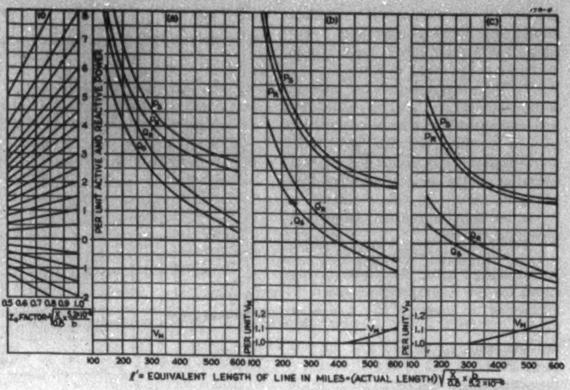

Figure 4. **Steady-state stability curves. $E_1=E_2=1.0$, $r/x=0.1$, base kva = base kw = $(kv)^2$**

(*a*)—Line alone with infinite bus at each end of line

(*b*)—Line with synchronous terminal equipment. Generator plus transformer impedance = 40 per cent on kilovolt-amperes at sending end of line. Receiving end impedance (including transformer) = 25 per cent on kilovolt-amperes at receiving end of line

(*c*)—Same as (*b*) but with 25 per cent stability margin

NOTE: *P* and *Q* are active and reactive power, respectively, in per unit of $(kv)^2$, the subscripts *S* and *R* indicating sending and receiving ends of the line, respectively. V_M is maximum voltage along the line under load

As shown by figure 2, the surge impedance loading can be obtained up to about a quarter wave length (approximately 750 miles at 60 cycles). Beyond this distance the power that can be transmitted falls off rapidly for the condition of no overvoltage along the line. The effect of terminal impedances and the necessity of operating with a stability margin reduce the limits shown on figure 2 still further. These effects are shown in figures 4 and 5.

The curves of figures 4 and 5 summarize the steady-state stability studies made on the a-c network analyzer for conventional lines and compensated conventional lines with compensation uniformly distributed. It can be shown that a transmission line with synchronous terminal equipment is defined by (1) *r*/*x* ratio, (2) equivalent length, (3) Z_0 factor, (4) equivalent steady-state terminal reactances.[2] Figures 4 and 5 differ only in the r/x ratio. In figure 4, $r/x=0.1$; in figure 5, $r/x=0.2$. r is the line resistance per mile and x the inductive reactance per mile. For a compensated line, x is the resultant inductive reactance per mile after series compensation; r is unchanged by compensation if the series capacitors have negligible resistance; b is the resultant capacitive admittance after shunt compensation.

The equivalent length of line and Z_0 factor depend upon the choice of constants for the reference line. A line reactance of 0.8 ohm per mile and a capacity susceptance of 5.2×10^{-6} mhos per mile were selected. For a line with these constants, the equivalent length is the actual length and the Z_0 factor is 1.0.

For a given r/x ratio and given line constants x and b,

Equivalent length of line in miles = (actual length of line in miles) ×

$$\left(\sqrt{\frac{x}{0.8}\times\frac{b}{5.2\times10^{-6}}}\right) \qquad (1)$$

$$Z_0\text{ factor}=\sqrt{\frac{x}{0.8}\times\frac{5.2\times10^{-6}}{b}} \qquad (2)$$

Making use of equivalent length of line and Z_0 factor, with base kva = base kw = $(\text{kv})^2$, and equal voltages at the line terminals, figures 4 and 5 can be applied to conventional lines and compensated conventional lines with compensation uniformly distributed at any voltage and frequency. The equivalent length of line lies between 100 and 600 miles. The r/x ratios are 0.1 and 0.2. The terminal conditions are:

(*a*). Line alone with infinite bus at both ends and equal voltages maintained at the line terminals equal to rated line voltage.

(*b*). Line with synchronous terminal equipment. Generator equivalent steady-state reactance[3] plus transformer reactance = 40 per cent on kilovolt-amperes at sending end of line, receiving end equivalent steady-state reactance (including transformer) = 25 per cent on kilovolt-amperes at receiving end of line, equal voltages maintained at the line terminals equal to rated line voltage. A low value of generator reactance was selected for this study as it will usually be found economical when steady-state stability is a problem to use generators with considerably less than normal reactance.

(*c*). Same as (*b*) but with 25 per cent stability margin. The stability margin is the difference between maximum power and rated power, divided by rated power, where maximum power is the stability limit obtained with the terminal voltages maintained and terminal impedances corresponding to the equipment used for the transmission of rated power.

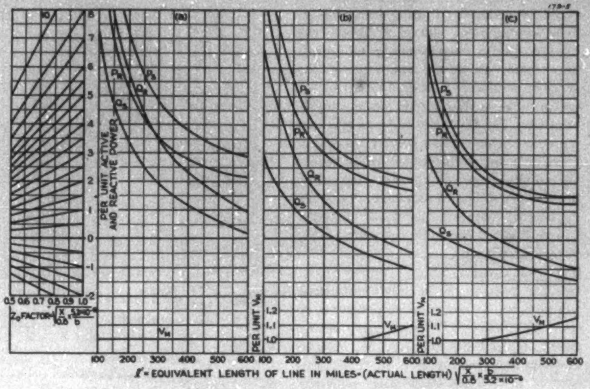

Figure 5. Steady-state stability curves. $E_1=E_2=1.0$, $r/x=0.2$, base kva = base kw = $(\text{kv})^2$

(*a*)—Line alone with infinite bus at each end of line

(*b*)—Line with synchronous terminal equipment. Generator plus transformer impedance = 40 per cent on kilovolt-amperes at sending end of line. Receiving end impedance (including transformer) = 25 per cent on kilovolt-amperes at receiving end of line

(*c*)—Same as (*b*) but with 25 per cent stability margin

NOTE: P and Q are active and reactive power, respectively, in per unit of $(\text{kv})^2$, the subscripts S and R indicating sending and receiving ends of the line, respectively. V_M is maximum voltage along the line under load

In figures 4 and 5 base three-phase power is numerically equal to $(\text{kv})^2$, where kv is the line-to-line rated voltage in kilovolts at the ends of the line. The line terminal voltages E_1 and E_2 are equal in magnitude. P and Q indicate active and reactive power, respectively, in per unit of $(\text{kv})^2$, the subscripts S and R referring to the sending and receiving ends of the line, respectively. Q_S and Q_R are positive when the equivalent synchronous machines at the sending and receiving ends, respectively, of the line are overexcited and negative when underexcited. V_M is the maximum voltage along the line under load.

To apply the curves to a transmission line connecting two synchronous systems with equal voltages held at the line terminals, r/x for the line and the equivalent terminal reactances are calculated or estimated. If $r/x=0.1$ or 0.2, and the terminal conditions correspond to (*a*), (*b*), or (*c*), the equivalent length of line and Z_0 factor are calculated by equations 1 and 2, respectively. With equivalent length of line as abscissa, and using the curves which correspond to the r/x ratio and terminal conditions of the given system, values of P_S, P_R, Q_S, and Q_R are read on the vertical scale corresponding to the Z_0 factor. The vertical lines are labeled for Z_0 factors between 0.5 and 1.0. If the calculated Z_0 factor does not fall within these limits, P_S, P_R, Q_R, and Q_S can be read on the vertical scale corresponding to a Z_0 factor of 1.0 and then divided by the calculated Z_0 factor. The following problems illustrate the use of figures 4 and 5.

EXAMPLE I

Given a 50-cycle, 330-kv 3-phase transmission line 550 miles in length: $r=0.07$ ohm per mile, $x=0.7$ ohm per mile, $g=0$, $b=4.4$ micromhos per mile. Equal voltages are maintained at the ends of the line. How much power can be delivered over the line with (*a*) infinite busses at the sending and receiving ends of the line, (*b*) with synchronous terminal systems at sending and receiving ends of the line having 40 per cent and 25 per cent reactances, respectively, based on sending and receiving end kilovolt-amperes, (*c*) with conditions of (*b*) but with 25 per cent stability margin?

Solution of Example I

$$\frac{r}{x}=\frac{0.07}{0.7}=0.1$$

$$e'=550\times\sqrt{\frac{0.7}{0.8}\times\frac{4.4}{5.2}}=475\text{ miles}$$

$$Z_0\text{ factor}=\sqrt{\frac{0.7}{0.8}\times\frac{5.2}{4.4}}=1.015$$

Entering curves (*a*), (*b*), and (*c*) of figure 4 with $l' = 475$ miles and reading P_R on the vertical scale corresponding to the Z_0 factor of 1.015 (extrapolated), and V_M on its own scale,

(*a*). $P_R = 2.75$ per unit of $(330)^2 = 300{,}000$ kw
$V_M = 1.0$ per unit of 330 kv = not over 330 kv

(*b*). $P_R = 2.2$ per unit of $(330)^2 = 240{,}000$ kw
$V_M = 1.025$ per unit of 330 kv = 2.5 per cent overvoltage along line

(*c*). $P_R = 1.6$ per unit of $(330)^2 = 175{,}000$ kw
$V_M = 1.09$ per unit of 330 kv = 9 per cent overvoltage along line

In cases (*b*) and (*c*) there is overvoltage along the line under load. This suggests the use of shunt reactors to partially compensate for line capacitance.

EXAMPLE II

Given a 60-cycle, 230-kv, three-phase transmission line, 325 miles in length: $r = 0.12$ ohm per mile, $x_2 = 0.8$ ohm per mile, $b = 5.1 \times 10^{-6}$ mhos per mile. The equivalent steady-state reactance[2] of the generators plus transformers based on the kilovolt-amperes at the sending end of the line is 40 per cent, that of the equivalent system at the receiving end of the line, including transformers, is 25 per cent based on receiving end kilovolt-amperes. Equal voltages are maintained at the terminals of the line. How much power can be delivered with stability under steady-state with 25 per cent margin if the reactance of the line is one-fourth compensated? Find also P_S, Q_S, Q_R, and V_M.

Solution of Example II. With line reactance one-fourth compensated, assuming uniformly distributed compensation,

$$x = \frac{3}{4}(0.8) = 0.6$$

$$\frac{r}{x} = \frac{0.12}{0.6} = 0.2$$

$$b = 5.1 \times 10^{-6}$$

$$l' = 325 \times \sqrt{\frac{0.6}{0.8} \times \frac{5.1}{5.2}} = 280 \text{ miles}$$

$$Z_0 \text{ factor} = \sqrt{\frac{0.6}{0.8} \times \frac{5.2}{5.1}} = 0.875$$

Entering curve (*c*) of figure 5 with $l' = 280$ miles and reading P_R, P_S, Q_R, and Q_S on the vertical scale corresponding to a Z_0 factor of 0.875 and V_M on its own scale:

$P_R = 2.55$ in per unit of $(230)^2 = 135{,}000$ kw
$P_S = 2.95$ in per unit of $(230)^2 = 155{,}000$ kw
$Q_R = 0.43$ in per unit of $(230)^2 = 23{,}000$ kvars, overexcited
$Q_S = -0.55$ in per unit of $(230)^2 = 29{,}000$ kvars, underexcited
$V_M = 1.0$ in per unit of 230 kv = not over 230 kv

Figures 4 and 5 show that the surge impedance loading given in column 2 of table I can be realized under favorable conditions of low terminal impedances with lines of conventional design up to about 300 to 350 miles at 60 cycles, and to correspondingly greater distances at lower frequencies. For greater distances, a reduction in loading per $(kv)^2$ would be required with conventional overhead lines. For example, power could be transmitted about 500 to 600 miles at 60 cycles if loadings one-half of those given in column 2, table I, were tolerable. Such a decrease in loading with distance is expensive and undesirable and probably would make it impractical to use conventional a-c transmission for these distances.

CONCLUSIONS FOR CONVENTIONAL LINES LONGER THAN 300 MILES

1. The only limitation to the distance that power can be transmitted to a dead load corresponding to the surge impedance of the line is the line resistance losses, otherwise this amount of power can be transmitted any distance.

2. For transmission of power over lines having synchronous terminal equipment, the limiting distance for a line loading corresponding to unity power factor is, under favorable conditions, about 300 to 350 miles at 60 cycles.

III. Methods for Overcoming Stability and Loading Limitations of Long Lines

As transmission distances increase, the transmission line cost becomes a greater part of the total investment and therefore it becomes of increasing economic importance to maintain or, if possible, to increase the circuit loadings. Under some conditions, studies have indicated that equipment allowing an increase in loading above those shown in table I would be a worth-while investment even for lines of moderate length. Many methods have been proposed to overcome the stability and loading limitations of long lines:

(*a*). It has been suggested that quadrature boost transformers be used to decrease the phase angular displacement between the sending and receiving end systems. The method accomplishes this for a given load, but also decreases the angular displacement at which pull-out occurs, resulting in no gain in stability but a possible decrease for the same line voltage.

(*b*). It has also been suggested that series synchronous condensers be used to overcome the line reactance voltage drop. It can be shown that this method would require extremely large rotating apparatus with a large motor to keep the synchronous condenser in proper phase relation.

(*c*). Series capacitors[3] have been suggested for increasing the power limits. This method appears to be the most promising for the next increase in a-c transmission line distances; for example, from 300–350 to 600–700 miles at 60 cycles. In order to transmit power 600–700 miles by means of a conventional line with a loading equal to the loadings of table I, column 2, it would be necessary to compensate only half of the line reactance. The capacitor kilovolt-amperes required would be about 70 per cent of the kilowatts transmitted. In order to deliver this power at unity power factor, additional reactive kilovolt-amperes either in shunt reactors or in synchronous condenser lagging capacity, also about 70 per cent of the kilowatts transmitted, would be required. Therefore to transmit say 190,000 kw 700 miles at 60 cycles over a single circuit at 275 kv, unity power factor, would require 133,000 kva of series capacitors and 133,000 kva of shunt reactors. A possible doubling in conductor cross section to keep the losses down would also be required (this would be necessary for any electrical transmission method). If it is assumed that capacitors cost \$9.00 per kilovolt-ampere and reactors \$2.00 per kilovolt-ampere, this would amount to \$8.00 per kilowatt transmitted to overcome the stability limitations of transmitting a-c power 700 miles. For shorter distances, the required amount of compensation and therefore the cost per kilowatt to overcome the stability limitations would be correspondingly less.

If series capacitors are used without shunt reactors, the over-all effective surge impedance is reduced, and it is possible to deliver more power at unity power factor per $(kv)^2$ for the same distance. In this

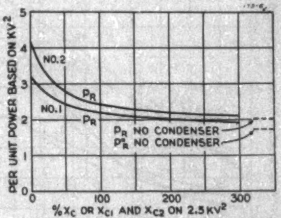

Figure 6. Receiving end power at steady-state stability limit for 600-mile 60-cycle conventional line with one and two intermediate stations as affected by intermediate station reactance

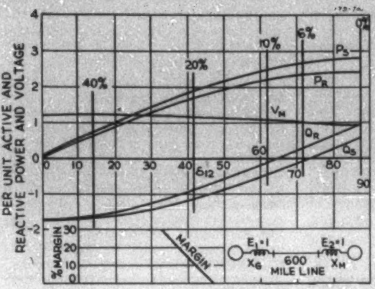
Curve number 1—One intermediate station, $E_1 = E_2 = E_C = 1.0$
Curve number 2—Two intermediate stations, $E_1 = E_2 = E_{C1} = E_{C2} = 1.0$
$x_G = 40$ per cent, $x_M = 25$ per cent $\Big\}$ based on $2.5\,(kv)^2$
$x = 0.8$ ohm per mile
$r = 0.08$ ohm per mile
$b = 5.2 \times 10^{-6}$ mhos per mile



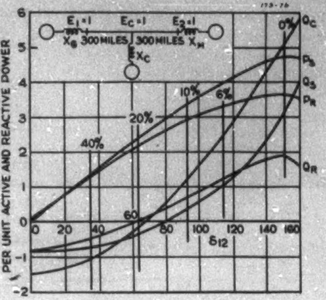


Figure 7. Characteristics of 600-mile conventional 60-cycle transmission line with synchronous terminal equipment, with and without intermediate stations

Base kva = base kw = (kv)^2

$x=0.8$ ohm per mile

$r=0.08$ ohm per mile

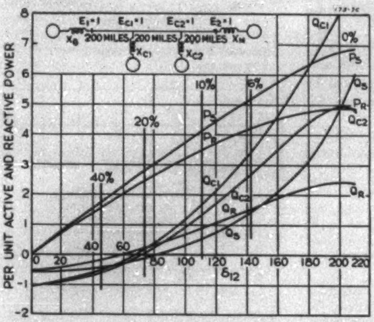
$b=5.2\times10^{-6}$ mhos per mile

Vertical lines give steady-state stability limits with equal terminal and intermediate station reactances indicated based on (kv)^2

(a) (upper left)—No intermediate stations, $E_1=E_2,\ x_G=x_M$

(b) (upper right)—One intermediate station, $E_1=E_2=E_{c1}\ \ x_G=x_M=x_c$

(c) (lower left)—Two intermediate stations, $E_1=E_2=E_{c1}=E_{c2}\ \ x_G=x_M=x_{c1}=x_{c2}$



way an increase in the loading per circuit can be accomplished. Thus series capacitors may be used to increase the loading per circuit or the distance of transmission or both.

In order to distribute the voltage drop across the series capacitors during either steady-state or transient conditions, it would be desirable to locate them along the line at possibly three to six locations for a line that is half compensated. The optimum arrangement can be determined by a study of the particular case under consideration. Protective equipment similar to that used with present-day lower voltage installations could be used to protect them during abnormal conditions. For lines of shorter length, less compensation would be required; while for longer lines, more compensation would be required for a given loading. One advantage in the use of series capacitors is that increased compensation need not be installed until load conditions requiring such compensation are reached.

(*d*). It has been suggested that frequency changers be used to produce lower frequency for the line and thus to extend the distance of transmission or the loading per circuit. Such equipment, in comparison with series capacitors, does not appear to be as economical except for distances appreciably above 700 miles. This method also has the additional disadvantage that the line cannot be as readily tapped and absorbed into the system high-voltage network as a line operated at normal frequency.

(*e*). In this same classification is the use of conversion equipment to impose at the receiving end a load having an impedance equal to the surge impedance of the line, the line being operated with variable voltage. The advantages of this method of overcoming the stability limitation are limited also to very long distances, possibly above 700 miles.

(*f*). It has been suggested that tuned transmission lines be used, possibly operating at higher than normal frequencies so that the line length corresponds to $^3/_4$, $^5/_4$, etc., of a wave length. This method has the disadvantage of requiring conversion equipment and the possibility of dangerous line voltages during fault conditions. Its usefulness therefore appears to be limited to extreme distances.

(*g*). It has been realized that the loading and distance to which power can be transmitted are materially increased by intermediate systems or condenser stations. In order to obtain an appreciable benefit by this method and so make it of practical importance, the intermediate system or station must have a relatively large kilovolt-ampere rating (or low reactance) compared to the power being transmitted. It has not been considered economical to install synchronous condensers for this purpose alone.

The effect of intermediate systems or condensers for the case of a 600-mile line is shown in figure 6. The ordinates are maximum per unit power while the abscissa is reactance of the intermediate system or systems. Curve number 1 of figure 6 is for one intermediate station located at the center of the line and curve number 2 is for two intermediate stations, evenly spaced along the line. It will be noted that the power limit increases rapidly as the reactance of the intermediate station or stations is decreased. If additional intermediate systems are located along the line the power limit is further increased. In appendix *B* is a more complete discussion of the effect of intermediate systems on the power transmitting ability of a line.

With the gradual natural development of a transmission grid over sections of the United States this method of transmitting power has already been accomplished, as many of the systems are normally interconnected, although in many cases the tie-line capacity is small compared to the system capacity.

(*h*). Another method of increasing the limits of a-c transmission is by the use of cable which has inherently a low reactance and would allow a considerable increase in the distance to which the desired circuit loadings could be maintained. Shunt reactors would probably be required to compensate for the excessive line charging capacity. This method depends upon the design of cable which can compete favorably in cost with overhead lines.

(*i*). D-c transmission of power has been much discussed as a method by which the loading per circuit can be materially increased for the same maximum circuit voltage and total effective conductor area. The advantages of direct current over alternating current increase with increase in the straightaway transmission distance, or when the terminal equipment cost becomes small compared with the line cost. On the basis that twice as much power can be transmitted by direct current as by alternating current for the same line cost, it is necessary that the total d-c terminal cost above the total a-c terminal cost (both ends) be less than one-half the a-c line cost if the capital investment is not to exceed that for alternating current. It is apparent therefore that the advantage of d-c over a-c transmission increases with the straightaway transmission line distance and the required cost per mile of line. As the cost of the conversion terminal equipment is reduced, the transmission distances at which d-c transmission compares favorably with a-c transmission become less.

CONCLUSIONS REGARDING METHODS FOR OVERCOMING STABILITY LIMITATIONS OF LONG LINES

1. Of all the methods proposed for transmitting 60-cycle power to greater distances and with loadings exceeding those of existing lines, the series capacitor used in conventional overhead lines appears most favorable at the present time.

2. A-c power may be transmitted across or through interconnected systems for considerable distances, provided the intermediate systems are connected to the transmission system by low-reactance ties and these systems have a kilovolt-ampere rating comparable to the transmitted power.

3. The stability limitation in long-distance a-c transmission is not present in d-c transmission. The advantages of d-c transmission increase with the straightaway distance of transmission and the cost per mile of line.

Nomenclature

e_s, e_r = vector line-to-neutral voltage at sending and receiving ends of line, respectively, in volts

i_s, i_r = vector line currents at sending and receiving ends of line, respectively, in amperes

f = frequency in cycles per second

r, x, z = resistance, reactance, impedance, respectively, in ohms per mile

g, b, y = leakance, capacity susceptance, admittance, respectively, in mhos per mile

α, λ, v = normal attenuation constant per mile, wave length in miles, apparent velocity of propagation in miles per second, respectively

Z_0 = surge impedance to neutral in ohms

θ = hyperbolic angle of the line

A, B, ϕ_a, ϕ_b = scalar value of cosh θ, scalar value of Z_0 sinh $\theta \times 10^{-3}$, impedance angle of cosh θ, impedance angle of Z_0 sinh $\theta \times 10^{-3}$, respectively

l, l' = actual and equivalent length of line in miles, respectively

kv = rated line-to-line voltage in kilovolts

E_1, E_2 = scalar values of line-to-neutral voltage at sending and receiving ends of the line, respectively, in per unit of rated line-to-neutral voltage

V_M, V_O = maximum voltage along the line in per unit of rated voltage under full load and no load, respectively

δ_{12} = electrical angular displacement between e_s and e_r

$\delta_{12(\max)}$, $\delta_{12(\min)}$ = electrical angular displacement between e_s and e_r for maximum and zero power, respectively

P_S, P_R = three-phase active power at sending and receiving ends of the line, respectively, in per unit of base three-phase kilowatts

P_L, P_{LO} = three-phase line losses at maximum load and at no load, respectively, in per unit of three-phase base kilowatts

P_R', P_R'' = three-phase active power at receiving end of line in per unit of base three-phase kilowatts, with equal terminal voltages of such magnitude as to produce no overvoltage along the line at no load and full load, respectively

Q_S, Q_R = three-phase reactive power at sending and receiving ends of the line, respectively, in per unit of base three-phase kilovolt-amperes

Q_O = three-phase reactive power at either end of line at no load in per unit of base three-phase kilovolt-amperes

Q_c, Q_{c1}, Q_{c2} = three-phase reactive power in per unit of base three-phase kilovolt-amperes at intermediate station indicated by subscript

E_c, E_{c1}, E_{c2} = scalar values of line-to-neutral voltages in per unit of base line-to-neutral voltage at intermediate station indicated by subscript

x_c, x_{c1}, x_{c2} = reactance of intermediate station indicated by subscript

x_G = equivalent steady-state reactance[2] of the generators plus transformers (or equivalent system) at the sending end of the line

x_M = equivalent steady-state reactance of the equivalent system (transformers included) at the receiving end of the line

δ_{GM} = electrical angular displacement between the voltages behind x_G and x_M

Appendix A. Characteristics of Symmetrical Three-Phase Transmission Lines With Uniformly Distributed Constants

The following equations[4] apply to transmission lines under balanced operating conditions:

$$e_s = e_r \cosh\theta + i_r Z_0 \sinh\theta \qquad \text{(A-1)}$$

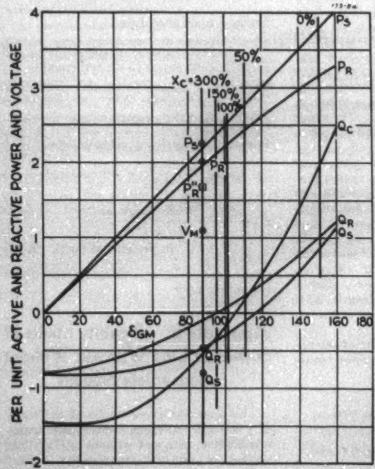
$$e_r = e_s \cosh\theta - i_s Z_0 \sinh\theta \qquad \text{(A-2)}$$

where

$$Z_0 = \sqrt{\frac{z}{y}} = \sqrt{\frac{r+jx}{g+jb}} \qquad z = r+jx$$

Figure 8. Characteristics of 600-mile conventional 60-cycle transmission line with one and two intermediate stations and synchronous terminal equipment

Base kva = base kw = $(kv)^2$
$x = 0.8$ ohm per mile
$r = 0.08$ ohm per mile
$b = 5.2 \times 10^{-6}$ mhos per mile
$x_G = 40$ per cent based on $2.5\ (kv)^2$ [16 per cent based on $(kv)^2$]
$x_M = 25$ per cent based on $2.5\ (kv)^2$ [10 per cent based on $(kv)^2$]



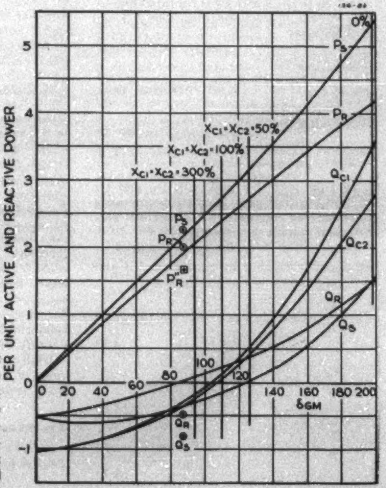
(a) (left)—One intermediate station—see figure 7b for sketch. $E_1 = E_2 = E_c = 1.0$

(b) (right)—Two intermediate stations—see figure 7c for sketch. $E_1 = E_2 = E_{c1} = E_{c2} = 1.0$

NOTE: Vertical lines give steady-state stability limits with intermediate station reactances indicated based on kva = $2.5\ (kv)^2$

⊙ Give P_S, P_R, Q_S, Q_R, and V_M at stability limit without intermediate station

⊡ Indicates P_R'', maximum power with equal terminal voltages and no overvoltage along the line under full load



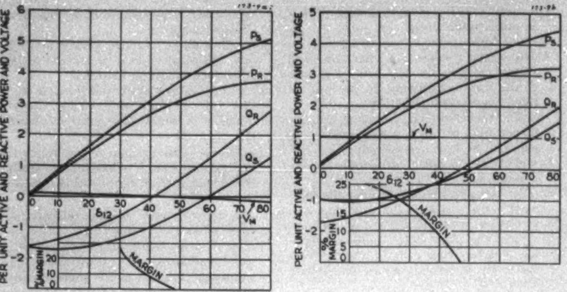


Figure 9. Characteristics of 600-mile conventional 60-cycle transmission line with series compensation infinitely distributed. Series line reactance one-half compensated

Base kva = base kw = (kv)^2
$x=0.8-0.4=0.4$ ohm per mile
$r=0.08$ ohm per mile
$b=5.2\times10^{-6}$ mhos per mile
Reactance of terminal equipment at sending end = 40 per cent on sending end kilovolt-amperes
Reactance of terminal equipment at receiving end = 25 per cent on receiving end kilovolt-amperes
(a) (above)—$E_1=E_2=1.0$
(b) (right)—$E_1=1.0$; $E_2=0.85$

$$\theta=l'\alpha \qquad y=g+jb$$

$$\alpha=\sqrt{zy}=\sqrt{(r+jx)(g+jb)}$$

Expressed in per unit, with base voltage equal to rated line-to-neutral voltage and base three-phase kilovolt-amperes and base three-phase kilowatts both numerically equal to (kv)^2, where kv is the rated line-to-line voltage in kilovolts, equations A-1 and A-2 become

$$E_1\underline{/\delta_{12}}=E_2\cosh\theta+\frac{P_R+jQ_R}{E_2}(Z_0\times10^{-3})\sinh\theta \qquad \textbf{(A-3)}$$

$$E_2\overline{\backslash\delta_{12}}=E_1\cosh\theta-\frac{P_S-jQ_S}{E_1}(Z_0\times10^{-3})\sinh\theta \qquad \textbf{(A-4)}$$

In equations A-3 and A-4, Q_R and Q_S will be positive or negative corresponding to over- or underexcited terminal synchronous machines, respectively.

Substituting $A\underline{/\phi_a}$ for $\cosh\theta$, and $B\underline{/\phi_b}$ for $Z_0\sinh\theta\times10^{-3}$ in equations A-3 and A-4 and solving for P_R, P_S, Q_R, and Q_S:

$$P_R=\frac{E_2}{B}[E_1\cos(\delta_{12}-\phi_b)-E_2A\cos(\phi_a-\phi_b)] \qquad \textbf{(A-5)}$$

$$Q_R=\frac{E_2}{B}[E_1\sin(\delta_{12}-\phi_b)-E_2A\sin(\phi_a-\phi_b)] \qquad \textbf{(A-6)}$$

$$P_S=\frac{E_1}{B}[-E_2\cos(\delta_{12}+\phi_b)+E_1A\cos(\phi_a-\phi_b)] \qquad \textbf{(A-7)}$$

$$Q_S=\frac{E_1}{B}[-E_2A\sin(\delta_{12}+\phi_b)-E_1\sin(\phi_a+\phi_b)] \qquad \textbf{(A-8)}$$

$$\text{Power loss}=P_S-P_R=\frac{1}{B}[(E_1^2+E_2^2)A\times\cos(\phi_a-\phi_b)-2E_1E_2\cos\delta_{12}\cos\phi_b] \qquad \textbf{(A-9)}$$

The voltage along the line at any point F with given values of P_R and Q_R can be obtained from equation A-3 if point F is considered the sending end of the line between F and the receiving end.

With any given voltages E_1 and E_2 maintained at the line terminals and an impedance load, P_R maximum occurs when $\delta_{12}=\phi_b$, P_S maximum occurs when $\delta_{12}=\pi-\phi_b$. With E_1 and E_2 maintained, and synchronous terminal equipment at the sending and receiving ends of the line of zero impedance (i.e., infinite bus at both ends of the line), the criterion of stability[5] is here taken as a positive rate of change of both receiving and sending end power with δ_{12}. For stability,

$$\frac{dP_S}{d\delta_{12}}\geqq0 \qquad \textbf{(A-10)}$$

and

$$\frac{dP_R}{d\delta_{12}}\geqq0 \qquad \textbf{(A-11)}$$

The value of δ_{12} at the steady-state stability limit, $\delta_{12(\max)}$, must satisfy both equations A-10 and A-11, and therefore is either ϕ_b or $\pi-\phi_b$, whichever is smaller. The range of δ_{12}, for stable operation with power transferred, lies between $\delta_{12(\min)}$ and $\delta_{12(\max)}$, where $\delta_{12(\min)}$ may be obtained from equation A-5 with $P_R=0$ and the restriction that $\delta_{12(\min)}$ must lie between $\delta_{12(\max)}-\pi/2$ and $\delta_{12(\max)}$. For a zero resistance line of less than one-half wave length, $\phi_b=\pi/2$, and therefore $\delta_{12(\max)}=\pi/2$ and $\delta_{12(\min)}=0$; while for a line between one-half and a full wave length, $\phi_b=-\pi/2$, and therefore $\delta_{12(\max)}=-\pi/2$ and $\delta_{12(\min)}=-\pi$. For a line of exactly one-half wave length, ϕ_b is indeterminate for a line of zero resistance, since $Z_0\sinh\theta=0$.

With resistance in the line, the operating range of δ_{12} for stability with power transferred is determined from ϕ_b.

If ϕ_b lies between 0° and $\frac{\pi}{2}$, $\delta_{12(\max)}=\phi_b$

If ϕ_b lies between $\frac{\pi}{2}$ and π, $\delta_{12(\max)}=\pi-\phi_b$

If ϕ_b lies between π and $\frac{3}{2}\pi$, $\delta_{12(\max)}=\phi_b$

If ϕ_b lies between $\frac{3}{2}\pi$ and 2π, $\delta_{12(\max)}=\pi-\phi_b$

For lines of low resistance, $\delta_{12(\min)}$ will be approximately zero for ϕ_b between zero and π, and approximately π for ϕ_b between π and 2π. The operating range of δ_{12} decreases as ϕ_b approaches π. For $\phi_b=\pi$, there is no value of δ_{12} which will satisfy both equations A-10 and A-11, and therefore no power can be transferred between two synchronous systems of zero impedance at the terminals of the line. This is true also of lines in which ϕ_b differs but slightly for π, as shown in figure 2 in the region of a half wave length line.

The line constants selected as representative for 60-cycle long-distance power transmission are

$x=2\pi fL=0.8$ ohm per mile
$b=2\pi fC=5.2\times10^{-6}$ mhos per mile
$r=0.08$ ohm per mile
$g=0$

Using these constants,

$$Z_0=\sqrt{\frac{z}{y}}=10^3\sqrt{\frac{0.08+j0.8}{0+j5.2}}=10^3\sqrt{\frac{0.804\underline{/84.29}}{5.2\underline{/90°}}}=393\underline{/-2.86}$$

$$\alpha=\alpha_1+j\alpha_2=\sqrt{zy}=10^{-3}\sqrt{(0.08+j0.8)\times j5.2}=10^{-3}\times2.044\underline{/87.14°}=10^{-3}(0.102+j2.04)$$

$\alpha_1=0.102\times10^{-3}$
$\alpha_2=2.04\times10^{-3}$

$$\lambda=\frac{2\pi}{\alpha_2}=\frac{2\pi\times10^3}{2.04}=3{,}080 \text{ miles}$$

$v=f\times\lambda=60\times3{,}080=185{,}000$ miles per second

Surge Impedance Load

If the line is closed at the receiving end through impedances to neutral equal to the surge impedance, $i_r=e_r/Z_0$; and from equation A-1,

$$e_r=e_s/(\cosh\theta+\sinh\theta)=e_s\epsilon^{-\theta}=e_s\epsilon^{-l(\alpha_1+j\alpha_2)}$$

Power at the receiving end in watts =

$$3e_r\cdot i_r=3e_r\cdot\frac{e_r}{Z_0}=\frac{3|e_s|^2}{|Z_0|}\epsilon^{-2l\alpha_1}\cos(\text{angle of } Z_0)$$

$$P_R=\frac{E_1^2\epsilon^{-2l\alpha_1}\cos(\text{angle of } Z_0)}{|Z_0|\times10^{-3}} \text{ in per unit of (kv)}^2 \qquad \textbf{(A-12)}$$

where bars enclosing a quantity indicate its magnitude only.

Appendix B. Stability Limits of 600-Mile Line With and Without Intermediate Stations

This appendix gives results of the study of a 600-mile, 60-cycle, conventional transmission line, with and without intermediate system or synchronous capacity located along the line. Included also are curves showing the results of series line reactance compensation by means of series capacitors, and line charging compensation by means of shunt reactors, compensation being assumed uniformly distributed.

Figure 7(*a*) shows the sending and receiving end active and reactive power, and the maximum voltage along the line at different angular displacements between the two ends of the line for the conventional line with terminal voltages equal to rated voltage and no intermediate station. Reactive power is positive when the equivalent synchronous machines at the line terminals are overexcited and negative when underexcited. Some overvoltage exists along the line for all angular displacements up to 70 degrees. This overvoltage can be corrected either by shunt reactors along the line, or by the reduction of sending end or receiving end voltage or both. The vertical lines indicate the angles at which maximum receiver power is obtained with stability for different terminal reactances, equal at the two ends of the line and of the magnitudes indicated based on rated voltage and kilovolt-ampere numerically equal to $(\text{kv})^2$. It will be noted that maximum receiver power is 2.4 $(\text{kv})^2$ and occurs at an angular displacement of 87.5 degrees. Steady-state stability at this angular displacement requires zero terminal impedances.

If the line voltage is 230 kv and the sending and receiving end reactances are each 20 per cent based on 100,000 kva and rated voltage, these reactances based on a kva $=(230)^2=52{,}900$ kva are

$$x_G=x_M=\frac{0.20\times 52{,}900}{100{,}000}=0.106 \text{ per unit, or } 10.6 \text{ per cent}$$

The maximum receiver power with 230 kv and these terminal reactances from figure 7*a* is 2.15 $(230)^2=114{,}000$ kw. In a similar manner the reactive power requirements may also be determined. The maximum voltage along the line at this load is about five per cent above normal.

At the bottom of figure 7*a* is a stability margin curve which may be used for determining the line angle and the corresponding line condition of active and reactive power and voltage along the line for a given stability margin. This margin curve corresponds to the condition of $x_G=40$ per cent and $x_M=25$ per cent based on the kilovolt-amperes at the sending and receiving ends of the line, respectively.

Figures 7*b* and 7*c* are similar to figure 7*a* except that they are for one and two intermediate systems, respectively. The reactances of the sending end, receiving end, and intermediate systems are all assumed equal. The curves also give the reactive kilovolt-ampere requirements of the intermediate system or systems for the transmission of power. It will be noted that although with intermediate systems the stability limits are greater, increases in loading above that corresponding to about the unity power factor loading of the line require large amounts of reactive kilovolt-amperes from the intermediate system or systems for the transmission of power. Accordingly, the transmission of power over conventional lines, even with intermediate stations does not necessarily allow for appreciable increases of the line loading above that obtained with existing transmission.

Figures 8*a* and *b* are similar to figures 7*b* and *c*, respectively, except the sending and receiving end reactances are kept constant corresponding to 40 per cent based on 2.5 $(\text{kv})^2$ [16 per cent based on $(\text{kv})^2$] and 25 per cent based on 2.5 $(\text{kv})^2$ (10 per cent based on $(\text{kv})^2$), respectively, while the intermediate system reactance is varied.

For purposes of comparison, figures 9*a* and 9*b* are included to show the effect of series line reactance compensation which may be obtained with series capacitance. Figure 9*a* is for equal sending and receiving end voltages, while figure 9*b* is for a receiving end voltage 85 per cent of the sending end voltage. As will be noted, equal voltage results in a somewhat higher power limit.

Figure 10*a* shows the effect of line charging compensation by the use of shunt reactors; figure 10*b* the effect of both series and shunt compensation. The compensation of the line charging current results in a slight reduction of the power limit. As shown by figures 4 and 5, line charging current is beneficial in increasing the power limit although it would necessarily require compensation at light loads.

System Lower-Harmonic Voltages—Methods of Calculation and Control by Capacitors

W. C. FEASTER
NONMEMBER AIEE

E. L. HARDER
MEMBER AIEE

I. Introduction

A LARGE capacitor bank recently installed at Winchester, Virginia, is supplied with a series reactor to tune it to the fifth harmonic of the power frequency. This is the pioneer installation in the United States of this novel means of reducing the fifth harmonic voltage over a broad expanse of system—33 kv in this case. The paper defines the field of application for this arrangement in comparison with other better known methods of harmonic control.

A technique of system study at harmonic frequency has been developed, based on these findings. Analysis of measurements of lower system harmonics on power systems under varying conditions has shown their chief source to be transformer magnetizing current when power rectifiers are not present. This makes possible analytical determination of the harmonics of interest in the application of shunt capacitors. It involves first, the laboratory determination of the internal voltage and reactance comprising the transformer equivalent circuit, second, the setup of the actual system on the a-c network calculator, using the equivalent circuit, and third, field tests to verify the findings of the network calculator studies, and to prove the adequacy of the tuned capacitor installation. This method of analysis is presented together with confirming tests.

II. Treatment of the Problem

In recent years the price of shunt capacitors has been periodically reduced by the manufacturers. These price reductions have greatly increased the possible savings obtained by the installation of such capacitors by either the power companies or their customers. The result is that the number of capacitor installations is continually increasing, and since the capacitors afford a low impedance path to harmonics present on the power system, due precautions must be taken to prevent their being overloaded from harmonic currents. Ordinarily the standard margin provided by the manufacturers in the up-to-date units is ample for the harmonics encountered. However conditions may arise in which overloading occurs from harmonics, particularly of older units, not provided with present day margins. As the number of capacitors on any system is increased, the general harmonic condition may become worse, and old installations as well as new ones may, under certain conditions, begin to give trouble in the form of fuse blowing, overheating, and excessive noise.

Source of Harmonics

Transformers are the principal source of the lower system harmonics, unless large rectifiers are present. Due to the characteristics of core iron, the exciting current must contain considerable harmonics in order to produce a sine wave voltage. The transformers supply the necessary harmonic voltage to circulate the required harmonic currents. When a low impedance external path is available, the harmonic voltage appearing at the transformer terminals is low. In this respect the transformers act much like constant current harmonic generators when the applied fundamental voltage remains constant. For the purpose of system study they can also be considered as harmonic generators of relatively high voltage and high internal impedance. The harmonic exciting currents decrease in magnitude very rapidly with frequency. The second harmonic and multiples of it are not generated within the transformer, unless d-c saturation is present, while the third harmonic and multiples of it are provided with low impedance circuits by transformers connected in delta. The fifth harmonic is therefore the one most likely to cause trouble to capacitors. Only in rare cases of sharp resonance will the seventh be bothersome.

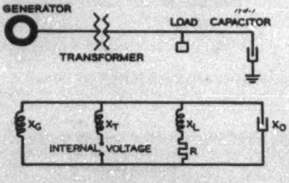

Figure 1. Elementary impedance diagram

Equivalent circuit of transformers connected to system showing possibilities of resonance at harmonic frequencies

The required exciting current of a transformer varies greatly with the applied voltage, a ten per cent overvoltage approximately doubling it. It is therefore important to prevent light load system overvoltage when a harmonic problem is encountered. Considerable improvement may be obtained by a change in the system voltage schedule.

Resonance Conditions

On a normal power system the load and generator impedances are low enough to maintain the harmonic voltage at low level when the system is loaded. At light load periods these impedances become higher and this will result in a considerable change in the harmonic voltage. As capacitors are added to a system a point will be reached where the capacitive reactance will equal the inductive reactance of the generators and load, for the harmonic involved. A condition of parallel resonance[3] then exists on the system and there is no available low impedance circuit for the transformer exciting current of that particular frequency. The result is a high harmonic voltage prevalent over the system.

A further increase of capacitors on the system will place a capacitive load on the transformers. A point may then be reached where the capacitive reactance of the system will equal inductive reactance of the transformer internal impedances. This is a condition of series resonance and the system harmonic voltage may be greater than the transformer internal voltage. In both cases of resonance the system load causes a loss in the tuned circuits and limits the voltage rise. As shown on figure 1, parallel resonance occurs when X_L and X_G in parallel numerically equals X_c. Series resonance exists when X_L,

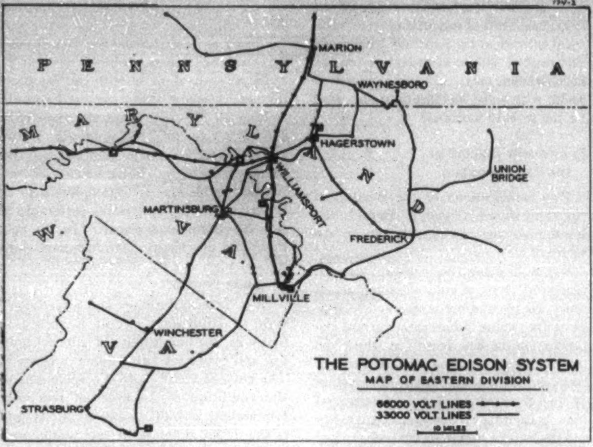

Figure 2. Diagram of Potomac Edison System

X_G, and X_c in parallel are capacitive in nature and equal to X_T.

THE POTOMAC EDISON PROBLEM

On the eastern division of the Potomac Edison System the fifth harmonic voltage was found to reach a peak of 12% of the fundamental; a condition which was general over the entire 33 kv network of approximately 450 circuit miles. Under such a harmonic voltage condition many small capacitors were overloaded with fifth harmonic current. Standard capacitors are designed to stand 135% of rated kva without overheating. Allowing for 10% overvoltage which loads the capacitor to 121% rating, 14% capacity will remain for harmonics. At the fifth harmonic the $\% \text{ kva} = 100\left(\frac{E \text{ harmonic}}{E \text{ rated}}\right)^2 \times 5$ which means the allowable 14% kva will be exceeded when the fifth harmonic voltage exceeds 17%, assuming other harmonics to be negligible. The local rise in voltage due to the leakage reactance of the transformer bank supplying the capacitors frequently increased the 12% harmonic voltage applied to them so that it was far in excess of the safe value. At these locations it was impossible to maintain the capacitors in service due to overheating or fuse blowing.

Table I. Current Wave Analysis Calculated From D-C Saturation Curve for Sine-Wave Flux

Using Fischer-Hinnen Method—All at 104 Per Cent Voltage

TUNED CAPACITOR

It is possible to place a short circuit to the fifth harmonic at some point on the system by means of a capacitor and series reactor adjusted to resonate at the harmonic frequency. This provides a filter, or circuit of low impedance, and it may be assumed that a large percentage of the system fifth harmonic current will flow through it. These currents can be determined approximately by a very simple method and the proper rating for the capacitor and reactor readily determined.

The maximum possible fifth harmonic current that will flow through the filter is the total fifth harmonic exciting current of the system transformers. Power transformers will on the average require a fifth harmonic exciting current of approximately 0.75% of the full load transformer current when operating at rated voltage. Allowing for some over-excitation, tests have shown that a value of 1% is a close approximation. Thus a system with 100,000 kva of connected transformers would supply $\frac{100{,}000 \times 1{,}000}{2{,}300 \times 1.73 \times 100}$ or 250 amperes of fifth harmonic on a 2,300-volt fundamental frequency base. A capacitor operating with a maximum of 7% overvoltage will be loaded to $(1.07)^2$ or 115% of its rated kva at 60 cycles. Thus 135%–115% or 20% of its rated capacity is available for harmonics. A capacitor's impedance at the fifth harmonic is $^1/_5$ of its impedance at 60 cycles. At fifth harmonic the % kva is $100\left(\frac{I \text{ harmonic}}{I \text{ rated}}\right)^2 \times 0.2$, or is 20% kva when the fifth harmonic current equals the rated current. This means that a capacitor can be operated at 7% overvoltage and still carry 100% of its rated current in fifth harmonic current. A current of 250 amperes at 2,300 volts is the current rating of 1,000 kva capacitor. Thus if the filter is so designed that the fundamental voltage rise through the series reactance does not apply more than 107% voltage to the capacitor, a 1,000 kva capacitor will safely carry all the harmonic current supplied by a system of 100,000 kva transformer capacity. This provides some margin in that not all the harmonic will flow through the filter. The 2,160 kva tuned capacitor described in this paper is applied on the Potomac Edison System having 250,000 kva total connected transformer capacity.

INSTALLATION AT WINCHESTER

Of the various possible remedial measures which were considered for lowering the harmonic voltage, it was decided to use the tuned shunt capacitor as outlined above. Figure 2 shows the extent of the lines comprising the Potomac Edison System and figure 4 shows the fifth harmonic voltage obtained at the Winchester Substation before any remedial measures were applied. Figure 3 illustrates the installation at Winchester. A 2,160 kva capacitor is connected through an 0.81 millihenry reactor to the 4 kv station bus.

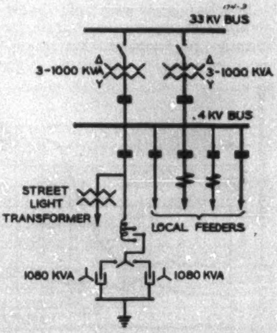

Figure 3. Tuned capacitor installation at Winchester

Table II. Fifth Harmonic Impedances of Loads

Feeder Description	Time	Voltage RMS	Amps. RMS	Fifth Harmonic Impedance, Per Cent on Load Kva Base
Woolen mill-industrial-weaving	Night	2,490	70	53
Commercial-industrial-domestic	Night	2,490	60	68
Commercial-industrial-domestic (unbalanced)	Night	2,490	100	115
Industrial and domestic, 300-hp synchronous motor included	Night	2,490	90	84

Normally, a 0.31 millihenry tap is used, which, in conjunction with the two transformer banks, tunes the complete capacitor to the 33 kv bus. The reduction in the harmonic at Winchester as a result of this measure is indicated in figure 4. It will be noted that the harmonic on the 33 kv system is reduced to approximately 1%. Improvement is also obtained in the harmonic voltage at other points of the system as a result of this installation. Figure 5 shows the harmonic voltage at Frederick, about 50 miles distant, with the filter at Winchester on and off. The results obtained are closely in agreement with the predictions from the analytical study to be described subsequently.

III. Analytical Studies

It was established by field tests on the Potomac Edison System that the fifth and seventh harmonic voltages and currents arose almost entirely from transformer magnetizing current.

In order to study analytically the performance of the system at these frequencies, to determine what remedial measures might be most suitable, it was necessary first of all to represent all the system elements of importance in an electrical network at the harmonic frequency. The method will be described as for the fifth harmonic only. The same procedure could, with some modifications, be used for the seventh harmonic.

Equivalent Circuit of the Transformers

Two modifications of the equivalent circuit are shown in figure 7. In each, the transformer magntizing branch is the source of harmonics.

Figure 7*b* shows the "constant current generator" type of equivalent circuit in which the transformer is assumed to supply a fixed value of harmonic current depending on the flux density at which the transformer is operating. The amount of harmonic current supplied to the system by any given transformer is determined from its exciting current and flux density and the use of a harmonic analysis curve,[7] which shows what proportion of the total exciting current is fifth harmonic. In the absence of data on the specific transformers, the fifth harmonic current from figure 8 may be used. This is expressed as a percentage of the exciting current of the transformer at rated voltage and is based on usual flux densities. This type of equivalent circuit can be used on a network calculator by setting up a voltage source and impedance for the magnetizing branch and adjusting one or the other until the desired current is obtained.

It has been shown,[3] however, that the harmonic current is not a constant for a given density. The curves of figure 9*a* show the effect of introducing reactance in series with the transformer while maintaining the average of applied voltage constant, at the transformer terminals, or while maintaining the fundamental frequency component of exciting current constant.

Figure 9*b* shows the reduction of fifth harmonic current as reactors are introduced, causing an increase in the terminal fifth harmonic voltage. This curve may be used as a criterion for determining whether the "constant current generator" type of equivalent circuit can be used. The curves show that a system harmonic voltage of 5% will cause the current to fall off 15 to 20%. Conversely, it will rise 15 to 20% if the system is capacitive at this frequency. Since in case of harmonic trouble the voltage is likely to be higher than 5%, it appears preferable to use the more exact circuit. In the case described previously, fifth harmonic voltages as high as 12% were encountered on the main system.

The "internal voltage and impedance" type of equivalent circuit is shown in figure 7*c*, the magnitudes of internal voltage and reactance being given in figure 8. The current value plotted corresponds to the condition of no external reactance (equivalent circuit short circuited) and is the upper envelope of test points on a number of transformers in the laboratory and in the field. These constants are dependent solely on the iron. The voltages are expressed in per cent of the normal fundamental frequency voltage corresponding to 100% flux density. The reactances are expressed in per cent on the rated voltage excitation kva base. For example, a 3,000 kva 33,000 volt transformer bank having 4% exciting current, has a rated voltage excitation kva of 120 kva. The equivalent circuit for fifth harmonic has, at normal density an internal voltage of 27% of $33{,}000/\sqrt{3}$ or 5,150 volts, line-to-neutral. The internal reactance is 150% on 120 kva or 13,500 ohms.

$$\text{ohms} = \frac{10\times\%\times\text{kv}^2}{\text{kva}} = \frac{10\times150\times\overline{33}^2}{120} = 13{,}500\text{ ohms}\Big)$$

The transformer rated exciting current is $0.04\times\frac{3{,}000}{33\sqrt{3}} = 2.1$ amps. It will be noted

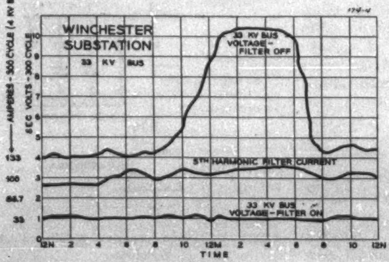

Figure 4 (left). Fifth harmonic voltage and current at Winchester

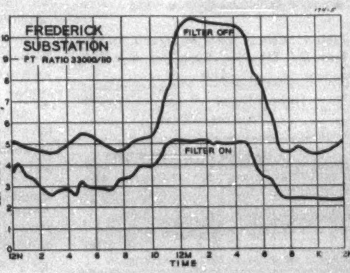

Figure 5 (right). Fifth harmonic voltage at Frederick

(A remote point on the system)

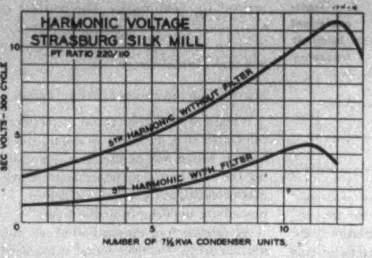

Figure 6. Harmonic voltage at Strasburg Silk Mill

that for zero system impedance the fifth harmonic current is 18% of 2.1=0.38 amp. Or it may be obtained as 5,150 volts÷13,500 ohms=0.38 amp.

At 110% of normal voltage the internal voltage becomes 37% or 7,100 volts, line-to-neutral and the reactance 70% on 120 kva or 6,300 ohms.

Equivalent Circuit by Test

The values of constants for the equivalent circuit, may be determined from test on a sample transformer using the same kind of iron, or may be calculated from saturation curves of the iron.

The circuit for the test method is shown in figure 9. A variable voltage source operating at rated frequency is required together with variable reactance between the source and the transformer under test. By varying the reactance in series with the transformer the internal reactance at a particular frequency can be calculated as the quotient of increase in terminal voltage divided by decrease in current of that frequency. The internal voltage can then be obtained as the terminal voltage plus the drop through the internal reactance just calculated, or may be read as the intercept with the voltage axis of the test curves of figure 9*b*. The reactance is the quotient of voltage and current intercepts.

The flux density should be maintained constant (rather than rms voltage) as the series reactance is varied. This is for the reason that radically different exciting currents may be obtained with the same rms voltage of different wave forms. For the same flux density the crest exciting current is the same, and also it can be shown that the average voltage is the same. Instruments are therefore required to hold crest exciting current or average voltage constant in these tests. The former is preferred because of the rapid variation of exciting current with flux density.

Harmonics Not Independent

Seventh harmonic test points have been plotted also in figure 9*b* and for the higher voltage the function is seen to be double valued. The reduction in seventh harmonic current is obviously not due alone to the increase in terminal harmonic voltage, since it continues to decrease even as the seventh harmonic voltage decreases, but as the fifth harmonic voltage is building up. This illustrates the somewhat expected fact, that the harmonics are not entirely independent as assumed in using the equivalent circuit. For this reason all of the tests were made in a three-phase circuit with the transformer having one delta connected winding, thereby providing a local path for triple harmonics and more closely simulating actual operating conditions.

Analysis From D-C Saturation Curves

The equivalent circuit may also be obtained direct from the saturation curve by analyzing, *first*, the exciting current wave resulting from pure sine wave flux; *second*, the voltage wave resulting from the flux wave which results from pure sine wave exciting current. Obviously, then, irons having the same saturation curves will have identical circuits at harmonic frequencies. Table I shows the harmonic current analysis from the saturation curves of five different irons employed in transformers now or in the past. The conclusion is drawn that for silicon steel the equivalent circuits do not vary widely so that the circuit developed from a sample transformer may be applied quite generally on a system.

Loads

For the fifth harmonic impedance of typical substation loads composed of a mixture of lighting and motor load, analytical estimates were based on 100 kva of load composed of 70 kva of lighting and other static load at a pf. of 95% and 30 kva of motor load consisting of 60 kva of induction motors running at 50% of full load. This combination reduced to its fifth harmonic impedance becomes $(9.3+j66.7)\%$ at 300 cycles on the load kva base. A limited number of field tests have been made the results being recorded in table II. The night time readings are in fair agreement with the theoretical value used in the studies. Caution must be used in the use of average load figures for individual resonance cases. For overall system studies of a network at 33 kv or higher, the resulting harmonic voltages are determined by the average of a large number of loads, and the average values of load impedance may be more safely used.

Generators

The D. and R. subcommittee[6] of EEI and Bell systems have conducted tests on a large number of generators showing their harmonic impedance, referred to fundamental frequency to be approximately 80% of the negative sequence reactance. This report also gives methods

LINES AND TRANSFORMERS

The methods of determining line and transformer impedances at various frequencies are well known.[5]

NETWORK CALCULATOR STUDIES

Using the methods outlined above, the Potomac Edison System was represented on the a-c network calculator on a fifth harmonic basis.

The "constant current generator" type of equivalent circuit was first used. Although it indicated correctly some of the trends as system changes were made, it proved unsuitable for quantitative results because large system harmonic voltages were developed in the conditions studied. This type of representation is quite inaccurate in such cases. Also, this method was very tedious since trial and error was required in adjusting all the transformer equivalent circuits to the desired current, in phase and magnitude.

The system was later set up using the "internal voltage and impedance" type of equivalent circuit for the transformers. Four conditions were studied corresponding to the light load condition which was taken as a uniform 35%* load on the system. These conditions were:

1. System normal.
2. All capacitors removed except natural capacitance of lines.
3. Normal except 2,160 kva capacitor added at Winchester.
4. Normal except 4,080 kva of capacitors added at three stations.

The results are indicated graphically in figure 10. Some field tests are also plotted on this curve. The light load reading was a single reading and could have been somewhat higher. The network calculator curve was based on all transformers operating at 10% overvoltage except those at generating stations or connected to the 66 kv line. This is somewhat more severe than the actual night-time condition. Since harmonics more than double with a 10% increase in voltage, these two factors appeared to account for the difference between test and calculation. On this basis, the actual characteristic was expected to be a curve as indicated dotted. It is similar in shape to the calculated curve since the shape is determined largely by the system constants.

It had been known previously, from theoretical considerations, that it would be possible for the capacitive paths for exciting current to resonate with inductive paths and result in an increase of harmonic voltage. This study showed quite conclusively that the system was operating in this region, and also provided the valuable information that the addition of an entirely practicable amount of capacity would take the system well "over the hump" and make it immune to further difficulty from fifth harmonic due to further increases in the amount of connected capacity.

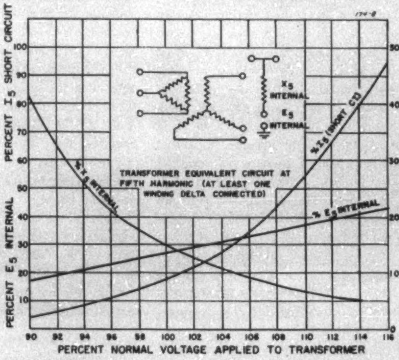

Figure 8. Values of voltage and reactance of equivalent circuit

Based on a normal density of 13,500 gausses

The idea was then conceived of tuning the capacitor to fifth harmonic by means of a reactor in series, and thereby still further lowering the harmonic voltage, a feature which was particularly desirable at neighboring stations where harmonic difficulties were being encountered. The calculating board study showed that the harmonic currents in the capacitor would not be excessive under this condition, a conclusion which has subsequently been verified by field tests. The method of analyzing the effect of the tuned capacitor is given under the heading "Method of Self and Mutual Drops".

METHOD OF SELF AND MUTUAL DROPS

When a system is set up on the network calculator it is desirable to obtain information which will be useful in determining the fifth harmonic performance under other conditions than those which are of immediate importance at the time.

An extension of the method of self and mutual drops[2] has been found convenient for this purpose. In this case the self and mutual drops Z_{11}, Z_{12}, etc. are defined as follows:

Z_{11} is the drop in voltage at point 1 per unit of current drawn from the network at point 1.

Z_{12} is the drop in voltage at point 2 per unit of current drawn from the network at point 1.

For the Potomac Edison network, for example, eight principal load points need to be considered. Nine sets of voltage readings are required. First, the voltages E_1', to E_8' at the 8 load points must be read as a basis for determining drops. Then with load terminal, 1, short circuited the current, I_1, and voltages at the other 7 points E_{12}, E_{13} to E_{17} are read. This is repeated in turn until all 8 points have been short circuited, one at a time. The drops are then computed

$$\left.\begin{aligned} Z_{11} &= \frac{E_1'-E_{11}}{I_1};\ Z_{12}=\frac{E_2'-E_{12}}{I_1};\ \text{etc.} \\ Z_{21} &= \frac{E_1'-E_{21}}{I_2};\ Z_{22}=\frac{E_2'-E_{22}}{I_2};\ \text{etc.} \end{aligned}\right\} \quad (1)$$

As a check

$$Z_{21}=Z_{12},\ \text{etc.} \quad (2)$$

Table III shows the resulting self and

---

* 35% of single step-down transformer capacity.

mutual drops for the Potomac Edison System. It also shows the open circuit voltages E_1' and E_6' for the 35% load condition.

As an example of the use of this method, let the effect of connection of various values of impedance at load point, 6 (Winchester), be determined. In particular what are:

(*a*). The fifth harmonic current and voltage at point 6 (Winchester), and

(*b*). The fifth harmonic voltage at point 1 (Union Bridge), a typical remote point on the system. Union Bridge is near Frederick for which tests of figure 5 apply.

Figure 11 shows the current and voltage at Winchester and voltage at Union Bridge obtained from the following relations:

$$I_6' = \frac{E_6'}{Z_{66}+Z_6} \qquad (3)$$

$$E_6'' = E_6' - I_6'Z_{66} \qquad (4)$$

$$E_1'' = E_1' - I_6'Z_{61} \qquad (5)$$

Z_6 is the reactance X, figure 11.

The following information is directly forthcoming from these curves.

(1). The fifth harmonic current drawn by the capacitor will be less if it is tuned to this frequency than if no reactor is used.

(2). The harmonic current will be within the rating of the capacitor, whether tuned by the reactor or not, provided the entire bank is in service. With only half of the bank in service with one or two transformers a dangerous current may flow, and high harmonic voltages occur.

The voltage reduction at Union Bridge (near Frederick) was verified by later field tests. See figure 5.

Field Tests

Transformers were determined to be the principle source of the fifth harmonic by the following considerations and field tests.

1. There were no large power rectifiers on the system.

2. The generator open circuit harmonic voltages were measured by a harmonic analyzer and the fifth and seventh harmonics found to be very low.

3. A large section of system was supplied over a single transmission line supplied from a single transformer and the transformer taps increased over a 10% range thereby over-exciting all the transformers on the supplied system by 10%. It was found that the fifth harmonic voltages throughout the system approximately doubled for the 10% increase in voltage, measurements being made at various points both during the increase and decrease of taps. Since the exciting currents of transformers are known to approximately double for 10% increase in voltage this gives rather pronounced evidence that fifth harmonic voltages were associated with the exciting currents.

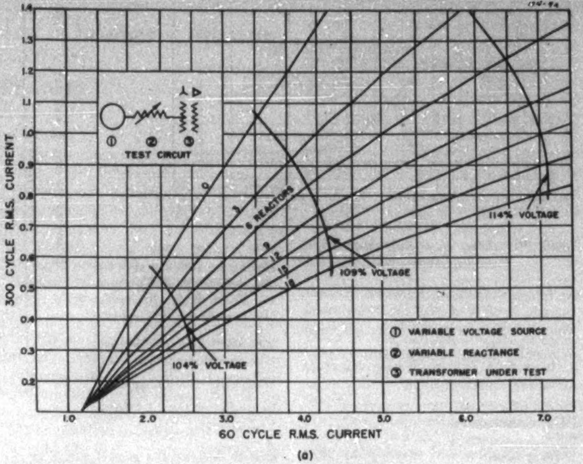

Figure 9a (above). Variation of fifth harmonic current with reactance in series with transformer

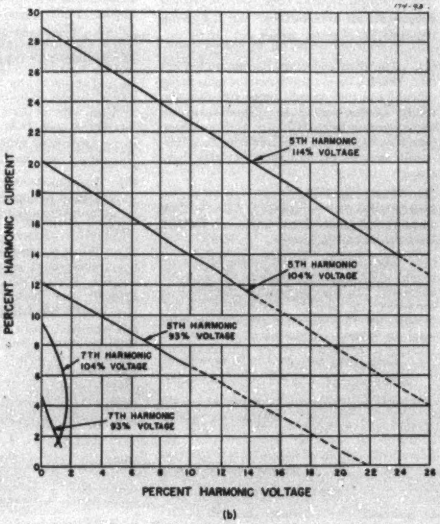

Figure 9b. Reduction of fifth harmonic current with increase in fifth harmonic terminal voltage as reactance in series with the transformer is increased

After the installation had been made further field tests were run to determine the effect on harmonics.

These tests were made at various points on the system and showed that the harmonic voltage was greatly reduced when the Winchester filter was in service. Figures 4 and 5 are the results of these tests. A test was also made at one point of local resonance (Strasburg Silk Mill, figure 6) and it was found that such conditions were also considerably reduced. Harmonic current tests were made on all capacitor banks which had been in trouble and it was found that they were now operating with a safe margin.

Figure 4 shows the current in the capacitor at Winchester over a period of time, including probably the most severe that will be encountered. The maximum

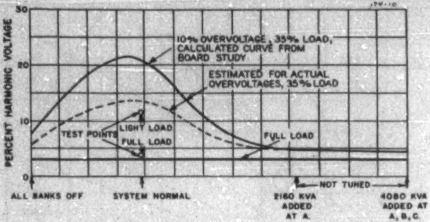

Figure 10. Effect of adding capacitors to Potomac Edison System

current is 40% of the capacitor rating which compares with the estimated value of 47 per cent.

Other field tests have been described previously in the paper.

Union Bridge (near Frederick) 13.2 per cent

IV. Conclusions

As a result of this investigation and the subsequent field tests on the tuned capacitor at Winchester, the following conclusions may be drawn:

(1). The fifth and seventh harmonics are due largely to a transformer magnetizing current and may be predetermined for particular system conditions. On this system there were no large six-phase or three-phase rectifiers connected which might be additional sources of fifth and seventh harmonics.

(2). The installation of a large capacitor tuned to the fifth harmonic is a practicable measure for reducing the harmonic voltage level throughout a system.

(3). The capacitor tuned to the fifth harmonic will be net inductive at the seventh harmonic. In the case studied this lowered somewhat the seventh harmonic voltages. In general, the effect on other harmonics than the fifth would not be large.

(4). The analytical methods developed for study of the harmonic problem adequately describe the general nature of the phenomena and give results suitable for making applications and predicting the resulting effects throughout the system. These methods are not limited to the study of this particular type of remedial measure.

(5). Tuning to the fifth harmonic is feasible whenever the capacitor bank represents at least 1% of the total connected transformer capacity. It may also be feasible for considerably smaller amounts, but in this range each case should be studied.

(6). Harmonic voltage reductions as much as 50% may be obtained at parts of the system remote from the tuned capacitor installation.

(7). When a tuned capacitor makes use of the transformers as part of the series reactance, voltage rise at the harmonic frequency may occur at the transformer low-tension bus, depending on what proportion the transformer reactance is of the total reactance. In this instance, the proportions were such that the harmonic voltage on the 4 kv bus was lower during the night with the capacitor in service than out of service; however, the possibility of harmonic voltage increase should be borne in mind in considering other applications.

A Thyratron Circuit for Theater Lighting

CARL R. WISCHMEYER
ASSOCIATE AIEE

AT present there is a definite need in small theaters, such as those in colleges and universities, for a flexible, highly advanced system of stage lighting control. During recent years such systems capable of supplying the relatively tremendous loads of the large muscial comedy houses—up to about 25 kilowatts individual circuit capacity—have been developed. However, little attention has been paid to the needs of the small legitimate theater, which requires just as much flexibility of light control and perhaps almost as many circuits, but of much smaller individual capacity—perhaps a kilowatt or two maximum. It is with circuits appropriated for this use that the present paper deals. Experimental circuits employing thyratrons as power rectifiers, supplying uni-directional current directly to a lamp load, were developed as part of the investigation and proved satisfactory.

The fundamental problem in stage lighting is that of supplying voltages of proper magnitude to appropriate lamp circuits in the required sequence. Although it may be difficult to decide which single feature is most desirable in a satisfactory theater lighting control system, a number of characteristics are agreed to be essential, and their comprehension lies in a brief analysis of a few typical examples of the operator's task.

As action on the stage progresses, it becomes necessary to increase the voltage on some circuits, possibly by a different amount on each circuit, to reduce that on some, and to allow that on others to remain constant. Presumably the controls of those circuits requiring changes in the same sense, for example those requiring an increase in voltage, may with more or less difficulty, be ganged mechanically. A moment later the voltages applied to all circuits in use may require other changes, both voltage increases and decreases of various magnitudes, irrespective of either the sense or magnitude of the preceding change. Hence, any grouping of circuits on the basis of changes required at any particular moment must suffer continual revision. With mechanical ganging this is not practicable if the changes are to occur in rapid succession.

The most satisfactory solution to date is embodied in the "preset" type of control, in which predetermined values of lamp voltages for a large number of circuits are selected in sequence. Let us suppose that a given circuit must operate at four different voltages in four successive scenes. The circuit is equipped with as many control handles, called "presets." With some sort of selector in position number one, the setting of preset control handle number one determines the lamp voltage for that circuit; the others may be manipulated without effect. Shifting the selector to position number two transfers control of the lamp circuit to preset control handle number two, effecting a gradual change in voltage from the first to the second of the four values as the setting of the selector is changed. By virtue of its function the selector has been given the name "fader." A large number of lamp circuits equipped with presets are operated from a common fader, thereby allowing simultaneous control of changes in voltage in all these circuits. With such a scheme it is possible to reduce the voltage on some lamp circuits while increasing that on others, since the change in voltage on any one circuit during transition depends only upon the setting of the two successive presets. Circuits to be operated at the same voltage in two successive scenes will have presets for those scenes set at the same value. In actual practice the length of time during which a transition from one set of lighting effects to the next occurs depends only upon how rapidly the operator manipulates the fader.

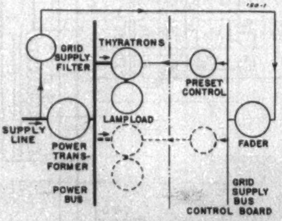

Figure 1. Block diagram showing component employed

From the foregoing, certain characteristics appear to be essential:

(1). A method of presetting in which the requirements of future scenes may be anticipated and the appropriate presets adjusted ahead of time, allowing selection of future lighting effects in rapid sequence if required and with no restriction either as to sense or magnitude of lamp voltage changes required.

(2). Completely centralized control vested in a single operator. (If required, a helper may be employed to adjust presets which are to be used later.)

(3). Transitions between predetermined sets of lighting effects which are smooth and simultaneous in all lamp circuits so controlled.

(4). Constancy during transition from one scene to the next of lamp voltages set for the same value in succeeding scenes.

To those already listed may be added the following requirements:

(5). Location of the control board in the orchestra pit in order that the operator may observe the effects produced. (This requirement places limitations upon the physical dimensions of the board and implies that any associated equipment be placed in some suitable remote location. Furthermore, operation must be noiseless.)

(6). Ease of combination of preset type of control with independent control of individual circuits and with control of a group of such circuits by "masters" where proportionate dimming of the group is required.

(7). Instantaneous response of the lamp voltage to control.

(8). Good voltage regulation for any load within the rated capacity of the circuits and at any voltage setting.

(9). High over-all efficiency.

(10). General simplicity, contributing to dependability of operation and ease of installation and servicing.

The circuit to be described offers all of these desirable features, thereby representing an advancement of the art in at least one important respect. Since its basis is the use of thyratrons as power rectifiers supplying uni-directional current directly to a lamp load, the mathematical analysis of its operation reduces to that of a single-phase full-wave rectifier supplying a non-inductive load.

Paper 41-50, recommended by the AIEE joint subcommittee on electronics, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 28, 1940; made available for preprinting December 12, 1940.

Carl R. Wischmeyer is instructor in electrical engineering at the Rice Institute, Houston, Texas. The investigation reported herein was begun while the author was a graduate student in the department of electrical engineering, Dunham Laboratory, Yale University, New Haven, Conn.

The author is indebted to B. R. Teare, formerly of the department of electrical engineering, Yale University, and now of Carnegie Institute of Technology, for his helpful suggestions and encouragement; to H. M. Turner of the department of electrical engineering, Yale University, for his constructive criticisms, to S. R. McCandless of the department of drama, Yale University, for his help in formulating the problem and in criticizing the performance of experimental circuits, and to Eugene Braun and Andrew Herzog of the Radio City Music Hall for their kind cooperation.

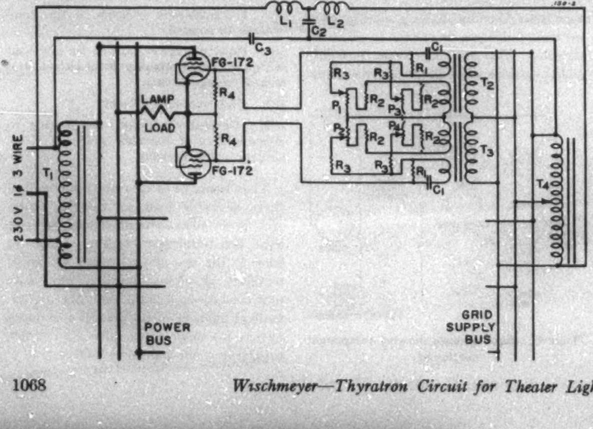
Basic Circuit

The diagram of figure 1 indicates the units required and their functions. The heavy lines represent load power connections and the light lines those of control power. Thyratrons controlled by an alternating grid voltage of variable phase are used in pairs to provide full-wave rectification.

Limitations as to size and power dissipation in control circuit parts seemed to indicate the use of thyratrons,[1,2,3] which inherently permits the control of a large amount of power in the anode circuit by a small amount of grid circuit power, which is independent of load. For any instantaneous value of anode voltage there exists a critical grid potential at which the initiation of arc discharge occurs. When the grid potential is increased from a large negative value to the critical voltage, electrons emitted by the hot cathode acquire sufficient velocity to ionize by collision the mercury vapor within the tube, and the arc is formed. The grid is then unable to stop or modify the discharge, which persists until the anode voltage is decreased below that required to sustain the arc. In the present application the periodic reversals in polarity of the alternating anode voltage continually interrupt the discharge, while the grid controls its restarting, thereby permitting adjustment of the magnitude of anode current.

The effective voltage output of a full-wave rectifier operating from a single-phase three-wire line will be less than the effective line-to-neutral voltage by the tube drop. Hence, the required line-to-line voltage must be slightly greater than twice the desired lamp voltage. Thus, to obtain a lamp voltage of 115 volts from a 230 volt supply it is necessary to provide by means of auto-transformer T_1, figure 2, an additional voltage of approximately 12 volts each side of the neutral. See appendix I for rating of this auto-transformer.

Figure 2. Wiring diagram of one lamp circuit equipped with four-scene preset control



In the interest of simplicity the use of half-wave rectification was considered, but appeared inadvisable because of perceptible flicker with lamps rated at less than about 100 watts.

While the power output of a pair of thyratrons may be increased by increasing the anode voltage, two transformations are necessary, since from practical considerations the lamp voltage must be 115 volts.

Grid-Voltage Phase Control

Grid circuit design comprises two problems: that of producing a control voltage of proper magnitude and phase, and that of incorporating the control elements in a circuit permitting presetting.

Tube characteristics for low anode voltages are shown in figure 3. Figure 4 shows the critical grid potential corresponding to instantaneous values of a sine wave of anode voltage. It should be noted that the angle of lag of grid voltage with respect to anode voltage is not equal to the angle of delay of conduction except at the two points where the critical grid potential curve crosses the axis. Although this difference is small, five degrees or less throughout the entire range of control in the experimental circuits, the analysis to follow is in terms of the angle of lag, account being taken of the increase in the angle of conduction.

Figure 5 shows the variation of effective output voltage with angle of lag for the full-wave grid controlled rectifier. Since at low anode potentials large positive grid voltages are required to produce arc discharge, a range of phase control of grid voltage of approximately 15 to 165 degrees lagging with respect to the anode voltage permits control of lamp voltage from a maximum value to zero. Further it is evident that making the maximum amplitude of the sinusoidal grid voltage large compared to the maximum negative critical grid potential minimizes the effects of changing or slightly dissimilar tube characteristics.

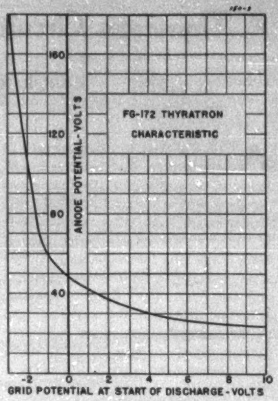


Figure 3. FG-172 thyratron characteristics

Shield grid connected to cathode, ambient air temperature 75 degrees Fahrenheit, heater voltage five volts

A method of obtaining a voltage variable in phase throughout the desired range is indicated in figure 6. The grid voltage E_G is the sum of two components: E_F, the phase and magnitude of which are fixed by the constants of the *R-C* circuit; and E_V, which is in phase with the anode voltage and the magnitude of which is varied by means of the preset potentiometer *P*. The vector diagram of figure 7 shows the phase of the grid voltage for several settings of the preset potentiometer. Although the magnitude of E_G varies with the phase angle, no objectionable effect is encountered provided the minimum peak value is large as compared to the maximum negative critical grid potential.

Presetting

The method of predetermining lamp circuit voltages is based upon the division of the individual preset potentiometers into two groups, energized by a variable

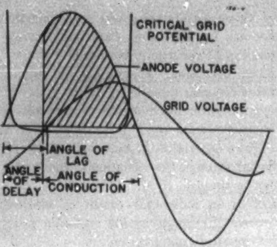

Figure 4. Voltages determining angle of conduction (one tube)

auto-transformer so connected that the sum of the voltages impressed upon the two groups is constant. See figure 8. As the voltage across one group is varied from zero to a maximum that across the other is varied simultaneously from a maximum of equal magnitude to zero, thereby transferring control, or "fading," from a preset potentiometer of one group to one of the other group. Hence, the variable component of grid voltage, E_V, is now the sum of voltages E_{V1} and E_{V2}, shown in the vector diagram, figure 9. The selection of individual preset potentiometers is accomplished by switches, only one potentiometer of a group being in use at a time.

The normal sequence of operation of the four-scene preset control shown is as follows: Suppose preset potentiometers P_1 and P_2 are connected. With the auto-transformer tap at A, figure 8, maximum voltage is applied to P_1 and none to P_2. The magnitude of E_V is then determined by the setting of the tap of P_1, which has been set to give the angle of lag of grid voltage corresponding to the desired lamp voltage in the present scene. The tap of P_2 is set to give the desired lamp voltage for the same circuit in the next scene. When it is desired to make the transition from the first to the second lamp voltage for the circuit, the auto-transformer tap is moved either rapidly or slowly, depending upon the speed with which the transition is to occur, from A to B. Control has now been transferred smoothly to P_2. Preparatory to transferring control or "fading" from P_2 to P_3, P_3 is connected and then P_1 is disconnected. Moving the auto-transformer tap back to its initial position A will then transfer control to P_3. Such a switching sequence is necessary in order not to open the grid circuit, which would result in immediate loss of control of the lamp voltage. The transitions from P_3 to P_4, and from P_4 back to P_1, and so on are made similarly. The capacity for any required number of presettings may be attained simply by providing enough potentiometers. Since only a few milliamperes of grid current are drawn through them, the potentiometers are inexpensive and compact and dissipate little power.

When both P_1 and P_3 are connected while energized, which would result only from a mistake on the part of the operator and which could be prevented by appropriate relays, current in excess of the potentiometer rating tends to flow if the settings of P_1 and P_3 are near opposite ends of the scale. Resistors R_2 and R_3, figure 2, serve to limit this current.

Operating Characteristics

In order to accomplish the subtle blending of the light output of the different lamp circuits, it is essential that all desired intensity changes occur simultaneously and, as a matter of convenience, approximately linearly with auto-transformer fader control, which is possible if the light output of a lamp circuit be made a linear function of the variable component of grid voltage E_V. An analysis of the factors involved shows a satisfactory approximation to be attainable.

The light output for several sizes of lamps is plotted as a function of applied voltage in figure 10, which together with the curve of figure 5, determines light output as a function of the angle of lag of grid voltage, shown in figure 11.

The phase angle of the R-C combination in figure 6 determines the phase of the fixed component of grid voltage E_F, upon which, together with the magnitude of E_F, depends the required range of the variable component of grid voltage E_V to give any resultant grid voltage phase. For the circuits constructed the variation of angle of lag with variable component of grid voltage E_V is shown in figure 12, which together with the curve of figure 11 determines the over-all characteristic of light output versus variable component of grid voltage, figure 13. Between 5 and 90 per cent of rated lumens output the curve approaches a straight line; below 5 per cent the number of lumens output is sufficiently small that the departure from linearity is not objectionable in practice, and above 90 per cent the departure is not noticeable because of the logarithmic response of the human eye.

In order to set the limits between which the light output of a circuit can be operated, means should be provided for adjusting the phase of grid voltage component E_F, which determines the minimum value, and for limiting the maximum value of E_V, which determines the maximum value. The former may be done by adjusting R_1, figure 2, the latter by adjusting the protective resistors R_2. A generally acceptable range of control from 0.03 of one per cent to 99 per cent rated lumen output means limiting control from the equivalent of 28 to 72 per cent E_V, figure 13.

It should be pointed out that dissymmetry of the curve of light output versus variable component of grid voltage E_V about its 50 per cent lumens output point will cause objectionable peaks during transition when the increasing light output from one circuit is added to the decreasing output of another.

As pointed out under essential control characteristics, it is sometimes necessary to maintain constant illumination intensity of one or more lamp circuits while others are varied. The transition from one presetting to another of equal intensity introduces no deviation, because

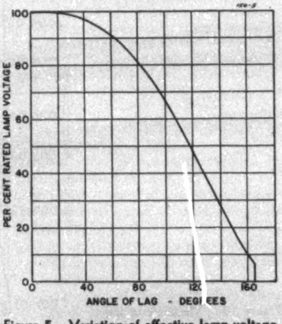

Figure 5. Variation of effective lamp voltage with phase of grid voltage

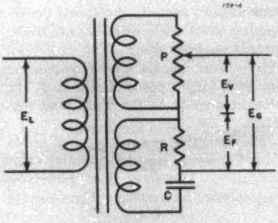

Figure 6. Basic phase-shifting circuit

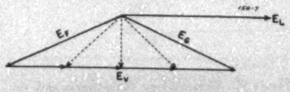

Figure 7. Resultant grid voltage the sum of fixed and variable components

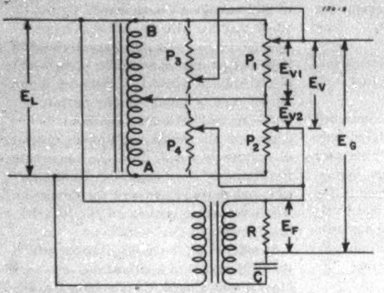

Figure 8. Basic phase-shifting circuit modified to permit presetting

the sum of the voltages applied across the two groups of preset potentiometers is constant. The total light output of two identical lamp circuits initially of illumination intensities *A* and *B* and finally of *B* and *A* respectively remains approximately constant during the transition, as shown in figure 14. The smooth and simultaneous changes in illumination intensity of two lamp circuits for a typical case in which all initial and final intensity settings are different are shown in figure 15.

Comparison With Other Types of Control

At present nearly all small theaters are equipped with the resistance type of dimmer, which has several serious limitations: the lamp voltage for any setting of the dimmer is dependent upon the number and size of the connected lamps; the flexibility with regard to presetting is limited; the size of the control board is necessarily large; and the power dissipated in the resistance dimmers is usually sufficient to produce an objectionably large amount of heat. Replacing the resistance units with variable auto-transformers obviates many of the objectionable features; but the space requirements are still large, power leads must be brought directly to the board, and presetting is limited.

The saturable reactor type of preset control possesses superior operating characteristics. However, since control is accomplished by varying a direct current through an inductive circuit (the d-c winding of the saturable reactor) there is an accompanying time lag, which is definitely objectionable in some instances. Since the reduction in lamp voltage is produced by an impedance drop, some sort of feed-back circuit is required to maintain constant lamp voltage independent of load if calibration of control setting is to be significant.

The preset type of control described in this paper embodies all the characteristics cited as desirable, including rapid response of light output with control, limited only by thermal lag in the lamps. Regulation is approximately that normally encountered with the supply transformers. Tube life of 3,000 hours is guaranteed by the manufacturer, but it is believed that in the present circuit, in which operation is at relatively low anode potentials, considerably better life may be expected. Like the other types of circuits mentioned, the present one may be operated from a three-phase supply. Aside from the division of the circuits into groups for operation from the separate phases, the only change required is the substitution of three auto-transformers mechanically coupled for the fader, each unit having one-third the capacity required for single-phase operation. Essentially the apparatus becomes three independent systems operated from mechanically coupled auto-transformer faders.

Since control of the lamp voltage is effected through the variation of one voltage in the grid circuit, independent control of an individual circuit or master control of several circuits requiring proportionate dimming is easily accomplished in essentially the same way as in resistance dimming, except that with the present thyratron circuit only control voltage need be varied.

When a large load is to be supplied, it is subdivided and connected to pairs of thyratrons the grids of which are operated in parallel for simultaneous control. This method has been found successful and from the user's standpoint is practical, since no individual load unit normally exceeds about one kilowatt.

With a grid controlled rectifier supplying a maximum load of the order of 100 kilowatts, as might be required by a small theater, the problem of telephone interference due to power line harmonics may become serious. For a three-phase installation this would mean a maximum load per phase of 30 to 35 kilowatts. However, a Fourier analysis of line current, the results of which are summarized in appendix II, shows that all higher harmonics present reach maxima for an angle of conduction of approximately 90 degrees, under which conditions a load of 30 or 35 kilowatts per phase at full voltage would be reduced to half. On the basis of the Fourier analysis a telephone influence factor of 1,200 was computed for an angle of conduction of 90 degrees. This

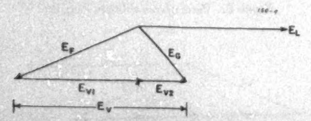

Figure 9. Grid-voltage components and resultant for intermediate setting of auto-transformer tap

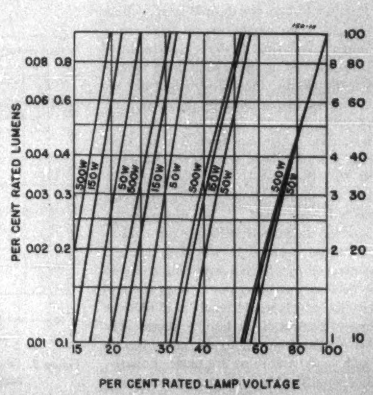

Figure 10. Variation of light output with voltage for several sizes of 115-volt lamps

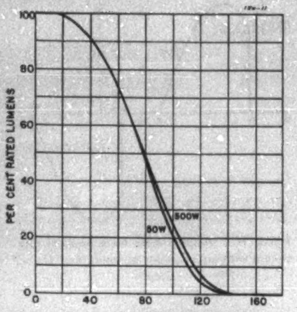

Figure 11. Variation of light output with phase of grid voltage

figure is somewhat high in view of the assumptions upon which the Fourier analysis is based. Furthermore it cannot be taken as representative of actual operation because it implies that all lamp circuits are adjusted to the same voltage. Should the attenuation of line harmonics in a particular installation be necessary, resonant shunts, or a combination of series inductance and shunt capacitance forming a low-pass filter, or series inductance in conjunction with resonant shunt capacitance may be employed.[5]

To prevent distortion of grid voltage wave form by line voltage harmonics a single T-section low-pass filter of cut-off frequency slightly above 60 cycles was interposed between the supply line and the auto-transformer fader. Condenser C_3, figure 2 compensates for the phase shift introduced by the filter.

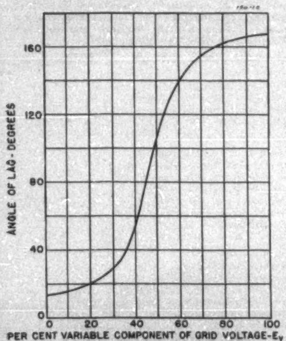

Figure 12. Variation of phase of grid voltage with variable component in experimental circuits

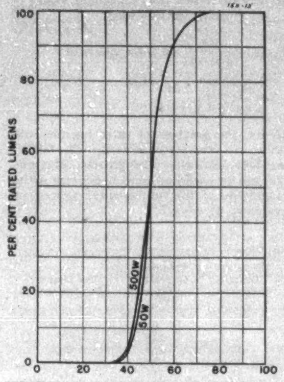

Figure 13. Variation of light output with variable component of grid voltage

At first difficulty was encountered with stray capacitance currents flowing in the grid circuit, the effects of which were minimized by electrostatic shielding of the grid supply and heater transformers, of the grid voltage phase shifting components, and of the grid leads. All transformer and control component shields were connected to the neutral of the supply line and that for each pair of grid leads to the cathodes of its associated pair of tubes. Shielded grid leads 200 feet in length were found to operate satisfactorily.

Appendix I. Anode-Transformer Rating

A transformer with two identical secondaries was connected as an auto-transformer to supply anode power. See T_1, figure 2. The secondaries are, therefore, loaded alternately. If iron losses are assumed constant, a conservative estimate of the permissible rating might be based on that loading which would not exceed in any part of the winding the copper losses in normal use.

Let—

I_p = peak value of primary current in normal use

I_s = peak value of secondary currents in normal use

N_p = number of turns of primary winding

N_s = number of turns of each secondary winding

r_p = copper resistance of primary winding

r_s = copper resistance of each secondary winding

I_p' = peak value of primary current when supplying a full wave rectifier

I_s' = peak value of secondary currents when supplying a full wave rectifier

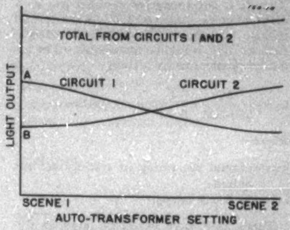

Figure 14. Characteristics of experimental circuits for transition from scene one to scene two

Equating secondary copper losses—

$$\frac{I_s^2}{2} r_s = \left[\frac{I_s'}{2}\right]^2 r_s$$

Equating primary and secondary magnetomotive forces—

$N_p I_p = 2 N_s I_s$ in normal use
$N_p I_p' = N_s I_s'$ in rectifier use

And—

$$I_p' = \frac{\sqrt{2}}{2} I_p = 0.707 I_p$$

Therefore, the rating for rectifier use with assumptions as stated is 70.7% of the normal rating.

If iron losses are assumed constant, an estimate of the permissible rating may be calculated on the basis of the constancy of total copper loss. Such an estimate may not be sufficiently conservative, since the division of losses between primary and secondary windings will be different.

Equating total copper losses—(same notation as before)

$$\frac{I_p^2 r_p}{2} + I_s^2 r_s = \frac{I_p'^2 r_p}{2} + 2\left(\frac{I_s'}{2}\right)^2 r_s$$

Equating primary and total secondary copper losses in normal use—

$$\frac{I_p^2 r_p}{2} = I_s^2 r_s$$

Solution with the magnetomotive force relations given above leads to—

$$I_p' = \sqrt{\frac{2}{3}}\, I_p = 0.817 I_p$$

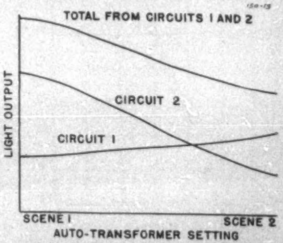

Figure 15. Characteristics of experimental circuits under typical operating conditions

Therefore, the rating for rectifier use with assumptions as stated is 81.7% of the normal rating. A value between those calculated, such as 75%, would be reasonable. The required rated capacity is then—

$$\text{kva} = \frac{23}{230+23} \times \frac{1}{0.75}\ \text{kw} = 0.126\ \text{kw}$$

where—

kva = normal use rating of transformer required

kw = d-c power output

Tubes used were FG-172's rated at 6.4 amperes average anode current, which in the present application means a peak tube current of 20 amperes and hence an effective load current of 14 amperes from two tubes. At 115 volts the individual circuit capacity is 1.6 kilowatts maximum, requiring an anode transformer capacity of 0.2 kilovolt-ampere per circuit.

Appendix II. Fourier Analysis of Line Current

Neglecting the effect of exciting current for transformers, inductance in the supply, change of lamp resistance with current, and arc drop, line current may be represented as follows:

$$\left.\begin{array}{ll} 0<\theta<\alpha, & f(\theta)=0 \\ \alpha<\theta<\pi, & f(\theta)=A\sin\theta \\ \pi<\theta<\pi+\alpha, & f(\theta)=0 \\ \pi+\alpha<\theta<2\pi, & f(\theta)=A\sin\theta \end{array}\right\}\text{See figure 16}$$

The wave contains no even harmonics and no uni-directional component. A general expression for the coefficient of the nth term is given by the following:

$$C_n = \frac{A\sqrt{2}}{\pi(1-n^2)}\left[(3+n^2)+(1-n^2)\cos 2\alpha - 2(1-n)\cos(1+n)\alpha - 2(1+n)\cos(1-n)\alpha\right]^{1/2}$$

where n is the order of the harmonic.

For the first term—

$$C_1 = \frac{A}{\pi}\left[(\pi-\alpha)^2+(\pi-\alpha)\sin 2\alpha - {}^1/_2\times \cos 2\alpha + {}^1/_2\right]^{1/2}$$

It may be shown that maximum values of C_n are given by the following:

$$C_{n\,\max.} = \frac{2A}{\pi(n-1)}\sin\alpha \text{ for values of}$$

$$\alpha = \frac{2\pi}{n+1}, \frac{4\pi}{n+1}, \frac{6\pi}{n+1} \ldots$$

Hence, the greatest of these maxima will occur in the vicinity of $\alpha=\pi/2$. The following table expresses the greatest of these maxima for each harmonic in per cent of the magnitude of the fundamental component evaluated at $\alpha=\pi/2$.

Order of Term n	Frequency Cycles Per Second	Per Cent of Fundamental
1	60	100.0
3	180	53.7
5	300	23.2
7	420	17.9
9	540	12.8
11	660	10.7
13	780	8.7
15	900	7.7
25	1,500	4.5
35	2,100	3.2
45	2,700	2.4
55	3,300	2.0
65	3,900	1.7
75	4,500	1.5

Introduction

A REVIEW of the literature has revealed very little information regarding the effects of small 60-cycle electric currents on man. These currents are not sufficient to produce unconsciousness or death but they are sufficient to produce involuntary muscular contractions. The hazard to the public has been increased because of the recent development and application of electrical devices with exposed electrodes, such as the electric fence, the electric fly panel, the electric insect trap, the electric cattle prod, and the a-c welding apparatus. The fatal accidents that have occurred due to these devices have emphasized the importance of obtaining additional knowledge on electric shock. This report is based on experiments just completed on 120 men. A preliminary investigation had been made during 1936–37 on 56 men.[1] Some of the data collected then have been included in the body of this paper, but not in the statistical analysis. It is hoped that the results may help to improve the design and safety of some of the new electrical devices and may be useful in clarifying the widespread misunderstanding of electric shock.

Before presenting the experimental results, a review of the effects of 60-cycle alternating current on man may be instructive. If the electrodes are held in the hands, the threshold of perception is about one milliampere. As the current is gradually increased, the sensation of tingling in the fingers, hands, and wrists is intensified. At the same time the muscles of the fingers and hands, and later also of the arms, tighten involuntarily. At the higher currents (six to eight milliamperes and above) the discomfort from severe muscle contraction is more evident than the sensation of tingling, and may even be painful. For currents of this magnitude the individual may still be able to release his grip of the electrode by a determined muscular effort. As the current increases, the involvement reaches the shoulder girdle and extends to the external muscles of the chest so that respiration becomes somewhat difficult. The higher currents cause a sensation of mental discomfort which may even amount to a nameless fear, although the individual knows that at any indication from him, such as a nod or a cry, the current would be shut off. Figure 12*a* is a picture of one of the subjects at his 60-cycle limit. Figure 12*b* illustrates the reactions at two milliamperes greater current. Figure 12*c* is a photograph of another subject and illustrates the muscular reactions and test procedure used in determining the let-go currents. The subjects were unaware that the pictures were about to be taken and the sittings were not posed.

This investigation was not concerned with currents that produce unconsciousness, accompanied by cessation of either respiratory or heart action, or of both. However, the higher values of the currents investigated, which produce nothing more than severe involuntary muscle contraction, can result in death. The cause of death is not definitely known, but is ascribed to exhaustion with respiratory failure and resultant asphyxia.

Problem

Because of the increasing prevalence of electrical devices with exposed electrodes and the likelihood that individuals may come in contact with them, it was considered desirable to investigate the effects of currents at different frequencies on voluntary muscular control. It is generally conceded that current and not voltage is the proper criterion of shock intensity. This fact was verified by an experiment in which subjects received open-circuit voltages varying from 5 to 9,720 volts. The muscular reactions and sensations, although varying to some degree, were substantially in agreement. Several factors must be considered in deciding what constitutes a maximum safe current. The victim of an accidental shock [illegible] often release himself by using muscles little affected by the current. The[illegible] muscular reactions may tend to break the circuit rather than to improve it, or loss of balance may free the victim. However, it is doubtful if any of these methods would be of avail when contact is established by gripping an electrified wire so that the path of the current extends across the body to the other arm or to the legs. Under these circumstances it is concluded that the safe electric current for man is that value which can be

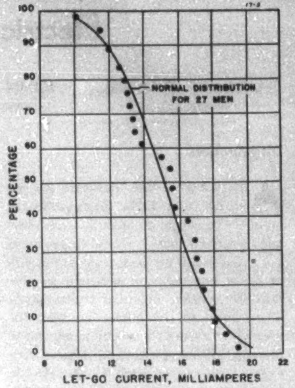

Figure 3. 25-cycle let-go current distribution curve

released by using muscles directly affected by the current. We have called the highest current at which an electrode can be released by muscular control the "let-go current." The let-go current was determined for frequencies ranging from 5 to 10,000 cycles on a group of 120 individuals. Direct current was also investigated.

Method

The subjects who volunteered for the tests were given physical examinations of the circulatory and respiratory systems. Electrocardiograms were also taken. Only those who were in good physical condition, who had not had recent illness, and who had normal blood pressures and electrocardiograms, were admitted. The age of most of the subjects ranged from 21 to 25, with about 15 between the ages of 26 and 46.

Preliminary tests indicated that it was immaterial whether the other hand or the feet were placed on the indifferent electrode. For convenience, the left hand was used in right-handed persons, and the right hand in left-handed persons. Furthermore, they showed that current values were unaffected by the surface condition of the test hand; that is, they remained the same whether the hand was dry, whether it was moist from perspiration, or whether it was wet with salt (sodium chloride) or weak acid solutions. In all tests included in the statistical analysis the hands were moistened with a weak salt solution. This was done in order to secure uniform conditions, to lower contact resistance, and particularly to lessen unpleasant sensations due to high-current densities at localized spots.

The general procedure was as follows: After the subject had placed his hands on two large brass electrodes, the current was turned on gradually. This permitted him to become accustomed to the particular sensations of the frequency used. Then the subject firmly grasped the test electrode, which consisted of a 12-inch length of number 6 copper wire connected to the circuit by a flexible lead. His other hand remained on the indifferent electrode, a brass plate eight inches in diameter. This permitted him to break the circuit should he so desire, even though it was necessary for an observer to hold this hand flat to prevent it from curling due to the muscular contraction.

When the subject was ready, the current was raised at moderate speed to a certain value, at which point the subject was commanded to drop the electrode. If he succeeded, the current values were increased by steps until he was no longer able to let go of the wire; if he failed, the test was repeated at a lower value. The end point was checked by several trials insufficient in number to fatigue the individual but enough to determine the let-go value accurately. In order to minimize the effects of fatigue, the number of tests at different frequencies on any one subject were limited to two or three per day.

Let-Go Currents

The tabulated data show the actual currents and the voltage across the body,

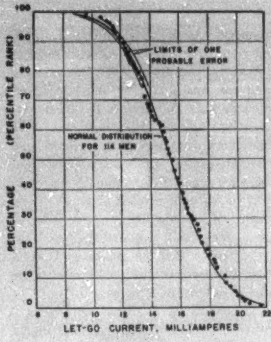

Figure 4a. 60-cycle let-go current distribution curve

corrections having been made for the instruments in the circuit. The 60-cycle let-go currents were determined using the commercial 60-cycle source regulated with a variac. The results are given in figure 4 and table I. Let-go currents for 114 men were: minimum, 9.7; mean 15.5; maximum, 21.6 milliamperes (rms). As previously stated, these results were obtained on the right hand in right-handed persons and on the left hand in left-handed persons. The values averaged about one-half milliampere less in the few cases in which the other hand was tested. Since voltages were considered relatively unimportant, only random measurements were taken in order to expedite the experimental procedure. The range observed was from 20 to 75 volts. The body resistance varied from 1,570 to 4,430 ohms. As the salt solution on the hands dried, the voltage and the resistance increased, although the let-go current remained approximately the same. This confirms the conclusion that current and not voltage is the proper criterion of shock intensity.

All values in table I are the results of the first 60-cycle test, although some subjects were tested first on other frequencies. It may be of passing interest to mention that a let-go current of 13.2 milliamperes was obtained for the one woman (subject 115) who took the test. A few of the subjects refused to take more than about five milliamperes, hence they were not included in the series. The preliminary results previously published gave the average let-go current for 42 men as 12.6 milliamperes.[1] The higher value obtained in the present series is believed to be due to improved technique.

The curve of normal distribution derived from these results approaches the 0 and 100 percentiles asymptotically, as shown in figure 4. Therefore an arbitrary choice of limits was required and the 99.5 percentile was chosen to permit a conservative conclusion. Statistical methods were then applied to examine the reliability of the results. The probable error of the mean was found to be 0.166 milliampere. The probable error of the 99.5 and 0.5 percentiles was found to be

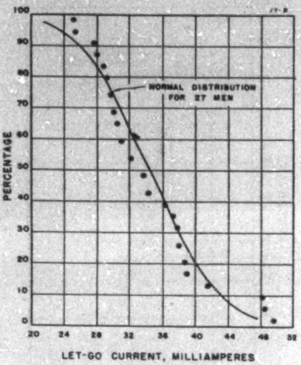

Figure 8. 2,500-cycle let-go current distribution curve

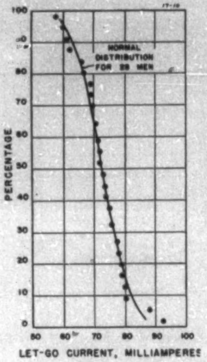

Figure 10. 10,000-cycle let-go current distribution curve

0.80 milliampere. Thus, if it is assumed that the 114 subjects represent an accurate sample of all normal men of the same age range, the following applies: If 1,000 men had been tested, 0.5 per cent or 5 men would have been able to let go of currents as high or higher than 22.3±0.8 milliamperes. Similarly, 99.5 per cent or 995 men would have been able to let go of 8.8±0.8 milliamperes or more, while five men would not have been able to let go of that value. Less conservative values may be taken directly from the curve of figure 4. For example, 97.5 per cent of all men should be able to let go of 10.4±0.3 milliamperes and 2.5 per cent, or 1 man in 40, would not. On basis of these data, the authors are of the opinion that eight to nine milliamperes is a reasonably safe 60-cycle current for normal men to handle. The value may well be less for women and children, and in the interest of safety no definite value should be stated until adequate investigations have been made.

For frequencies less than 60 cycles, two alternators mounted on a common shaft were driven at the proper speeds to generate 5, 10, and 25 cycles. The machines were connected in series and, in order to minimize harmonies in the output, the stator of one was shifted with respect to the stator of the other. The results are given in figures 1 to 3 inclusive. A beat frequency oscillator and a power amplifier were used to produce the higher frequencies Vacuum tube instruments were used for measurements and the let-go currents were determined at various frequencies up to 10,000 cycles. The equipment was adjusted to maintain sine wave shapes for all load conditions and the wave shape was continually observed with a cathode-ray oscillograph. The results are given in figures 5 to 10 inclusive. Statistical predictions for large groups other than on the 60-cycle tests were believed unwarranted because of the limited number of subjects used.

Tests with steady direct current produced a sensation of internal heating of the hands and arms with only slight muscular contraction, though a severe shock was experienced each time the circuit was broken. None of the subjects had any difficulty in releasing the electrode. Many stated that they would almost prefer to maintain contact in spite of the burning sensation, in order to avoid the severe shock that was produced when they released the wire. The values given in table II represent the limit of endurance instead of the let-go value. The prevalent opinion that direct current is safer than 60-cycle alternating current was confirmed. This should be of interest to operators of electrical devices, such as welding equipment, who work in hazardous locations and who may have a choice of power source.

Derived distribution curves of let-go current plotted against frequency are

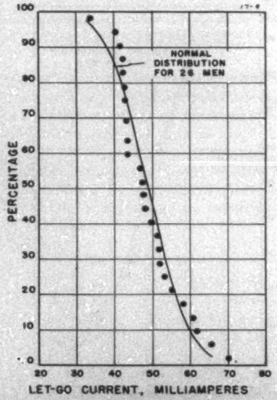

Figure 9. 5,000-cycle let-go current distribution curve

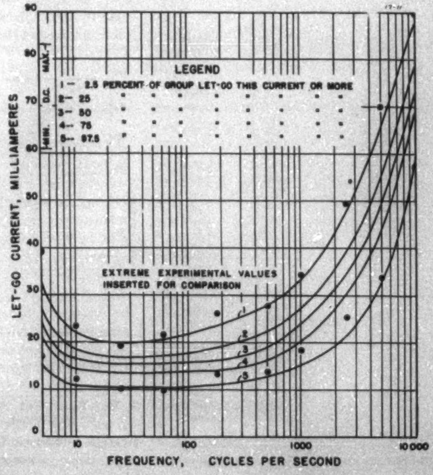

Figure 11. Derived let-go current distribution curves versus frequency

Figure 12a (left). Subject 65—at his 60-cycle let-go current (17.6 milliamperes)

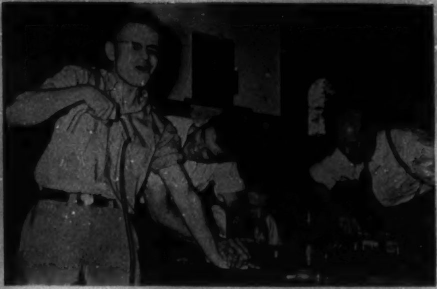

Figure 12b. Subject 65—about two milliamperes in excess of his 60-cycle let-go current

Figure 12c (right). Subject 82—at his 60-cycle let-go current (12.0 milliamperes)

shown in figure 11. The data were obtained from the normal distribution curves shown in figures 1 to 10 inclusive. The extreme points obtained experimentally, as well as values for direct current, have been inserted for comparison. The shape of the curves is not only interesting, but also instructive since it shows the ordinary power frequencies to be the most dangerous.

A summary of the experimental and significant statistical data is given in table III. The current values for 60 cycles agree very well with the values for 50 cycles obtained by Webber[2] and at the Electrical Institute of Zurich.[3] The values are considerably higher than those reported by the Underwriters' Laboratories.[4]

Effect of Electrode Size

Electrodes consisting of the number 6 copper wire and brass rods approximately one-half, three-fourths, and one inch in diameter were investigated by determining the let-go current at 60 cycles. Although variations occurred in individuals, the averages for the group were practically identical. The experimental results with the number 6 wire and the one-inch rod are given in table IV. It was concluded that the let-go current was independent of the size of the conductors used.

Effect of Repeated Trials

An attempt was made to determine the degree to which a person could develop an immunity to electric shock. It was felt that a definite psychological factor was involved which might be overcome by repeated tests at intervals on the same frequency. Naturally the well-being and strength of an individual varies from time to time, depending on sleep, diet, anxiety, etc. These physiological factors could not be controlled. The let-go current test at 60 cycles was conducted at weekly intervals on ten subjects. The data are plotted in figure 13. The results are too much at variance to permit any conclusions although the trend was upward.

Table III. Statistical Data and Measures of Validity

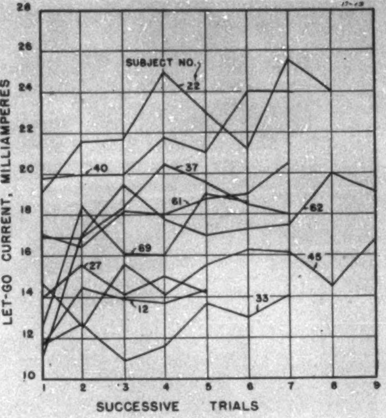

Figure 13. Effect of repeated trials on let-go for 60-cycle current

They demonstrate that variations due to psychological and physiological factors are important in an investigation of this type. These factors cause a distribution of results due to chance that require statistical methods for correct evaluation.

Effects of Wave Form

It was thought desirable to investigate the effect of wave form on let-go currents. In all tests the wave form was observed with a cathode-ray oscillograph, and the equipment was adjusted to maintain sine waves. A bank of three transformers, connected wye on the primary and broken-delta on the secondary, were energized from the 60-cycle commercial source through a three-phase phase-shifting transformer. The third harmonic obtained from the broken-delta was amplified and superimposed on the 60-cycle source to give the wave shapes of figure 14. The combined output was controlled with a potentiometer and metered by means of an iron vane milliammeter and a vacuum tube voltmeter connected to a shunt and calibrated to read peak milliamperes. To obtain comparative results, tests were taken of the three wave shapes on the same afternoon. The sequence of the wave shapes was taken at random in order to minimize the effects due to fatigue. The wire test electrode was used in these tests. The results are given in table V. Inspection of the averages indicates in a striking manner that muscular response depends on the crest value of the current and not on the rms value.

Table V. Effect of Wave Form on 60-Cycle Let-Go Current

Subject Number	Peak Wave: Crest (Milliamperes)	Peak Wave: RMS (Milliamperes)	Flat Wave: Crest (Milliamperes)	Flat Wave: RMS (Milliamperes)	Sine Wave: Crest (Milliamperes)	Sine Wave: RMS (Milliamperes)

(b)—Peaked wave
(c)—Flat wave

Conclusions

1. The maximum safe noninterrupted electric current is that value which can be released by using the muscles directly affected by it. For man, the safe 60-cycle current is eight to nine milliamperes.

2. Muscular reactions are proportional to the peak value of the wave and *not* to the rms value.

3. The let-go currents are affected by frequency. Unfortunately for man, the minimum values are in the range of commercial power frequencies.

4. The let-go current is unaffected by the surface condition of the hands or the size of the electrodes.

5. The voltages which correspond to the limit of muscular control are relatively low. For a current pathway between the hands, with the hands moist but skin intact, the minimum observed 60-cycle value was only 20 volts.

6. It is possible for man to develop a degree of immunity to electric shock, however the increase is negligible from a practical standpoint.

7. The results of the investigation emphasize the importance of continual vigilance and education of both the public and the electrical workers with regard to hazards and safe procedures in the use of electrical apparatus.

Rural Automatic Telephone Networks

C. F. FFOLLIOTT.
MEMBER AIEE

Introduction

THE communication problems of rural areas offer an unique opportunity for the application of automatic switching methods. In no other situation is the combination of factors so favorable. Automatic exchanges are particularly suited to rural needs, especially when they are installed as unattended units in connection with nearby attended exchanges. The principal benefit springs from the fact that in a small manual exchange the number of operators cannot be adjusted to take care efficiently of the maximum traffic, because too often there is not enough traffic to occupy the time of even one operator.

The low traffic factor in rural areas therefore results in a twofold handicap—a handicap which only automatic equipment has been able to remedy. Experience has shown first that it is the infrequency of calls in an exchange, rather than high traffic, that makes the operator inattentive, and often causes delay in putting through calls. Service being the essence of all telephone facilities, this is a condition which cries aloud for a remedy.

The second phase of this handicap is its economic inefficiency, because of the low number of calls even during the busiest hours. Small exchanges, if they give twenty-four-hour service, have an irreducible minimum of three operators per twenty-four hours. Yet calls come in very infrequently during the night and other off-peak periods. The operator's time is therefore very incompletely utilized.

Where two or three nearby communities each can be served by an automatic exchange, the local calls can be handled by the automatic units while the toll calls for the entire area can be centralized at a nearby attended exchange. In this way, the maximum benefits are derived from automatic service, while the operator is not only kept efficiently occupied, but is concerned solely with duties that call for personal judgment.

The problem of rural exchanges is not new—the first of the so-called community automatic exchanges was installed in Fifield, Wisconsin in 1916—but its solution is not well enough known. This paper will therefore review a number of the factors entering into the operation of a network of rural automatic exchanges.

Technical Considerations

A network of automatic exchanges may take either of two general forms. The first type consists of a number of exchanges arranged in a long line with a trunk line or lines connecting the first to the second, to the third, etc., and finally to a toll center. In general, only the toll center is attended by an operator and it is equipped with control means to enable her to switch calls between the various exchanges of the group, as well as between any of the exchanges and points outside the group. This type of network is usually dictated by geographic conditions and would be used, for example, to serve communities located along a valley.

The second type of network is more common and may in fact include the first. In this type all or most of the small unattended exchanges are connected by trunk lines directly to the toll center. The exchanges not connected directly to the toll center have indirect connections through other exchanges of the group. Figure 1 shows a block diagram of the two types. Each of the lines connecting the various exchanges represents one or more trunk lines. The number to be provided in each case will be determined by the traffic requirements.

The local exchange equipment at the toll center may be of any type either manual or automatic, because all the traffic to and from the outlying exchanges is handled by a toll operator. The type of toll board used is immaterial, although the remote control toll board[1] is being used by several companies with conspicuous success.

The outlying exchange equipment will be determined by the requirements of the community in which it is to be installed. It has been found in practice that they will vary in size from a dozen or so lines up to two or three hundred lines. The smaller sizes usually serve only party lines, whereas the larger ones provide all types of service in the towns and party line service in the country.

The very small automatic exchanges are particularly worthy of note. A typical board is arranged to serve 19 lines and 3 trunks and is equipped with 4 finder-connector link circuits. The

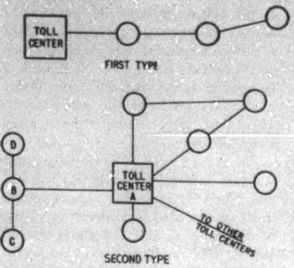

Figure 1. Block diagram of network types

finders and connectors are of the rotary switch type, which reduces the size of the unit. Telephones may be of the following types:

1. Individual line.
2. Two party divided ringing, full selective.
3. Ten party divided code or harmonic ringing.
4. Five party bridged code or harmonic ringing.
5. Post-payment paystation.

These classes of service are provided on a common battery, full metallic basis, but grounded line adapters can be used if required. These boards come fully equipped and self-contained with batteries, charging and switching equipment all in one cabinet.

Two types of cabinet are available, one for indoor mounting and the other which is weatherproof, for outdoor pole mounting. Pole mounting of automatic exchanges is a comparatively new idea and it has met with great success. It is probably not suited to all climates, but where the weather is favorable it is a useful method. It does away with the necessity of finding a suitable room in a satisfactory building as well as the expense of renting it. If a room is not available, it eliminates the expense of erecting a building. This type of exchange is mounted on a platform built between two poles as shown in figure 2. The two poles are located at any convenient place in the pole line where power is available. Since power is usually available anywhere, the switchboard can therefore be located at the most advantageous point from the wire plant standpoint. This may or may not be in the center of the town. In a number of cases it has been a cross road in open country. The simplicity of this type of mounting makes it extremely flexible. If the traffic outgrows the capabilities of the board, the latter can easily be removed and a larger exchange installed in a permanent building. If the expected traffic fails to materialize the board can be removed entirely without any great loss of installation expense.

The switching equipment for the larger exchanges may be of any of the well known automatic types. The type chosen will depend somewhat on the size of the exchange as well as on the preferences of the operating company. In general, relay type equipment is only suitable for exchanges of less than 200 lines ultimate capacity[2,3] but standard Strowger switches used with either plunger lineswitches, rotary lineswitches, or finders are suitable for use in systems up to any ultimate capacity. Systems of less than 100 lines are not ordinarily equipped with selectors but those of more than 100 lines are equipped with selectors.

Figure 3 shows a photograph of a small exchange designed to serve 50 or 90 subscriber lines and 10 trunk lines. This board is equipped with rotary switch 50 point finders and Strowger type two-motion 100 point connectors. The finders are arranged in two groups of 50 and 40 lines, only one of which need be installed originally. The additional group can be added whenever growth requirements justify it. The following classes of service can be supplied.

1. Individual—metallic or ground-return lines.
2. PBX trunk.
3. Two party, full selective—metallic lines only.
4. Four party, semi-selective—metallic lines only.
5. Ten party, semi-selective—metallic lines only.
6. Twenty party, semi-selective—metallic lines only.
7. Ten party bridged—metallic or ground-return lines.
8. Twenty party bridged—metallic or ground-return lines.
9. Post-payment paystations.

Figure 4 shows a trunking diagram of a typical rural exchange of the larger type. This particular exchange is equipped with linefinders and first selectors. It will be noted that both trunk lines and subscriber lines terminate on line equipment. When a subscriber wishes to initiate a call his line is found by the finder in the usual manner. If he wishes

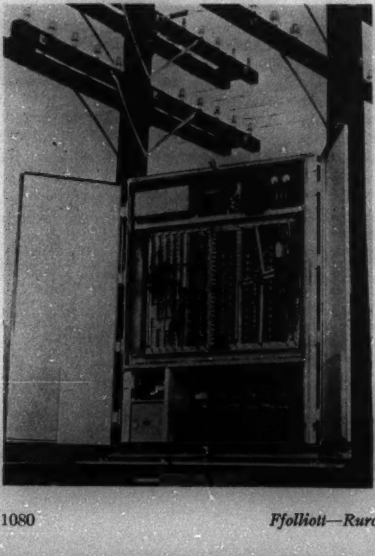

Figure 2. Pole-mounted exchange showing method of mounting and with doors open for inspection

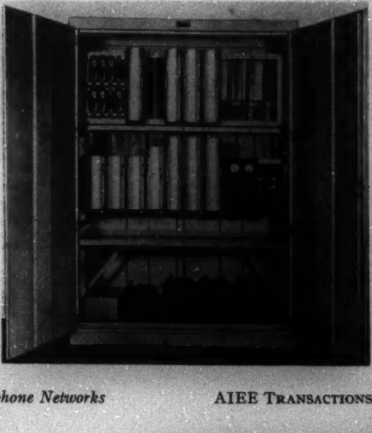

Figure 3. Small automatic exchange to serve 50–90 lines

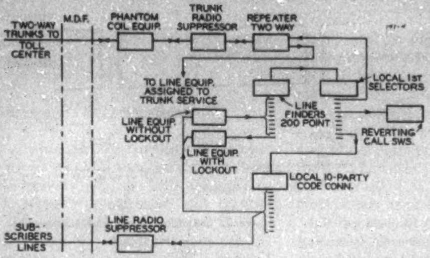

Figure 4. Trunking diagram of a small automatic exchange to serve more than 100 lines

to make a local call he dials two and goes out over the second level of the selector bank to the connector which responds to the last two digits, and completes the call. If he wishes to make a call to an outside point he first dials zero and goes out over the tenth level of the selector, through the repeater over the trunk line to the operator in the toll center. He then gives his instructions and the operator completes the connection.

An incoming call to the exchange comes over the trunk line, through the repeater and the line equipment to mark a contact on the finder bank. The finder finds this contact and connects the toll operator through to the first selector which returns dial tone. Upon hearing the tone she completes the call by dialing the subscriber's number in the usual manner.

It will be observed that the line equipment associated with the first finder level is furnished with "line lockout" but that the remaining line equipments are not. This feature is designed to disconnect automatically from the switchboard a line which becomes "permanent" due to faulty line conditions or failure of the calling party to dial promptly after dial tone is received. Inasmuch as rural lines are more likely to develop faults than are the town lines it is the usual practice to equip only the rural lines with the lockout feature.

Automatic exchanges must provide some means by which a subscriber can call another station on his own line. In the exchange illustrated in figure 4 this is done by means of reverting call switches. To make a call of this type with this equipment the subscriber must dial a special number. The first digit of the special number is that of the selector level to which the reverting call switches are connected (in this case seven) and the second and third digits are the code digits (usually the last) of the called and calling subscribers' numbers. After the number has been dialed, the calling subscriber hangs up to allow ringing to proceed. The called subscriber's code is rung first followed by the calling subscriber's code. These continue alternately until the called subscriber answers. This stops the ringing and so notifies the calling subscriber that his call has been answered and that he should pick up his receiver to complete the talking connection. If the subscribers' bells are on the same side of the line or if bridged ringers are used, only the called party's code is rung which both subscribers hear. If they are on opposite sides of the line each will hear only his own code. In this system the finder, selector, and reverting call switch are held during the conservation.

Small exchanges that do not require selectors sometimes use another type of reverting call service in which the reverting calls are made by directory number. As its name implies in this system it is not necessary to dial a special number to call a party on your own line. The calling subscriber dials the directory number of the wanted subscriber and then hangs up when he gets busy tone. Ringing takes place in the manner previously described, except that the calling subscriber does not hear it unless he is on the same side of the line with the called subscriber or unless bridged ringing is used. When the ringing stops or after a suitable length of time, the calling subscriber lifts his receiver to complete the talking connection. In this system all the switches are released after the talking connection has been established and talking battery is fed from the line relay.

A reverting call tone has recently been used on some exchanges to give the answering subscriber a warning that the call he has answered is from someone on his own line and that he should not hang up until the calling party has a chance to pick up the receiver.

It is the practice of most companies to provide at least one paystation in each community. The line thus equipped usually allows free local service, but provides means to give the operator in the toll center a distinctive signal whenever a toll call is originated from that station.

The exchange illustrated in figure 4 is of the finder type. The use of plunger or rotary lineswitches would change only the first portion of the switch train leaving the part from the selector onward very much as it is shown. Figure 5 shows a typical unheated building used to house an exchange of this type.

With reference again to figure 1, it will be noted that in both types of network some of the exchanges do not have direct trunk lines to the toll center. Some means must therefore be provided to allow the operator to supervise the calls between each pair of tandem exchanges, as well as calls from them to the outside. This is accomplished by the use of revertive call repeaters.[4] These repeaters may take several different forms to suit particular local conditions but they all have the essential feature of allowing the toll operator to dial back over the same trunk on which she was called. By this means she can, for example, set up a call between subscribers in exchanges *B* and *C* or between exchanges *C* and *D* of figure 1. After the connection is completed she retains supervision over the trunk line, and can therefore time the call and make the appropriate charge. The advantages of this system are briefly:

1. The transmission circuit includes only the trunk line between the two subscribers.
2. Only one trunk line to the toll center is held during the conversation.
3. The operator retains full supervision.

A variation of this scheme has also been used in which the operator does not retain full supervision but releases the trunk line as soon as the call is set up. She can check in on the progress of the call by dialing back at some later time over a monitoring circuit. This method of handling revertive dialing allows more efficient use of the trunk lines at the ex-

Figure 5. Type of unheated building used to house unattended exchanges

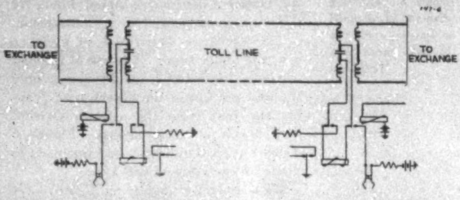

Figure 6. Simplified diagram of loop-dialing circuit

pense of less efficient supervision. There are in general, three methods of dialing between exchanges.[5,6]

1. Loop dialing. (Figure 6)
2. Simplex dialing. (Figure 7)
3. Composite dialing. (Figure 8)

Each of these is designed to suit particular conditions. Loop dialing is the simplest and it is usually used when the trunk lines are not too long. The circuit consisting of the operator's dial, the two wires of the trunk line, and the pulsing relay in the distant exchange, is broken momentarily by the impulse springs of the dial, allowing the pulsing relay to fall back. The details of the general method are too well known to require further description. In long dialing circuits of this type (and the other types as well) the battery supplying the dialing current is always located at the originating office, the reason for this being that if it were reversed the line leakage would tend to make the pulsing relay sluggish in its action. Furthermore in two way circuits, such as shown here, there is no battery drain due to line leakage such as there would be if the connections were reversed.

The simplex method makes use of both line wires in parallel as one leg of a ground return dialing circuit. This method is used on trunk lines which are too long for loop dialing but which are not part of a phantom group.

Simplex dialing is sometimes used on subscriber's lines that are longer than the allowable loop pulsing limit. For this use the dial is connected between the mid-point of the ringer coils and ground, and the line is simplexed at the exchange.

Composite dialing is used wherever the trunk lines are arranged in phantom groups. This method provides an extra leg that can be used as a spare dialing circuit or may be used as a telegraph wire.

In addition to the three methods discussed above there are two alternating current methods that have been used. These are known usually as low frequency a-c dialing and as voice frequency dialing.[7] The first of these uses 60 cycle alternating current and the second uses 1,000 cycle alternating current. The low frequency method has been used quite extensively in Europe and has been tried but not generally adopted in this country. The voice frequency method is in use over long toll circuits in South America, and it has been used to some extent here. They are mentioned only for the sake of completeness.

The resistance, the capacitance, and the leakance of a trunk line all tend to distort the dial impulses traveling over it. For this reason it may be necessary to introduce pulse correcting repeaters at various points of the circuit. It is the usual practice to have incoming and outgoing repeaters on all trunk lines. Tests have been made on circuits of this type where the impulses were repeated 10 times before reaching the final switch. In one particular test the impulsing circuit was about 170 miles long which was beyond the range of good transmission.

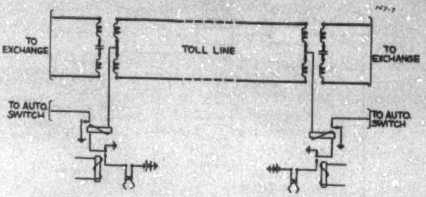

Figure 7. Simplified diagram of simplex-dialing circuit

A rural automatic network offers a unique opportunity for toll dialing. By this term is meant a system of operation in which the originating toll operator dials the subscriber in the distant office directly without the help of another operator. The originating operator reaches the distant exchange by dialing from one exchange to the next until she finally comes to the one she is seeking. She does this by dialing up the incoming selector of each exchange in turn to the correct level to give access to the next office until finally in the last one she dials the subscriber's directory number.

The advantages of this method of operation are:

1. The elimination of the time of one operator on each call.
2. An increase in the capacity of the trunk lines by eliminating any waiting time in dealing with the distant operator.
3. The elimination of errors and wrong numbers due to misunderstandings between operators.

To make this scheme effective complete directories of all exchanges must be maintained in each of the offices doing inter-exchange dialing. In the few cases

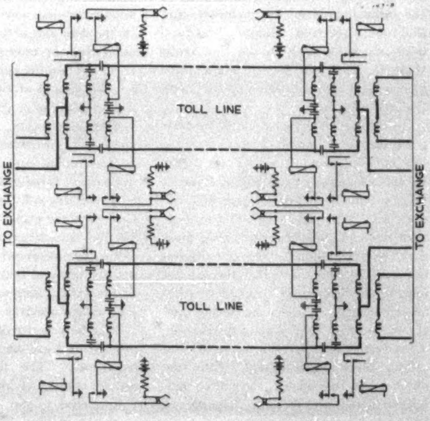

Figure 8. Simplified diagram of composite dialing on a phantom group

where the number cannot be found in the directory the operator obtains it from the distant information clerk and then dials the number herself.

Economic Considerations

It has been the experience of the companies operating rural networks that the subscribers offer very little opposition to conversion to automatic and that all opposition disappears soon after the cut-over. In the smaller communities the residents are usually more concerned over what is to become of the operator after the conversion than they are over any other phase of it and they may insist that she be properly taken care of before they will consent to a change. This concern is undoubtedly present because the operator in a great many cases acts as a sort of community secretary and has therefore a wide circle of friends who are solicitous as to her future.

The usual practice of one company in arranging for a change to automatic is to obtain the cooperation of the subscribers and the town council who petition for the conversion, with an increase in rates if any is required, to bring them into line with similar exchanges in other parts of the network. This method has been found most satisfactory since the subscribers do not feel that something is being forced on them against their will.

The Carolina Telephone and Telegraph Company, which operates one of the largest rural networks in the country from a standpoint of number of exchanges, has found that they can install a pole mounted automatic to serve a minimum of 35 subscribers. It has been their experience that invariably the number of subscribers increases greatly soon after the cut-over and may continue to increase until a larger exchange is required. In one case of phenomenal growth a pole automatic installed for 15 advance subscribers grew within a few months to 93 stations. They have found that in addition to increasing subscribers there is also a marked increase in the amount of toll traffic. This is attributed to the better grade of service available as well as to greater secrecy, because of automatic operation and because of the fact that the toll operator is in another town and is unknown to the subscriber or his neighbors.

It sometimes happens that a small community around a cross road, for instance, may be served by one or two multi-party lines from a large exchange some distance away. Such a location makes a very good nucleus for a pole mounted exchange.

In rural networks, particularly in agricultural districts, the rural lines make the town lines more valuable and a company can afford to break just even on them because of their value to the town.

The method of providing paystation service for the very small requirements of a small exchange is something of a problem. If has been found by experience that paystations will not be used for local calls, but that they are necessary for occasional toll calls made by nonresidents. The method of handling this problem used by a large operating company can be considered as typical. This company provides two general classes of paystations, semi-public and full public. The first of these classes is sub-divided into partial paystations and guaranteed paystations. The partial paystation plan is used mainly in the smallest exchanges. Under its provisions the regular business telephone of one of the subscribers (who pays the regular business rate) is equipped with a coin box for toll service. As an inducement the subscriber gets a single party line for price of a four-party line.

Under the terms of the guaranteed paystation plan a regular three-coin paystation is installed in some business house for their regular use. The owner of the establishment guarantees to pay for his local calls at the rate of five cents each with a minimum number such that the total amount paid is 50 cents less than the regular business rate. The guarantor then gets a 25% commission on excess local calls but gets no commission on toll calls.

Full public paystations are installed on a commission basis only in public places such as hotel lobbies, drug stores, railway stations, and the like.

It is the practice in many places served by manual exchanges and volunteer fire departments for the telephone operator to sound the fire alarm and call the firemen. When such an exchange is converted to automatic, there are a number of ways in which the alarms can be handled. In some places the telephone assigned to fire alarms is located in an all night business and the person there gives the alarm and calls the firemen. In other places an a-c relay is connected in parallel with the fire alarm telephone. The relay locks up when the telephone is called and sounds the alarm. The difficulty with this system is that there is no check on false alarms. One unique system makes use of a 10-party line as the fire telephone. The town in which this system is used is divided into ten districts and subscribers in each district report a fire by dialing the fire number with the last digit corresponding to their own location. When the telephone at the fire station rings it automatically codes the location of the fire.

Conclusion

It has been approximately 25 years since the first unattended community automatic exchange was installed. Since that time the design of boards to serve localities of various sizes has become crystallized to the point where today standard equipment is available to meet the needs of any operating company. On the other hand the basic units are so flexible that they can easily be adapted to any special requirement that may arise.

Especially noteworthy is the attitude of the user after a community automatic exchange is placed in service. Before a conversion, objections to change in the form of service, while seldom serious, do sometimes arise. Once the users experience the benefits of automatic service, however, they invariably become enthusiasts. All things considered there is every reason to believe that the number of automatic networks will continue to increase.

Powerton-Crawford 220-Kv Line—System Operating Features and Terminal Design

H. E. WULFING
MEMBER AIEE

T. G. LeCLAIR
FELLOW AIEE

Synopsis: A 220-kv line, 150 miles long has been constructed between Powerton Station near Peoria, Illinois, and Crawford Station in the city of Chicago. This line will probably operate continuously near the static stability limit and will deliver 150,000 kilowatts to the city from Powerton Station near the coal fields of southern Illinois. This line has the highest capacity of any in this area and includes several novel features, such as a unique carrier current system for tripping the breakers at the remote end of the line, for telemetering, load control, and communication.

The 180,000-kva transformer bank at Powerton has two 22,000-volt primary windings connected to different busses. The Crawford transformer bank has a 150,000-kva winding at 220-kv, a 75,000-kva winding at 12-kv, and two 90,000-kva windings at 69-kv for connection to separate 66-kv systems. Regulating transformers are provided at both terminals. A 75,000-kva synchronous condenser at the Crawford terminal is connected to the 12-kv transformer winding for voltage control. No 220-kv breakers are used at either end of the line.

This paper describes only the operating features and the terminal facilities; a companion paper by Messrs. Oldacre and Wollaston describes the construction features of the line.

Introduction

THERE are four generating stations within the Chicago city limits, all depending upon the flow of the Chicago River for condensing water. The flow of the river has been limited to 1,500 cubic feet per second by U. S. Supreme Court order, so that even with their ultimate developments the present generating stations would not be adequate to supply the Chicago load. The lake front would be an ideal location for generating stations, but has been dedicated for park and other recreational purposes and is restricted against the building of industrial plants. Therefore, Chicago must depend for some of its supply on sources outside of its boundaries.

The locations of the four generating stations are shown in figure 1.

It is interesting to note the effect during the past ten years of these limitations on the various generating sites in the development of the Commonwealth Edison Company bulk power supply system.

In the year 1928 less than 5 per cent of the electric energy distributed in the city of Chicago came from sources outside the city limits; in the year 1939 one-half the energy distributed in the city came from this source. This is a remarkable change in the eleven years and is due partly to the fact that the newer stations outside of the city are more efficient, having been built prior to the beginning of the modernization of some of the older stations within the city.

Powerton Station

One of these new efficient generating plants is Powerton Station, 150 miles southwest of Chicago, within fifty miles of a substantial coal field and with ample cooling water for a generating capacity of 800,000 kilowatts.

Powerton Station comes very near to fulfilling the requirements of "mine-mouth generation" which was a popular subject for discussion some years ago. This station is on the edge of an unlimited coal supply and on a river with ample condensing water. It has a further advantage in being at the center of a reasonably good load area which would justify its construction whether or not additional capacity were required to supply Chicago. These various considerations were responsible for the development of Powerton Station as a necessary source and as an adjunct to the sites within the city which are fast reaching their maximum capacity.

Powerton Station was originally connected by 132-kv overhead lines to the system of the Public Service Company of Northern Illinois and other systems in the territory between Powerton and Chicago. After these lines were completed for local transmission, comparatively inexpensive reinforcements and extensions made possible the transmission of 50,000 kilowatts to 100,000 kilowatts over this transmission system to the city. Further increases in the load required by Chicago seemed to justify a direct transmission system connecting the two points. An

J. Oil capacity of each	6,640 gallons	5,250 gallons
VII. Control		
Location of equipment	Carrier-current control house contains carrier-current equipment and control for 220-kv disconnect switch. Condenser house contains all relays and recording equipment. Control room (main station) contains all controls and metering equipment	Two control houses contain panels for carrier current, instrument transformer secondary transfer, and relaying, control and indicating equipment
VIII. Fire protection		
A. Type of fire walls	Concrete	Concrete
B. Size of walls between main power transformers	34′ high x31′8″x12″ to 15″ thick	30′6″ high x24′x6″ to 15″ thick
C. Stone fill under transformers	3′5″	24″
D. Size of walls between voltage regulating units	22′ high x25′4″x12″ to 15″ wide	24′6″ high x21′x6″ to 12″ wide
E. Stone fill under regulators	3′5″	18″
F. Fire fighting equipment	Bulk CO_2 system on transformers and synchronous condenser	Water and portable foam equipment

economic analysis indicated that such a tie was advisable.

Such a direct transmission system into a congested territory immediately met with right-of-way limitations. The necessity of transmitting an ultimate of 400,000 kilowatts on one right-of-way practically compelled the use of the highest transmission voltage then available, which was 220,000 volts at the time this project was initially authorized. Calculations showed that it was possible to deliver nearly 400,000 kilowatts with a double-circuit transmission line over the 150-mile route by loading these transmission lines practically to their maximum stability limit.

Electrical Characteristics of the 220-Kv Line

The fundamental design of the transmission system produced some interesting technical problems. The line is intended to deliver 150,000 kw or more per circuit at a delivered power factor of 85 per cent. This is a very high loading for a transmission line of this length and requires special consideration to overcome the voltage drop in the line, which would be nearly 40 per cent including the transformer drop. The use of taps in the transformer windings or separate regulating transformers could be adopted to overcome this voltage drop. However, tap changers set for a voltage boost of 40 per cent or more in the direction of transmission would increase the current excessively in the sending end of the line and would also result in extremely high voltage in case the line opened at the receiving end while carrying full load.

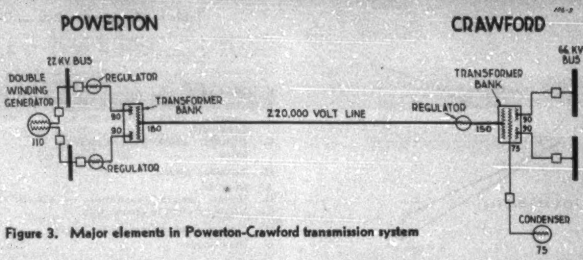

Figure 3. Major elements in Powerton-Crawford transmission system

Another method of controlling voltage regulation would be the use of synchronous condensers at the receiving end to operate the line at approximately constant voltage. In this case the capacity of synchronous condensers required at the receiving end would be approximately the same as the kw of power delivered. The cost of these synchronous condensers would be excessive. A careful study of the problem indicated that the most economical solution to the problem was to obtain half the compensation by the use of a synchronous condenser and the remainder by the use of tap changers. Transformers at both the sending and receiving end of the line have a fixed ratio equivalent to 5 per cent boost from Powerton towards Chicago. A regulating transformer bank is used at each end of the line with a range of plus and minus ten per cent; in addition, a 75,000-kva synchronous condenser is connected to the tertiary winding of the receiving transformer bank. This combination not only results in the minimum total cost for transmission but has certain other advantages illustrated in figure 2.

At full load, the power factor is approximately the same at both the sending and receiving end of the line and is within the normal range for satisfactory operation of the generators. The use of synchronous condensers on a tertiary winding protects the line to a marked degree against overvoltages should the circuit breakers open at the receiving end while carrying full load. The synchronous condenser is also used to energize the line during the starting process before it is synchronized to the system. This eliminates the voltage disturbance which would be created by closing 37,000 kva of line charging current to a generating station bus.

The total range of the tap changing equipment is from a 30 per cent boost in one direction on the line to 10 per cent in the reverse. This is accomplished by fixed taps in addition to the tap changer units. The result is that the line can operate at full load from Powerton to Chicago or at approximately half load from Chicago toward Powerton. There is no indication of any bus loading conditions which would call for more than half load in the reverse direction.

The essential parts of the transmission link, including terminals, are shown in figure 3. This one-line diagram shows the three-winding transformer bank at Powerton which is used to supply the line from two different 22-kv bus sections. At the Crawford end of the line, power is delivered to two separate 66-kv systems. Therefore, the Crawford transformers have two 66-kv windings in addition to the 220-kv winding and the 12-kv winding for the synchronous condenser.

Operating this line so near its stability limit has an interesting effect on the short-circuit currents. For a symmetrical three-phase short-circuit on the 66-kv winding of the Crawford terminal transformers the short-circuit current sent out from Powerton is nearly equal in value to the normal full-load current at Powerton. For a short-circuit on the 220-kv side of the Crawford transformers, the short-circuit current is somewhat higher but the increase in current is not sufficient for relaying purposes.

Relaying of the 220-Kv Line

Relaying for ground faults on the transmission line is comparatively simple. There are no high-voltage circuit breakers and any neutral current indicates a fault on this line. Therefore, a simple neutral relay can be set selective for faults on the full length of the line. The relaying for faults between phases is by means of high-speed impedance directional type relays.

Faults in the transformers or regulating units are detected by transformer differential relays. These relays trip the circuit breakers on the low-tension side at the near end of the line. However, with no high-voltage breakers it is necessary to trip the breakers at the distant end of the line. For reasons previously mentioned, the relays at the distant end of the line cannot be sufficiently sensitive to detect transformer short-circuits. Therefore, it was necessary to adopt some scheme to trip the circuit breakers at the remote end of the line in the event of transformer failure.

Carrier-Current Relaying

The scheme adopted was the use of a carrier current system for tripping breakers at the remote end of the line. The normal carrier current relaying scheme uses the carrier for blocking the tripping impulse on high-speed line relays. In this case the carrier channel is used to transmit a tripping impulse to the breakers at the remote end of the line.

When a carrier scheme is used for tripping breakers, there must be some assurance of a continuously available channel. The method of accomplishing this continuous check on the availability of the carrier channel is quite novel and interesting. One carrier channel is used to transmit carrier frequency in one direction over one pair of conductors of the line and an additional channel transmits a continuous carrier signal in the reverse direction over a separate pair of conductors of the line. Each of these carrier channels is modulated by several modulating frequencies for various purposes to be described later. As a part of the remote tripping scheme, one of the modulating channels is used to transmit a continuous signal from Crawford to Powerton which picks up a relay to return continuous modulating signals over the other carrier channel to Crawford. So long as both carrier sets are in operation, a signal light is lighted on the switchboard. Any trouble in either the carrier or modulating frequencies breaks this circuit and rings an alarm. Separate modulating channels on the same carrier frequency are used for sending the tripping impulses. The tripping and blocking circuits are so interlocked as to maintain

practically constant supervision over this tripping circuit in a manner not described in detail in this paper.

Additional Uses of the Carrier Current

Carrier equipment for tripping of the breakers at the remote end of the line was a necessity for protection of costly terminal equipment. Having justified the carrier equipment for this purpose, it was relatively inexpensive to extend the carrier scheme for the five following major purposes:

1. Tripping of circuit breakers at the remote end of the line for transformer or terminal equipment failures.
2. Transmitting from Powerton to Chicago, telemetering impulses to indicate at the dispatcher's office the total output of the Powerton Station.
3. Transmitting from Chicago to Powerton telemetering impulses which indicate at Powerton the total output of all generating plants in the Chicago district system.
4. Transmission of impulses from Chicago to Powerton to control the loading of turbines.
5. Two-way telephone communication for dispatching and routine business.

Figure 4 is a block diagram showing the elements involved in this carrier scheme. As a further insurance of the reliability of the carrier channels, each carrier channel is coupled to two phases of the transmission line. The carrier transmitters have sufficient power, should one conductor be open-circuited or grounded, to continue to operate satisfactorily with phase-to-ground coupling on the remaining line conductor.

Referring again to figure 4, the communication unit has a single carrier band to be modulated with voice frequencies. The other two channels each have one carrier frequency modulated with six or eight separate audio frequencies used in connection with the several purposes of the carrier scheme.

As a result of the high-speed relaying and remote trip, it is expected that even without high-tension breakers on the transmission circuit, faults will be cleared from the system in less than one-sixth second.

Line Terminal at Crawford Station

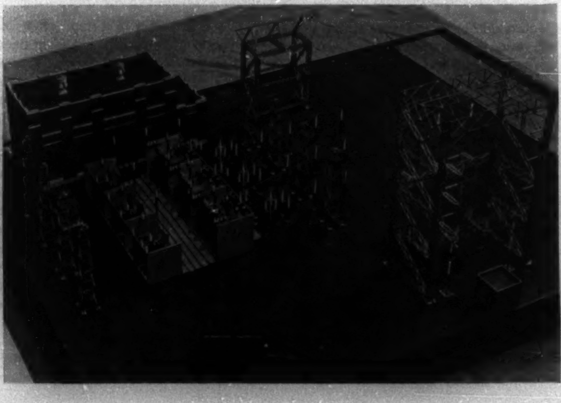
The terminal for the line at Crawford Station presents a number of novel features. In addition to being the first transmission terminal for 220,000 volts between the Alleghenies and the Rockies, this terminal receives an unusually high load per line. The amount of load on the one line is such that for operating safety it is desirable to divide the output of the line between the so-called "red" and "blue" systems in Chicago. These are the two halves of the 66,000-volt transmission system which operate as parallel paths between all stations. To meet this condition a transformer bank was designed with four separate windings; one winding at 220 kv with a capacity of 150,000 kva, two 66-kv windings, each with a capacity of 90,000 kva, and a fourth winding at 12 kv with a capacity of 75,000 kva for direct connection to the synchronous condenser. The division of reactive kva and power flow is such that all four windings may be loaded to rated capacity at the same time.

Figure 5 is a photograph of the Crawford terminal. Actually, the photograph is of a scale model made in advance of construction in order to assist the designers in working out some of the more complicated design details. Because the model is quite complete, it is used to show the complete structure more effectively than a drawing. The three conductors of the 220-kv line are connected to three strain insulators in the foreground on the tall rectangular tower. This tower is constructed so that a second line, when built, may be terminated on the opposite side.

There are no high-voltage circuit breakers, and the 220-kv disconnects are directly beneath the large strain tower. The lightning arresters are adjacent to the transformer compartments in order to have them as near as possible to the transformer bushings for maximum protection.

Figure 5. Crawford terminal

Photograph of scale model used in working details of design



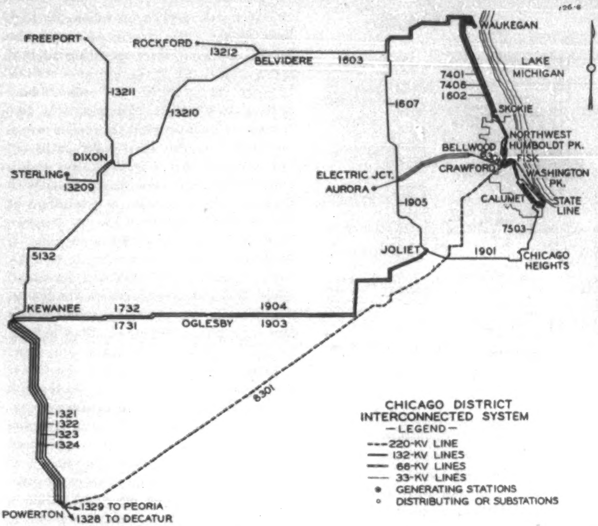


Figure 6. Chicago district interconnected system

This map, approximately to scale, shows the relation of the new 220-kv line to the existing 132-kv system between Powerton and Chicago

The entire structure is covered by a network of overhead ground wires for lightning protection. The line ground wires are brought into the top of the 125-foot rectangular tower in the foreground to complete the lightning shield.

Each of the three single-phase transformers is in a separate compartment, mounted on a movable truck, and located over an oil pit filled with crushed stone. Each regulating transformer is in a separate tank in a separate compartment opposite the main transformer on the corresponding phase. Each of the main transformers covers a ground area of approximately 29 feet by 22 feet, and is nearly 20 feet high. The total height of the bus is slightly more than 30 feet. Each unit contains 24,000 gallons of oil and weighs 491,000 pounds.

The regulating units cover a ground area of 18 feet by 15 feet and are 15 feet high. The regulating transformers contain about 6,600 gallons of oil.

Synchronous Condenser Building

The large building in the background houses the 75,000-kva synchronous condenser in the left end of the building. In the right end of the main portion of the building is the pit which is used for assembling and maintaining the transformer units. There is a 200-ton crane in the building with a maximum lift of 60 feet above the floor of the transformer pit. The purpose of the pit for handling the transformers is to reduce the total height of the building and use the same crane for assembling the synchronous condenser and the transformers. The transformer pit is 31 feet by 36 feet and 18 feet below the main floor level.

Synchronous Condenser

The 75,000-kva 514-rpm condenser weighs 690,000 pounds. The heaviest part is the rotor, which weighs 350,000 pounds. It is started by a separate motor of 3,750 horsepower. This motor is appreciably larger than necessary for starting purposes alone. It is used to excite the transmission line and synchronize it with the system to avoid the voltage disturbance caused by closing the circuit breaker on a long line with a high charging current. The transmission line is connected to the synchronous condenser at rest and the condenser brought up to speed with the starting motor. Then the field is applied to the synchronous condenser to bring the line up to normal voltage for synchronizing with the 66,000-volt system.

The relay boards, the auxiliary power, and miscellaneous electrical equipment are housed in the south end of the synchronous condenser building in a number of separate rooms. This end of the building also includes a heating plant. The control for the synchronous condenser and the switching equipment is located in the main station control gallery about 1,000 feet from the synchronous condenser building. Here it is under the supervision of the same operators who control turbines and outgoing lines.

The oil handling equipment is in an underground section to the east of the synchronous condenser house. The two 25,000-gallon oil storage tanks are in a separate underground room beyond the oil handling equipment.

The 12-kv outdoor oil circuit breaker which connects the synchronous condenser to the 12,000-volt winding is located just to the west of the synchronous condenser house adjacent to the main transformer bank.

Spare Equipment

The terminal is provided with a spare single-phase main transformer unit mounted on a truck. In event of transformer failure, the defective transformer can be rolled out of place and into the building for repairs. The spare unit can then be rolled into the place of the one removed. Such a replacement, including the disconnecting of oil and water pipes, bushings, etc., can be accomplished in a few hours.

There is also a spare regulating transformer unit. This regulating unit can also be wheeled into place as a substitute for any regulator which might fail in service. The use of regulating transformers in separate tanks has been standard practice with this company for many years because regulating transformers have many more parts subject to failure than do the main transformers. Experience has shown that it is economical to separate the tap changing equipment from the main unit so that trouble, if it should occur, would be confined only to the smaller capacity regulating transformer.

The small building directly in front of the tall tower contains the carrier relaying and communication equipment. The photograph of the model shows only two of the carrier coupling units. Carrier coupling units are used on all three phases in order to perform the several functions previously referred to.

Line Terminal at Powerton Station

The Powerton terminal is similar to the Crawford terminal for the same line in some respects. However, the Powerton transformer bank contains three windings in contrast to four at Crawford, and obviously, no synchronous condenser is necessary at the sending end of the line. The transformer handling house is much smaller than the one at Crawford because it contains space for the transformer and oil handling only.

Comparison of Powerton and Crawford Terminals

Tabulation I attached includes a number of detailed figures on the Powerton and Crawford terminals. For comparison the essential features of the two terminals are shown in parallel columns. There is a surprising similarity between the designs in spite of the fact that the two terminals were designed by different engineering organizations, and that one terminal includes four-winding transformers and a synchronous condenser while the other terminal has three-winding transformers and no synchronous condenser.

In both terminals it was found to be necessary to have a building with a crane for assembling and possibly repairing transformers. This was in part dictated by the fact that the transformer units were so large that they could not be shipped completely assembled. The core and coils had to be sent in shipping tanks and assembled on the job in the main transformer tanks with radiators. The transformer handling house is different in the two cases for a very good reason. At Powerton the only large equipment to be handled is the transformer and, therefore, it was economical to build a tall building with the transformer on the ground level and with clearance below the crane rails sufficient to lift the core and coils out of the tank. At Crawford the heaviest single part of the synchronous condenser is near the same size as the heaviest single part of a transformer. However, the synchronous condenser requires much less head room than that needed to remove core and coils from the transformer tank. Therefore, the most economical building design was obtained by having the clearance under the crane sufficient for the synchronous condenser and by digging a pit at one end into which the transformer could be lowered for removing core and coils. With this design, the total volume of building is considerably less than would be the case if the crane rails were high enough for transformer handling.

The local conditions at Powerton and Crawford have a very material effect on the steel structure where the line terminates. At Powerton where ample land is available and where a future outgoing line would be on a separate single-circuit tower line, no structure is provided for any future high-voltage switching equipment. At Crawford a future second circuit will be brought into the station on the opposite side of the same double-circuit tower and brought around the terminal. The terminal tower is, therefore, built to take the strain of the present and future incoming line; also, the structure is complete for a later installation of the line and transformer circuit breaker when they are required in connection with the second parallel circuit. This difference between the two terminals accounts for the larger amount of structure at the Crawford terminal.

Spare Equipment

There is another material difference between the local conditions at Powerton and Crawford. Powerton Station, being farther away from the city, has neither the men nor machinery available for rapid changing of transformers in case of failure. It was, therefore, decided to have the spare transformer and spare regulating units permanently installed. Bus work is provided so that in the event of transformer failure the spare transformer can be connected in the proper phase of the line without any physical moving of the equipment. Such a change can be made with a relatively small force in a few hours. The intention was that the time required to make replacements would be of the same order of magnitude at both ends of the line.

Conclusion

The building of this 150-mile 220-kv transmission line with two terminals results in a material improvement in the reliability of the bulk power supply to metropolitan Chicago. The line and terminals are built to be physically much more reliable than any others in this area. In addition to this, the line traverses a route which is entirely different from that of any existing 132-kv line supplying Chicago. It seems reasonable to assume that no sleet storm or any other contingency would simultaneously strike the routes of all these transmission lines. In the event that some disturbance would take out part or all of the 132-kv lines going north from Powerton, much of the generating capacity can be transferred to the 220-kv line and delivered to Chicago over this route.

Figure 6 is a map of the interconnected system showing all of the 132-kv lines in addition to the new 220-kv line. With this transmission system power from outside sources can enter Chicago through three different gateways. By so diversifying the routes it is believed that the reliability of supply from these stations at some distances from Chicago is satisfactory for the high service standards necessary in a large city.

Television Transmission Over Wire Lines

M. E. STRIEBY
FELLOW AIEE

J. F. WENTZ
ASSOCIATE AIEE

Synopsis: Intercity networks appear vital to the success of television broadcasting. Experiments with wire lines for this purpose and for local transmission of present-day television signals are reported herein. The design and construction of the equipment used are described and its performance characteristics given.

The intercity lines discussed involve carrier transmission over coaxial cable with repeaters which pass a net band of about $2^{3}/_{4}$ megacycles. For local intracity connections video transmission of about a 4 mc band is obtained over existing telephone plant or by means of special low attenuation cable. Various circuit arrangements including the facilities used in bringing scenes from the Republican Convention in Philadelphia to the N.B.C. in New York are shown together with their overall television transmission characteristics.

Introduction

If the development of television broadcasting follows in the footsteps of its predecessor in the sound broadcasting field, networks for interconnecting television stations will be very important. In fact many students[1] of the problem believe that such networks are a virtual necessity because of the expected high cost of programs.

Considerable progress in the development of a wire line technique for this purpose has been made in connection with the Bell System's study of coaxial conductor systems for use in wide band telephony. Data previously published[2,3,4] have been supplemented recently by certain tests and experiments in the transmission of 441-line television images, the results of which are presented in this paper. This will cover the transmission characteristics of facilities both for intercity and local distribution, including the wire lines which were used during the television broadcast in New York of the proceedings of the Republican Convention in Philadelphia during the last week of June 1940. This broadcast was undertaken jointly by N.B.C. and A.T.&T. and its associated companies as an experiment in the furtherance of the television art. A large part of the experimental facilities used were manufactured by the Western Electric Co.

Long Haul Coaxial Systems

For long distance broad-band transmission, coaxial systems have certain natural advantages which have been previously pointed out. In common with all long distance systems for multiplex telephony, the carrier method of transmission is essential and has been found to be relatively straightforward. For long distance television transmission, the carrier method is necessary with the present coaxial lines and coaxial repeaters, due to the fact that satisfactory long distance transmission cannot be obtained at the very low frequencies involved in a video television signal. Hence for television the entire signal must be raised bodily to a higher frequency. The modulating means developed for this purpose will be described in detail later. In this section we will confine discussion to the transmission of a broad-band of frequencies independent of how this band is used.

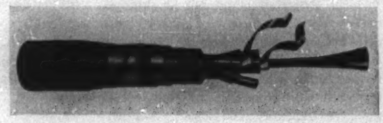

Figure 1. Photograph of coaxial cable

Cable

The transmission characteristics of ideal coaxial cables have long been known. The properties of practical structures so far built including matters of crosstalk or shielding are also now well understood.[5,6] Certain mechanical improvements in construction have been made recently[7] and may be illustrated by a photograph, figure 1, of the recently installed Baltimore-Washington coaxial cable. A similar construction was used in a cable completed last summer between Stevens Point, Wisconsin and Minneapolis, Minnesota.

These cables each contain 4 coaxial units. Two of these are used to provide a normal broad-band system having one pipe for each direction of transmission. The other two provide spare facilities for each direction. The construction of the coaxial unit itself can be seen from the photograph to use a single longitudinal copper tape for the outer conductor. This is formed into a tube which is held to a fixed diameter by the width of the tape and is prevented from collapsing by the interlocking of its saw-toothed edges. Two layers of steel tape provide the needed support against buckling and also give additional shielding. This construction results in somewhat improved transmission characteristics and lower manufacturing costs as compared with other types of construction with which we have experimented. Improvements in transmission include lower attenuation, due to a reduction in the effective resistance of the outer conductor, and a smoother impedance frequency characteristic due to greater mechanical uniformity. In spite of the thinner outer conductor satisfactory crosstalk characteristics are obtained.[8] Typical attenuation, crosstalk, and impedance characteristics of this cable as a function of frequency are shown in figures 2 and 3 for a 5-mile length of installed cable.

Repeaters

The band width of a coaxial system, at least over regions which we have studied, is limited only by the amplifiers with which it is provided. The amplifiers which have been built most recently for use in these systems are known as "3-megacycle amplifiers" and were intended to provide about a 2-megacycle band of suitable characteristics for telephone purposes or about a $2^{3}/_{4}$ megacycle band suitable for television transmission.

Figure 4 shows one of these amplifiers. It is a three stage feedback device using two small pentodes in parallel in each stage. The mathematical design of the circuit is beyond the scope of this paper and has been treated elsewhere.[9] This type of pentode has an initial transconductance of from 2,000 to 2,500 micromhos and an output power of .1 to .2 watt at 130 volts as used in this system. These tubes are in parallel only to give added reliability. The gain of this amplifier is very roughly the complement of the line loss as a function of frequency. With this amplifier and the cable described above, these repeater sections are about $5^{1}/_{4}$ miles in length. As illustrated in figure 5, the difference between the gain

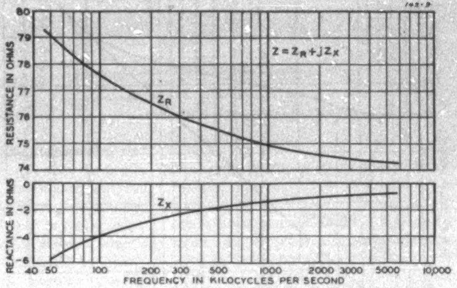

Figure 3. Impedance of five miles

and line loss is made up by a line equalizer so that to a first approximation, zero loss in transmission is obtained at all frequencies within the band over each repeater section. About 30 db of feedback is effective over the telephone frequency band (i.e. up to 2,000 kc) around the entire amplifier with about 10 db additional around the final stage. From 2 mc up to 3 mc the feedback gradually falls off about 10 db. This arrangement gives the high degree of transmission stability and linearity required for long telephone systems with hundreds of amplifiers in tandem and satisfactorily meets present requirements. Limited experience with television transmission so far indicates satisfactory performance. The linearity is illustrated in figure 6 which shows measurements of 2nd and 3rd order modulation products of a 1,000 kc signal in a typical amplifier at various signal levels. As in previous coaxial systems, power for operating the amplifiers is transmitted at 60 cycles over the coaxial cable itself from main stations located at about 50-mile intervals.

REGULATION

In order to compensate for changes in attenuation due to temperature change of the copper conductors, the gain of the amplifier is regulated automatically by a device located at each amplifier point which is operated from a pilot channel. In this system a pilot frequency of 2,064 kc is transmitted along the line with the signal. At the output of each amplifier, a high impedance highly selective crystal filter is bridged on the circuit to select the pilot frequency. This is then amplified, rectified, and used to control the output of an oscillator. The oscillator output in turn is used to control the resistance of one element in the feedback circuit of the amplifier. This variable element is a very tiny thermistor[10] made up of certain oxides which have a very large negative temperature coefficient of resistance. The regulator is "back-acting" and maintains a substantially constant output voltage at the pilot frequency over a range of about 9 db in input voltage. The feedback circuit of the amplifier is so designed that the changes in the resistance of the thermistor produce changes in gain over the entire frequency band in such a way as to compensate for the changes in loss in the coaxial conductors, as illustrated in figure 7. Changes there shown are for ±70°F., which is about the maximum which is expected in a repeater section, even though the cable is of the aerial type.

In a long system, it has not been feasible to make the accuracy of equalization and regulation in each 5-mile section sufficient to give the desired overall uniformity of transmission. Hence, certain supplementary adjustment is required. Devices for such adjustment have been installed at 50-mile points on the Stevens Point-Minneapolis system with satisfactory results. Also, two additional pilot channels have been provided, one at 64 kc and one at 3,096 kc. These serve to indicate the circuit performance and the need for manual adjustment. These pilots could be used to actuate automatic regulators if desired. For longer systems, it is expected that additional, and necessarily more complicated, supplementary devices will be required at intervals of perhaps 200 to 500 miles.

PERFORMANCE

A complete repeater containing amplifiers for each direction of transmission, automatic regulators, equalizers, power supply, and various automatic alarm features is mounted in a box about 2x2x1 ft. as shown in a photograph (figure 8). Measurements on the overall performance of systems with many such repeaters in tandem indicate a high degree of transmission stability and freedom from noise. In the neighborhood of the pilot frequency the transmission variations are in the order of 0.1 db. At other frequencies there are slow drifts due to aging of tubes which, when they reach a few db, will require readjustment. These changes are now effected manually at the attended stations.

Interference from all sources both external and internal is very low in this system. The largest contributions of such interference are from tube noise and from thermal agitation in the conductors and circuit elements. The effect of interference from external sources so far encountered is lower than the above, although the presence of radio broadcasting stations can be detected. Intermodulation of signals traversing the system simultaneously has been very carefully

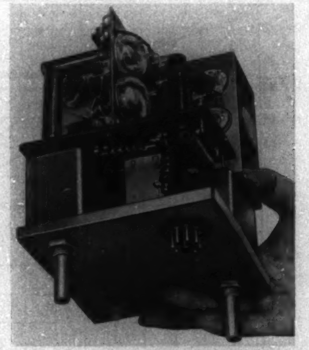

Figure 4. Three-megacycle amplifier in hand

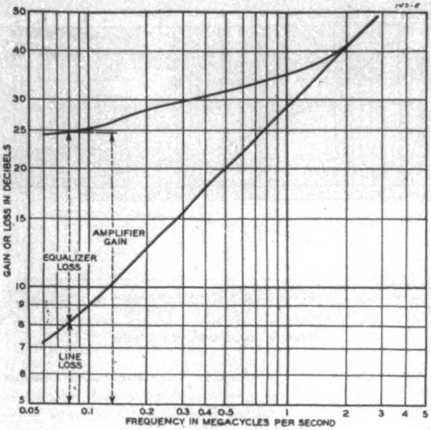

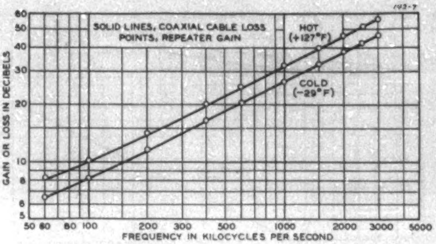

Figure 5 (left). Repeater-gain, line-loss, and equalization characteristics

Figure 7 (above). Regulation hot and cold versus frequency

measured because of its importance for multichannel telephony and television. In telephony, because of the large number of modulation products, principally 2nd and 3rd order, these appear as random interference.

The method of measurement of interference from all sources was to transmit over the system a wide band signal having a continuous spectrum such as thermal noise. At the sending end a narrow band elimination filter was inserted. At the far end the noise was measured within that same band.

The total noise so measured depends upon the signal energy levels at the input and the output of the repeaters, the former controlling the effect of line and resistance noise and the latter controlling the effect of modulation. These levels in turn are a function of repeater spacing. The tests that have been made indicate that it is practicable to keep this type of interference within desirable limits on long telephone or television circuits.

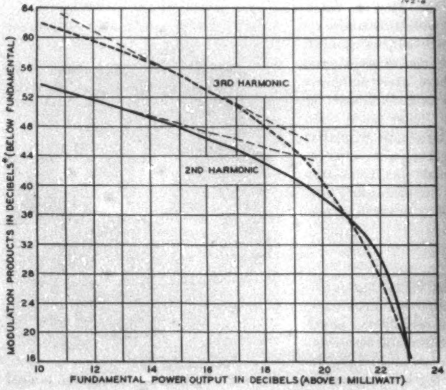
Due to the 60 cycle power supply used on the system, power frequency modulation products require special attention. Sixty cycle sidebands are produced on all signals transmitted due to the traces of nonlinearity in the system. As these are very small in magnitude and result mostly in a 120 cycle component they are unimportant for telephony. However, in the television transmission system used, this component is larger because of the presence of a strong carrier and one or more pilot channels. Also 120 cycle sidebands produce a very disturbing type of horizontal bar pattern across the picture. This type of interference will increase as the circuit length is increased, and may become more visible as receiving tubes are improved. On systems so far available for test, however, it has been possible to hold this type of interference within acceptable limits, on present day television broadcast images.

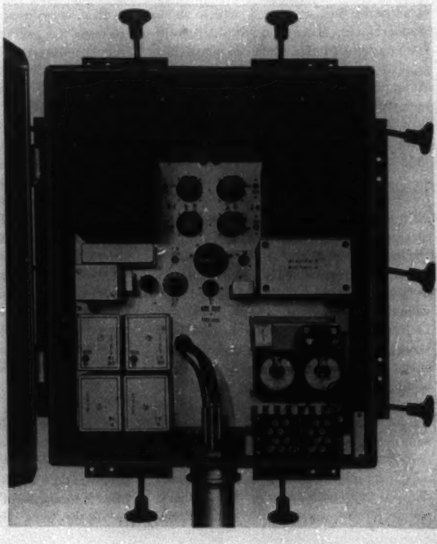
Distortion in Television Images

Departures from ideal transmission in the line, equipment or in a radio path

Figure 6 (below). Amplifier linearity

Figure 8 (right). Complete repeater





produce distortion in the form of negative or positive fringes or "ghosts." These occur when there is a lack of proportionality between phase shift and frequency through the system. This trouble in television images is perhaps more easily understood if one thinks of it as an actual difference in time of transmission of various parts of the signal. In discussing this matter in this paper, we will use the term "delay" to mean the time of transmission of the envelope of a modulated wave. This quantity is often more accurately referred to as "envelope delay."[11] If this quantity varies too widely there is an actual difference in the time of transmission of various parts of the signal, producing distortion in the form of fringes or "ghosts" which are exhibited by many television images today.

BAND WIDTH

A band width of about 3 mc is required to give equal resolution in the vertical and horizontal directions in a 441-line, 30-frame interlaced image. Recent experiments[12] with out-of-focus moving pictures have shown not only that the eye is quite insensitive in its requirement for equal detail in the two directions but also that the loss of detail due to a narrowing of the frequency band from 4 mc to $2^{3}/_{4}$ mc will pass unnoticed by many careful observers at normal viewing distance.

Television on Coaxial Systems

As mentioned above, no practical method has been found for transmitting television over long haul coaxial circuits in the video frequency range. By the carrier method, however, the video frequency band may be raised to a region suitable for transmission. To conserve frequency space, single sideband transmission, of course, is desirable. The actual method chosen involves also a modest vestigial band since it appears impracticable to select a single sideband involving video frequencies as low as 45 cycles in any other way. The present coaxial amplifiers pass a band from about 64 kc to about 3,100 kc. The region useful for television, however, appeared to be somewhat less than three megacycles on account of the difficulty of equalizing the delay distortion near the lower edge of this band. About 100 kc was allotted to obtain proper shaping of the vestigial sideband. The carrier was, therefore, placed at about 300 kc and a net television band of about $2^{3}/_{4}$ mc was obtained. If we attempt to move a 3 mc video band up 300 kc in a single step of modulation, the result is an overlapping of the sidebands which hopelessly distorts the signal. Two steps of modulation are therefore resorted to as shown in figure 9.

Figure 10. Box diagram of carrier terminals

The energy of a television system is concentrated in the lower frequencies or, in a carrier system, near the carrier. To take most advantage of the coaxial system, the carrier should be at the low end where the full feedback in the amplifiers is available. The four lines in figure 9 illustrate the four stages of modulation, two at the transmitting terminal and two at the receiving terminal. As can be seen the signal is first modulated with a carrier of about 8 megacycles and the lower sideband, part of the carrier, and a portion of the upper sideband, are selected by a band filter. This signal is then modulated again with a carrier of about 8.3 megacycles and the lower sideband again selected. In this position of the signal, which is the position at which it will be transmitted over the coaxial line, the frequency which corresponds to d-c in the video signal sideband is at 311 kc, the main sideband extends from 311 to 3,111 kc and the vestigial sideband from 311 kc down to 200 kc.

The receiving terminal is in general the inverse of the transmitting terminal and will not be discussed in detail. The sideband shaping[4] is accomplished by the four filters, two at the transmitting terminal and two similar ones at the receiving terminal, acting in conjunction. The re-

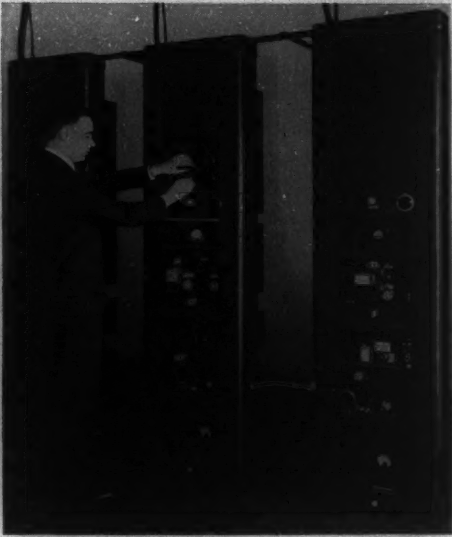

Figure 12. Carrier terminals

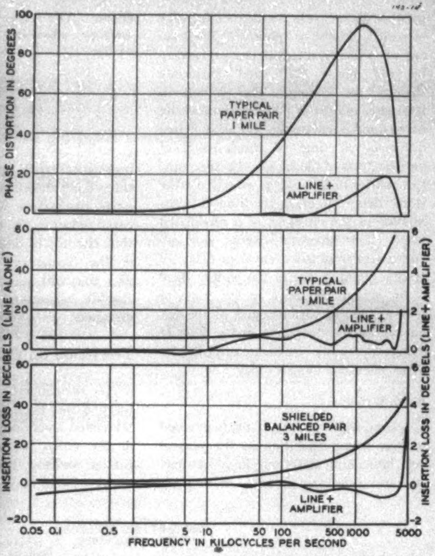

Figure 14. Transmission characteristics of cables

sult is that at the final stage of demodulation the contribution from the vestigial sideband when added to the contribution from the shaped portion of the main sideband gives back very nearly an undistorted video signal. This last stage of demodulation is accomplished in a linear detector. The carrier amplitude at the input terminals of this detector is about six db greater than the amplitude of the video envelope of the modulated signal, the amount of carrier which was mixed with the sidebands at the output of the first modulator having been adjusted to achieve this result. The reason for using this amount of transmitted carrier is the relatively narrow vestigial sideband—111 kc vs. a main sideband of about $2^3/_4$ mc. With such a narrow vestigial sideband the quadrature component of the carrier envelope is relatively large, resulting in objectionable distortion at sharp changes in the picture signal if the greater ratio of carrier to sideband is not employed.[13]

Figure 13. Photograph of video amplifier

Figure 10 shows a box diagram of the terminal arrangements. In addition to ordinary video amplifiers and modulators and filters mentioned above, a "pre-emphasizer" and a "restorer" are shown. These networks partially equalize the energy in the various components of the signal, and thus help to override the noise and spurious modulation products introduced by the line and amplifiers. A phase equalizer is also shown which, in conjunction with a similar equalizer at the receiving end, is designed to correct for the phase distortion in both the transmitting and the receiving terminals. Before transmission over the coaxial, pilot frequencies of 64 kc, 2,064 kc, and 3,096 kc are added, as well as a program channel from 73–84 kc. Figure 11 shows the frequency allocation of the television signal and its associated channels on the coaxial line.

At the receiving end the pilot frequencies and the program channel must be removed. The 64 kc pilot and the program channel are eliminated by the 200–3,111 kc filter which precedes the first demodulator. The 2,064 kc and 3,096 kc pilots, however, are within the transmitted television band. The frequency allocation was so chosen as to place them approximately in the center of the "empty energy regions"[14] of the television spectrum where they can be eliminated by sharp selective networks without appreciably distorting adjacent television signal components.

Three carrier television terminals are

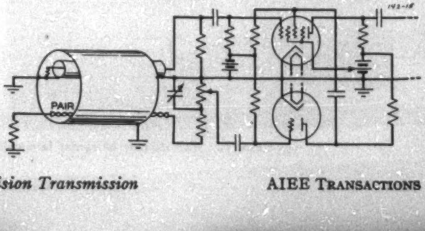

Figure 15. 60-cycle balance on coaxial line

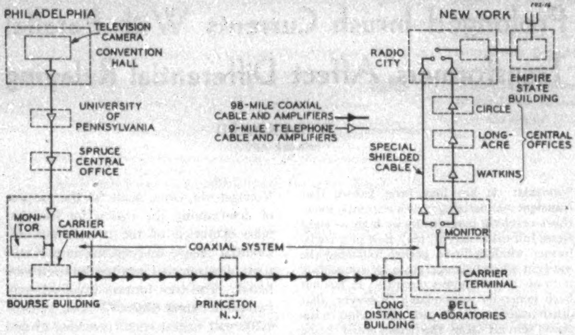

Figure 16. Map of New York-Philadelphia network

shown in the photograph, figure 12. The one on the right is a transmitting terminal, the two on the left receiving terminals. Each terminal occupies one six foot relay rack bay and is complete with power supply and means for adjustment.

Short Haul Lines for Television

For the pickup or transmission of television within cities or metropolitan areas, it appears to be more economical, as would be expected, not to use the carrier method described above but to transmit "video" frequency signals over cable circuits. For this purpose existing telephone cables may be used or special cables may be provided. In either case amplifiers and special equalizers are required which will overcome the attenuation and delay distortion of the cable circuits. Because of high frequency crosstalk usually only a small fraction of the circuits in any existing telephone cable can be used simultaneously.

Video Amplifiers and Equalizers

Television pickup and broadcasting equipment is quite naturally designed on an unbalanced (i.e. one side grounded) basis. Unbalanced amplifiers for the video band have been available for some time.[15] New amplifier designs have been worked out for use with balanced lines. In general, the problem is to provide approximately zero loss and constant delay between unbalanced terminals a mile or more apart. Thus, an unbalanced to balanced amplifier is required at the sending end, the converse at the receiving end. If the circuit is long, balanced amplifiers are most convenient for use at intermediate points. The equalization problem has been successfully met even if ordinary telephone cables are used. A series of variable equalizers have been experimented with which have several degrees of flexibility. A variety of circuits ranging in length up to 9 miles have been equalized with this arrangement with considerable success. A typical amplifier, equalizer, and power supply are shown in the photograph, figure 13.

Telephone Cables

Ordinary fine wire paper insulated cables have very high attenuation at the frequencies required. Typical values for loss and net loss after amplification and equalization are shown in figure 14. Experience has shown that the noise levels in such cables even at the higher video frequencies are rather high so that amplifiers are required at intervals of a mile or even less. Local telephone cables are usually laid out with many branches. At high frequencies these branches introduce irregularities which, similar to those produced by obstacles along a radio path, cause delay distortion. Plant changes are frequently required to obtain a clean circuit free from such bridged taps. When amplifiers and proper equalizers are added, however, substantially flat transmission is obtained as shown in the figure.

Phase distortion characteristics of a typical cable circuit are also shown in figure 14. After the amplifiers and equalizers are added, the phase distortion is made substantially negligible.

Coaxial Cables

Coaxial cables may be used for video transmission for short distances but power or other low frequency interference may introduce serious problems. Coaxial units of the size discussed above have been used in a few cases a mile or so in length. Even for such distances, however, it has been found desirable to reduce the power interference by balancing it out. One method which we have used is shown in figure 15. This has given an improvement at power frequencies of the order of 50 db in certain cases.

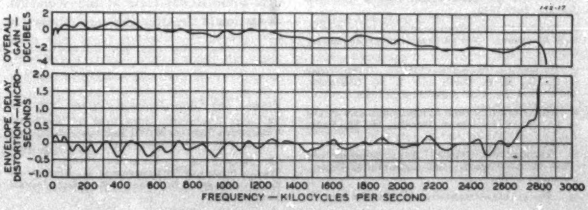
Balanced Shielded Cables

The ideal type of transmission line for video signals combines the balance feature with low attenuation and a high frequency shield. The distance over which such cables could be used appears to depend upon the perfection of balanced video amplifiers and the equalization, although power interference may also present difficulties. Such cables have been built using a pair of wires and a disc type of insulation analogous to the coaxial structure described above. Attenuation measurements on a 3-mile test length installed in New York City are shown in figure 14. This figure also shows the net result after amplifiers and equalizers were added. The attenuation of this special type of cable is such that amplifiers would be required at only about 5-mile intervals. The useful range of such a cable for video transmission has not been determined but in any case it should be considerably greater than that of the paper-insulated telephone cable circuit.

Experiment in Network Broadcasting

During the last week of June 1940, the proceedings of the Republican Convention in Philadelphia were broadcast in New York by television. The facilities

Figure 17. Attenuation and delay—New York-Philadelphia network



used included the 3-megacycle coaxial system plus certain video connections at each end as shown in figure 16.

Because of the interest in this circuit and its good performance in transmitting 441-line television, the overall attenuation and delay characteristics are given on figure 17. It will be noticed that a net band of about $2^{3}/_{4}$ megacycles was transmitted and that over most of that band the delay distortion did not exceed ±0.2 microsecond. The random noise, modulation, and other distortions introduced by the wire line network appeared to be unimportant when viewed on a commercial television receiver.

Conclusion

The experiments so far made in the transmission of present-day television indicate that wire lines can be provided at least for moderate size intercity networks, also, that such lines if properly equalized for delay and attenuation do not materially alter or distort the transmission of present-day 441-line images, even though the frequency band is somewhat narrower than the nominal 4-mc band.

The use of ordinary telephone cables for local television connections also has been found to be feasible for all of the conditions so far tested. The $2^{3}/_{4}$ mc television transmission experiments over wire lines reported herein have proved very successful. Experiments with wider band coaxial systems are being undertaken.

Prolonged Inrush Currents With Parallel Transformers Affect Differential Relaying

C. D. HAYWARD
MEMBER AIEE

Synopsis: It has long been known that transient magnetizing inrush currents, sometimes reaching magnitudes as high as eight times full-load current, may flow in a transformer winding for a period following the moment when it is energized by connecting it to an electric power circuit.[1] It has not been generally appreciated, however, that other transformers already connected to the power circuit near the transformer being switched may also have transient magnetizing currents of considerable magnitude at the same time, although they themselves are not switched but remain continuously connected to the power circuit, carrying load. It has not been appreciated, moreover, that with this arrangement the transient periods of the inrush currents may be very long, the currents dying away at a much slower rate than would the inrush current of the transformer being switched if the others were not connected. This paper discusses the cause of these phenomena and describes tests made to investigate their occurrence. The results of a mathematical analysis for the currents in the circuit under various conditions, supporting and extending the test results, are given in the appendix. The amount of resistance in the transmission line circuit connecting the parallel transformers with the generating source is shown both by tests and mathematics to be a determining factor; the magnitude of the inrush current in the already connected transformers increasing to values of over twice full load current as the line resistance increases.

Magnetizing inrush currents tend to operate the transformer differential relays, causing the circuit breakers to trip and remove the transformer from service when no fault exists within it. Various means have been devised to prevent the operation of the relays on magnetizing inrush current. This paper discusses the effectiveness of these various means when subjected to the inrush currents occurring with parallel-connected transformers, with particular reference to the harmonic restraint relay described in a recent paper.[2]

Ohio Edison Company Tests

In some recent tests at the Wood St. station of the Ohio Edison Company in Youngstown, Ohio, made for the purpose of determining the reason for frequent false operation of the transformer differential relays, magnetizing inrush currents of extremely long time duration were found. The transformers involved were two similar three-phase, 60 cycle, 23,000/2,300 volt banks, each consisting of two 3,333 kva single-phase transformers connected in open-delta. The two banks were connected in parallel to busses on both the high and low voltage sides. Load was fed from the 2,300 volt bus, while the 23 kv bus was supplied through two transmission lines, each of which led back to generation over a network of lines having an equivalent single-line length of about five miles. The oscillogram figure 1 was taken during a light load period with only one of the two lines feeding the station in service. One transformer bank was in use, carrying about 20 per cent normal load. The other transformer bank was switched on the 23 kv bus with its 2,300 volt side open. The three traces on the oscillogram show the three phase currents in the 23 kv line feeding the bus. The currents are magnetizing inrush currents to the two transformer banks superimposed on the 20 per cent normal load current being carried by the first bank. The currents decay at a very slow rate;

(Lower three traces are a continuation of the upper three)

Figure 1. Long duration magnetizing inrush currents obtained with parallel transformer banks at Wood Street station of the Ohio Edison Company

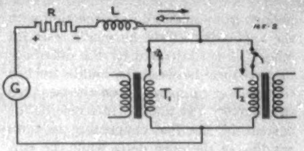

Figure 2. Schematic diagram of circuit used in laboratory tests

the magnetizing inrush components at the end of the oscillogram, 66 cycles after the second bank was switched on, are still of nearly full-load current magnitude. Other oscillograms taken with the first bank disconnected from the bus while the second was switched on showed magnetizing inrush currents of much shorter duration, the rate of decay as measured from the oscillograms being over ten times as fast. The time constant as measured from the oscillograms was 1.68 seconds when the parallel transformer was connected compared with 0.166 second when it was not connected.

Laboratory Tests

Following the Ohio Edison Company tests the occurrence of inrush currents in parallel transformers was extensively investigated in the General Electric Company laboratories. In one series of tests, two identical single-phase, 333 kva, 60 cycle, 13,800/460 volt transformers were used in a circuit shown schematically in figure 2. For convenience, connection was made to the 460 volt windings of the transformers from a 500 volt source. With one transformer already connected to the source, the second was switched in parallel with it by means of a synchronous closing switch set to close at the zero point of the voltage wave to obtain maximum inrush current. In addition, the direction and magnitude of the residual core flux in the transformer being switched was fixed before each test by passing a direct current through the transformer winding for a short period. The oscillogram figure 3*A* is representative of a series taken with no load on either transformer. The trace of vibrator No. 2 shows that an inrush current flows in the transformer being switched as would be expected. The trace of vibrator No. 3 however, shows that an inrush current having a maximum amplitude about one-third as great flows in the transformer which is already connected. The inrush current peaks in the two transformers occur on alternate half-cycles and are oppositely directed as is verified by the wave of the current in the incoming line traced by vibrator No. 4.

The amount of resistance in the incoming line circuit was found to be a great factor in determining the magnitude of the inrush current in the transformer already connected. Curves showing the variation of the maximum amplitude of the currents in the two transformers with change in line-circuit resistance are shown in figure 4. It should be noted that increasing the line resistance rapidly increases the maximum current in the already connected transformer up to a certain point after which it increases at a much slower rate with further increase in resistance. The maximum crest occurs at increasingly early current cycles as the resistance is increased as is indicated by the cycle number marked for each observed point. Other curves drawn in broken lines on the diagram show the crest amplitudes of the current at various numbered cycles after the start of the transient. These show that the two currents have the same amplitude after the first few cycles and die away at the same slow rate. This indicates a current composed of the direct current and even harmonic components circulating in the loop circuit of the two transformer windings without flowing in the incoming line. The slow decay is due to the very low R/L ratio of this circuit owing to the high magnetizing inductance of the transformer. Due to saturation of the core by the direct current the effective inductance is not as high as would be indicated by calculation from exciting current measurements made at normal voltage without the direct current. Calculations made from the rate of decay measured on the oscillograms indicate an effective inductance of only about 2.5 per cent of this value. Even with this great reduction, however, the inductance is still high enough to cause the rate of decay to be very slow. On one test made with a long oscillograph film the inrush current was found still to have a crest value equal to the crest value of a sine wave current of 30 per cent full-load magnitude after 150 cycles.

Increasing the inductance of the incoming line circuit has little effect except to reduce the magnitudes of both the inrush currents.

Increasing the resistance of the transformer loop circuit rapidly reduces the magnitude of the inrush current in the transformer already connected and increases the rate of decay of the circulating current. This represents the case of two parallel transformers separated by an appreciable length of transmission line instead of being connected directly to the same bus.

Loading the transformer already connected to the bus reduces the inrush current to it by only a small amount while affecting current in the transformer being switched even less. The oscillogram figure 3*B* shows a test made under the same conditions as for oscillogram figure 3*A* except that a steady resistance load equal to 87.5 per cent of rating was applied. The trace of vibrator No. 3 shows the inrush current superimposed on the load current. In a differential relay circuit, of course, the load current would be subtracted and the inrush current would appear alone.

A series of three-phase tests was made with small transformers connected in various delta and wye combinations to determine if any new phenomena not shown by the single-phase tests would be found. In particular, it was thought possible that some switching sequence and timing might set up a circulating current in a single delta-connected bank. No such effect was found, however, although extensive tests were made on delta-delta, wye-wye, delta-wye, wye-delta, and open-delta connections both with and without the neutral points grounded. When a three-phase transformer is switched in parallel with another three-phase transformer the long time constant circulating current is set up between corresponding phase windings in the two transformers in the same way as for single-phase transformers. When delta or open-delta primary connections are used the two delta-winding inrush currents combine to form a line current having a different wave form because of cancellation of certain harmonic components. This will be explained in more detail in connection with the application of the harmonic restraint relay. It is illustrated by the difference in wave form between the middle trace in the oscillogram figure 1 and the two outside traces. The middle trace records the current in the line connecting to both winding of the open delta while the outside traces record the single winding currents in the other two lines.

Cause of Phenomenon

The cause of this phenomenon, as first suggested by Mr. L. F. Blume, may be explained by reference to the diagram figure 2. Before the switch is closed the generator G sends a steady-state alternating current through the transmission line and the winding of transformer T_1. When the switch is closed, connecting transformer T_2, a magnetizing inrush current is drawn through the generator, transmission line, and the T_2 winding having a direct current component whose magnitude and direction depend on the point of the voltage wave at which the switch is closed. For the present discussion it may be assumed to be in the direction indicated by the solid arrows on the diagram. This direct current component produces a d-c IR drop voltage across the total resistance R of the transmission line and generator circuit having a polarity indicated by the plus and minus signs. This voltage, being applied to the winding of transformer T_1, causes a direct current to begin flowing through the circuit made up of the generator, transmission line, and the winding of transformer T_1 in series, the direction of which is indicated by the dotted arrows. This current increases at a rate determined by the IR drop voltage, and the R/L ratio of the circuit in which it flows. At the same time, the IR drop voltage, acting in the circuit consisting of transformer T_2, the transmission line, and the generator, causes the current indicated by the solid arrows to decrease at a rate determined by the R/L ratio of this circuit. After a time the two currents become substantially equal, and since they flow in opposite directions in the transmission line, they cancel each other and produce no more drop across the line resistance. The two currents then become substantially a single circulating current, flowing around the loop circuit made up of the two transformer windings in series and slowly dying away at a rate determined by the R/L ratio of the transformer windings.

The flow of direct current in the transformer windings causes the cores to become saturated in one direction. As a result the a-c exciting current becomes unsymmetrical, being greatly increased due to saturation of the iron on the half-cycles in which the transformer core flux required to support the a-c voltage is in the same direction as the flux produced by the direct current and being reduced practically to zero on the intermediate half-cycles when the two fluxes are in opposite directions. Since the direct current flows in opposite direction in the two windings, the cores become saturated in opposite directions and hence the current peaks in the two windings occur on alternate half-cycles.

Relay Application

Induction relays, of either the percentage-differential or overcurrent types, are most commonly used for differential protection of transformer banks, particularly banks of low kva rating. These depend on current setting and their inherent time-delay operation to ride over the magnetizing inrush period without tripping. This is quite satisfactory for general applications where parallel transformers are not involved and where the moderately long time delay operation introduced on internal faults is of no great importance either from the point of view of increased damage to the equipment or of system stability. Where parallel transformers are involved, however, the extremely long-time and high-current settings necessary to prevent operation on the long duration magnetizing inrush currents may reduce the protection afforded so seriously as to make it practically ineffective. In some cases it will be found that the maximum time setting available on standard relays is insufficient to prevent the tripping.

Several methods of preventing operation on magnetizing inrush, applicable to high speed relays, have been devised. These involve the use of auxiliary relays, operating on the transformer voltage, which in effect desensitize the differential relays sufficiently to prevent tripping on the inrush current during a set time delay period following the application of voltage to the transformer. Any of these methods would obviously be ineffective in preventing operation on inrush current flowing in the transformer already connected to the bus when the second transformer is switched on since, with voltage continuously applied to the transformer before and during the inrush period, the voltage relays cannot reset and apply the desensitization. The differential relays, with the inrush-trip-preventing device inoperative, are unable to distinguish between the inrush current and an internal fault current of equal magnitude. As a result, then, in a transformer station having two or more transformers connected to a common bus, switching one transformer on the bus might cause all the others to be tripped out, completely dropping the load on the station.

The harmonic restraint type transformer differential relay, in contrast with the others described, is admirably well suited for the protection of parallel banks. This relay, described in a recent paper,[2] is able to distinguish between the differential current due to an internal fault and that due to magnetizing inrush by their difference in wave form, operating with high speed on the fault current and being reliably restrained from operating by the magnetizing inrush current. The current due to an internal fault is nearly sinusoidal in wave form, containing little or no harmonic components. The magnetizing inrush currents, on the other hand, as may be seen from the oscillogram figure 3A, are nonsinusoidal, containing, in addition to the fundamental, large proportions of harmonics, principally the second and third. The fundamental component tends to operate the relay while the harmonic components tend to restrain it. Operation occurs only when the harmonic percentage is below the minimum amount occurring in magnetizing inrush currents. The harmonic restraint is effective as long as the magnetizing inrush current lasts, hence the relay will not operate on the magnetizing inrush current no matter how long it lasts, yet it is instantly ready at all times to operate on internal fault currents.

In the application of harmonic restraint relays to parallel transformers each transformer bank should, in general, be protected by a separate set of relays. The practice sometimes followed in the past of including two or more parallel transformers within a single differential zone with one set of relays may result in magnetizing inrush tripping due to cancellation of both the second and third harmonics in the differential current. When a delta or open-delta connection of the transformer primary winding or a delta connection of the current transformers is employed cancellation of the third harmonic occurs due to combination of the delta currents in the line. In the worst case, when the switch is closed at such a point on the voltage wave that equal inrush currents of opposite polarity occur in two of the windings, complete cancellation of the third harmonic occurs and the second is reduced to 57.7 per cent of its percentage in the winding. The harmonic

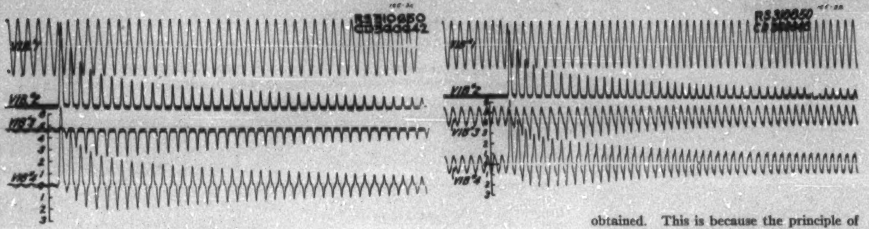

Figure 3. Oscillograms obtained in laboratory tests

Vibrator 1—Transformer bus voltage

Vibrator 2—Primary current in transformer T_2 being switched on bus

Vibrator 3—Primary current in transformer T_1 already connected to bus

Vibrator 4—Current in line. Calibration scale in multiples of one transformer full-load current crest amplitude

For these tests the line resistance was 0.0165 ohm, transformer T_1 resistance, 0.0026 ohm, transformer T_2 and switch resistance, 0.0034 ohm. The line inductance was 0.00005 henry, while the effective inductances of transformers T_1 and T_2 calculated from exciting current at normal voltage were 0.045 and 0.054 henry, respectively

Oscillogram *A* (left)—No load

Oscillogram *B*(right)—Resistance load of 87.5 per cent normal rating on transformer T_1

restraint setting of the relay is such, however, that even with this reduced amount of harmonic current reliable restraint is obtained. If in addition, however, the two transformer banks are included within the same differential zone, cancellation of the second harmonic occurs in the latter part of the transient, due to combination of the inrush currents to the two banks, since these two currents are opposite in polarity and differ 180 degrees in phase position. The center trace on the oscillogram figure 1 shows the nearly sine-wave form assumed by the current when both these effects occur together. If the power transformers are wye-wye connected and the current transformers are also wye-connected, the third harmonic is not lost and may be relied on to restrain relay operation alone if a slightly lower harmonic restraint setting than the normal 25 per cent is used. In this case it would be permissible to include both transformers within the same zone with one set of relays if desired. With only one set of relays, of course, a fault in either transformer will require both to be removed from service.

Conclusions

1. When a transformer is switched on an electric power circuit in parallel with one or more other transformers at a point some distance from the system generators, magnetizing inrush currents of considerable magnitude flow, not only in the transformer being switched but also in the other parallel transformers. (By "parallel" it is meant that the transformers are connected to the same power circuit on the side being switched. The other windings of the transformers may or may not be paralleled.)

2. The magnitude of the inrush current in the parallel transformers not being switched increases as the equivalent resistance of the transmission line circuit connecting the parallel transformers to the generators is increased.

3. Line inductance has little effect except to reduce the magnitudes of all the inrush currents.

4. Load carried by a parallel transformer does not prevent the inrush currents from flowing in its winding although the magnitude is slightly reduced and the rate of decay somewhat increased.

5. Induction type percentage-differential or overcurrent relays commonly used for transformer differential protection may be unsatisfactory when applied to parallel transformers because of the high current and long time settings necessary to prevent tripping on the long-duration magnetizing inrush currents.

6. High speed differential relays using transformer-voltage-operated auxiliary relays to prevent tripping on magnetizing inrush are unsatisfactory for application to parallel transformers under conditions where the inrush currents described occur because the inrush-trip-preventing device is inoperative on the transformers not being switched.

7. The harmonic restraint transformer differential relay is well suited to the protection of parallel transformers giving high speed sensitive operation on internal faults while being reliably restrained from operating on the long-duration magnetizing inrush currents, provided only one transformer is included within the differential zone.

Appendix

Mathematical Analysis

An accurate mathematical solution for the currents flowing in the various circuit branches, including the effect of saturation of the transformer cores, cannot readily be obtained. This is because the principle of superposition on which the methods of the operational calculus,[3] commonly used for the solution of circuit problems, are based does not apply when the circuit inductances vary with changes in current magnitude, as is the case when core saturation occurs. An analysis has been made, however, assuming the inductances to remain constant. The results of this analysis are given below. While admittedly not giving the current magnitudes and wave forms accurately, these results do show in a general way the steady-state and transient current components present in the various branches and indicate the way in which the magnitudes and time-constants of these components depend on the inductances and resistances of the various circuit branches. The analysis is thus an aid in visualizing and understanding the phenomena observed in test as well as in qualitatively predicting the effects of circuit changes not covered by tests.

General Formulas

The current in transformer T_1 already connected to the bus:

$$\begin{aligned} i_1(t) = E\Bigg[& \frac{1}{Z_1}\sin\,(\omega t+\theta-\beta)+ \\ & K_{11}\sin\,(\omega t+\theta-\alpha_1)+K_{12}\sin\,(\omega t+\theta-\alpha_2)- \\ & K_{11}\sin\,(\theta-\alpha_1)\epsilon^{-b_1t}-K_{12}\sin\,(\theta-\alpha_2)\epsilon^{-b_2t}\Bigg] \end{aligned}$$

The current in transformer T_2 being connected:

$$\begin{aligned} i_2(t) = E\Bigg[& -K_{21}\sin(\omega t+\theta-\alpha_1)- \\ & K_{22}\sin\,(\omega t+\theta-\alpha_2)+ \\ & K_{21}\sin\,(\theta-\alpha_1)\epsilon^{-b_1t}+K_{22}\sin\,(\theta-\alpha_2)\epsilon^{-b_2t}\Bigg] \end{aligned}$$

The current in the line:

$$\begin{aligned} i_0(t) &= i_1(t)+i_2(t) \\ &= E\Bigg[\frac{1}{Z_1}\sin\,(\omega t+\theta-\beta)+ \\ & (K_{11}-K_{21})\sin(\omega t+\theta-\alpha_1)+ \\ & (K_{12}-K_{22})\sin\,(\omega t+\theta-\alpha_2)- \\ & (K_{11}-K_{21})\sin\,(\theta-\alpha_1)\epsilon^{-b_1t}- \\ & (K_{12}-K_{22})\sin\,(\theta-\alpha_2)\epsilon^{-b_2t}\Bigg] \end{aligned}$$

These are the currents which flow after the switch is closed, assuming that the voltage on the bus is $E\sin\,(\omega t+\theta)$ previous to the closing of the switch at time $t=0$.

$$Z_1=\sqrt{R_1^2+(\omega L_1)^2}$$

$$\beta=\tan^{-1}\frac{\omega L_1}{R_1}$$

$$K_{11}=\frac{R_0-L_0b_1}{Bb_1-2C}\cos\alpha_1$$

$$K_{11}=\frac{(R_0+R_1)-(L_0+L_1)b_1}{Bb_1-2C}\cos\alpha_1$$

$$K_{12}=\frac{P_0-I_0b_2}{Bb_2-2C}\cos\alpha_2$$

$$K_{22}=\frac{(R_0+R_1)-(L_0+L_1)b_2}{Bb_2-2C}\cos\alpha_2$$

$$\alpha_1=\tan^{-1}\frac{\omega}{b_1}$$

$$b_1=\frac{B}{2A}-\sqrt{\left(\frac{B}{2A}\right)^2-\frac{C}{A}}$$

$$\alpha_2=\tan^{-1}\frac{\omega}{b_2}$$

$$b_2=\frac{B}{2A}+\sqrt{\left(\frac{B}{2A}\right)^2-\frac{C}{A}}$$

$$A=L_0L_1+L_1L_2+L_2L_0$$

$$B=R_0L_1+R_0L_2+R_1L_2+R_1L_0+R_2L_0+R_2L_1$$

$$C=R_0R_1+R_1R_2+R_2R_0$$

L_0 and R_0 are respectively the total equivalent inductance in henries and the total equivalent resistance in ohms of the transmission line and generation circuit supplying the transformer bus. L_1 and R_1 are the magnetizing inductance and resistance of transformer T_1. L_2 and R_2 are the magnetizing inductance and resistance of transformer T_2.

Case of Two Identical Transformers

These general formulas appear rather complicated but if the assumption is made that the two transformers are identical a great simplification results.

Placing $R_2=R_1$ and $L_2=L_1$ we find that the equations for the currents become:

$$i_1(t)=E\left[\frac{1}{2Z_1}\sin(\omega t+\theta-\alpha_1)+\frac{1}{2Z_{01}}\sin(\omega t+\theta-\alpha_2)+\frac{1}{2Z_1}\sin(\theta-\alpha_1)\epsilon^{-\frac{R_1}{L_1}t}-\frac{1}{2Z_{01}}\sin(\theta-\alpha_2)\epsilon^{-\frac{2R_0+R_1}{2L_0+L_1}t}\right]$$

$$i_2(t)=E\left[\frac{1}{2Z_1}\sin(\omega t+\theta-\alpha_1)+\frac{1}{2Z_{01}}\sin(\omega t+\theta-\alpha_2)-\frac{1}{2Z_1}\sin(\theta-\alpha_1)\epsilon^{-\frac{R_1}{L_1}t}-\frac{1}{2Z_{01}}\sin(\theta-\alpha_2)\epsilon^{-\frac{2R_0+R_1}{2L_0+L_1}t}\right]$$

Where:

$$Z_{01}=\sqrt{(2R_0+R_1)^2+\omega^2(2L_0+L_1)^2}$$

$$\alpha_1=\tan^{-1}\frac{\omega L_1}{R_1}=\beta$$

$$\alpha_2=\tan^{-1}\frac{\omega(2L_0+L_1)}{(2R_0+R_1)}$$

Both α_1 and α_2 will be very close to 90 degrees in practical cases.

The transient components of the currents are shown to consist of two parts: one, a current circulating around the loop formed by the two transformer windings in series without flowing in the transmission line as evidenced by the form of the exponent of the first exponential term:

$$\frac{R_1}{L_1}=\frac{R_1+R_2}{L_1+L_2}$$

and the other a current flowing in the circuit consisting of the transmission line and generator in series with the two transformer windings in parallel as shown by the exponent of the second exponential term:

$$\frac{2R_0+R_1}{2L_0+L_1}=\frac{R_0+\dfrac{1}{\dfrac{1}{R_1}+\dfrac{1}{R_2}}}{L_0+\dfrac{1}{\dfrac{1}{L_1}+\dfrac{1}{L_2}}}$$

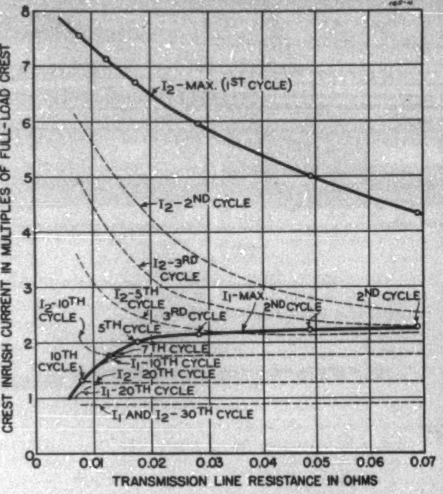

Figure 4. Variation of magnetizing inrush current crest values with line resistance

Measured from oscillograms similar to figure 3*A*. Circuit constants except for line resistance same as for figure 3*A*

I_1—Current in transformer T_1 already connected

I_2—Current in transformer T_2 being switched

This may be proved by solving for the circulating current:

$$\frac{i_1(t)-i_2(t)}{2}=\frac{E}{2Z_1}\sin(\theta-\alpha_1)\epsilon^{-\frac{R_1}{L_1}t}$$

and for the line current:

$$i_1(t)+i_2(t)=E\left[\frac{1}{Z_1}\sin(\omega t+\theta-\alpha_1)+\frac{1}{Z_{01}}\sin(\omega t+\theta-\alpha_2)-\frac{1}{Z_{01}}\sin(\theta-\alpha_2)\,\epsilon^{-\frac{2R_0+R_1}{2L_0+L_1}t}\right]$$

An important difference between this equation for line current and the actual trace of the line current shown by vibrator No. 4 on the oscillogram figure 3*A* should be noted here. The oscillogram shows the effect of the long time constant circulating current, whereas the equation does not contain the circulating current transient term. This difference is due to the assumption made in the analysis that the circuit inductances remain constant. Actually the variation in the transformer inductances caused by the circulating current causes a variation in the magnitudes of the steady-state terms which has the appearance of a transient.

It is interesting to note that the circulating current, both with respect to magnitude and rate of decay, is entirely independent of the characteristics of the transmission line circuit, being determined solely by the inductance and resistance of the transformers themselves in conjunction with the initial bus voltage, the frequency, and the switching angle.

The two transient current components in the expression for $i_1(t)$ have opposite signs whereas in the expression for $i_2(t)$ they have the same sign. In practical cases the amplitudes are nearly equal but the rates of decay may be quite different, depending largely on the magnitude of R_0 in comparison with R_1, since L_0 is small compared with L_1. Curves of the two transient current components are shown in figure 5 together with the curve of their sum which represents the total transient current in the transformer T_2 being switched and the curve of their difference which represents the total transient in the parallel transformer T_1. The latter curve has been drawn in the inverted position above the zero axis rather than in its true position below the zero axis to conserve space. The close correspondence between the forms of these curves and the forms of the direct current components of the actual currents shown by the oscillogram figure 3*A*, or of curves drawn through their maximum values, should be noted.

The reason for the dependence of the current in the two transformers on the resistance in the transmission line is now apparent. If R_0 becomes very large Z_{01} increases so that the amplitude is reduced. At the same time the exponent $(2R_0+R_1)+(2L_0+L_1)$ becomes very large and the rate of decay becomes very fast. In the limit the current in both transformers would approach the value of the circulating current alone, assuming the initial voltage could be applied to the bus through the high resistance transmission line. At the other limit is the case where both R_0 and L_0 approach zero. This is the case of a generator directly connected to the transformer bus with no intervening transmission line. In this case the two transient current components approach equality both in amplitude and rate of decay. The transient current in the transformer being switched approaches double its value at the end of the high resistance line while the transient current in the parallel transformer approaches zero.

CASE OF TRANSFORMERS OF UNEQUAL SIZE OR MORE THAN TWO TRANSFORMERS

The case of transformers of unequal size may be investigated by substituting:

$R_2 = mR_1$
$L_2 = mL_1$

in the general equations, where m is a constant which may take any positive value, either greater or less than unity. This substitution assumes that as the size of the transformer varies the ratio of its resistance to inductance remains constant. This assumption does not hold strictly in practice; in general the ratio of resistance to inductance tends to become smaller as the size of the transformer increases. The great simplification of the general equations obtained by this substitution, however, seems to justify examining the results obtained even though it is understood that they apply in the strict sense only to a special case. The trend of effects to be expected when the R/L ratio varies over the range normally found in practice can be deduced therefrom without too great error. The effects produced when several transformers are already connected to the bus when one is being switched on can be approximated by combining their resistances and inductances to obtain the equivalent resistance and inductance of a single transformer. This approximation should be reasonably close if the transformers do not differ greatly in their R/L ratios. The results of the substitution are as follows:

$$i_1(t) = E\left[\frac{m}{(1+m)Z_1}\sin(\omega t+\theta-\alpha_1) + \frac{m}{(1+m)Z_{0m}}\sin(\omega t+\theta-\alpha_m) + \frac{1}{(1+m)Z_1}\sin(\theta-\alpha_1)\epsilon^{-\frac{R_1}{L_1}t} - \frac{m}{(1+m)Z_{0m}}\sin(\theta-\alpha_m)\epsilon^{-\frac{(1+m)R_0+mR_1}{(1+m)L_0+mL_1}t}\right]$$

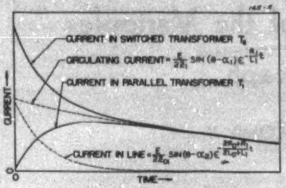

Figure 5. Transient current components as derived by mathematical analysis

$$i_2(t) = E\left[\frac{1}{(1+m)Z_1}\sin(\omega t+\theta-\alpha_1) + \frac{1}{(1+m)Z_{0m}}\sin(\omega t+\theta-\alpha_m) - \frac{1}{(1+m)Z_1}\sin(\theta-\alpha_1)\epsilon^{-\frac{R_1}{L_1}t} - \frac{1}{(1+m)Z_{0m}}\sin(\theta-\alpha_m)\epsilon^{-\frac{(1+m)R_0+mR_1}{(1+m)L_0+mL_1}t}\right]$$

where:

$$\alpha_m = \tan^{-1}\frac{\omega[(1+m)L_0+mL_1]}{(1+m)R_0+mR_1}$$

$$Z_{0m} = \sqrt{[(1+m)R_0+mR_1]^2+\omega^2[(1+m)L_0+mL_1]^2}$$

and the other quantities have the same values as for the case of two equal transformers.

Consider first the case of a small transformer being switched on the bus in parallel with either a single large one or a number of transformers whose aggregate size is relatively large. For this case m has a value greater than unity in the equations. Examining the first transient term it is seen that the circulating current has the same rate of decay as before but its magnitude is greater in the ratio $2m/(1+m)$ than it would be if it were switched on in parallel with another equal small transformer. (The Z_1 used in the equations for two identical transformers becomes mZ_1 in making this comparison, since the impedance Z_2 of the small transformer is equal to mZ_1.) Examining the second transient term, which governs the transient current flowing through the transmission line and dividing between the two transformers in parallel, we see that the division of current between the transformers is in inverse ratio to their impedances as would be expected. The magnitude in each transformer is smaller in the approximate ratio of $2/(1+m)$ than it would be if the transformer were paired with one of equal size. (This assumes Z_{0l} approximately equal to Z_1 and Z_{0m} approximately equal to mZ_1 which is permissible since the magnetizing reactance ωL_1 appearing in the impedance expressions is large compared with the line reactance and the resistances.) The rate of decay is modified, having a value between the values it would have for two equal transformers of the smaller size and that for two equal transformers of the larger size supplied from the same transmission line circuit. The net result is that the maximum amplitude of the total transient current in the small transformer being switched is about the same as it would be if switched in parallel with another of equal size while the amplitude of the current in the large transformer is less in the approximate ratio of $2/(1+m)$ than it would be if another equally large transformer were switched in parallel with it.

Consideration of the case of a large transformer being switched on in parallel with a small one, in which case the value of m is less than unity, leads to the conclusion that the maximum amplitude of the transient current in the small transformer is larger in the approximate ratio of $2/(1+m)$ than it would be if both transformers were small. This ratio approaches the value 2 as m approaches zero, which means that the d-c transient current approaches the magnitude it would have if the small transformer were switched on the line without the other transformer being connected. The maximum amplitude of the total transient current in the large transformer is about the same as it would be if the transformer were switched on in parallel with another of equal size but the rate of decay is faster; approaching the rate it would have if the transformer were switched on the line alone, without the presence of the smaller transformer; when m approaches zero.

Basic Principles of the Varioplex Telegraph

PHILO HOLCOMB, JR.
MEMBER AIEE

Synopsis: A new kind of channel-sequencing system allots the full capacity of a telegraph circuit to the busy channels alone. A busy channel cuts itself out of its sequential position by becoming idle but may re-enter the sequence at will by offering one letter for transmission. Entry, mixing, and exit are accomplished by electromechanical control of standard start-stop and multiplex printing telegraph apparatus. Special signal or code combinations are used to denote changes in the pattern of subchannels cut in, and to act as a check on correct distribution. For greater efficiency, ordinary message letters, by a new method, may be interspersed among successive elements of switching combinations, and the cascading of combinations is also employed. Dummy channels, high-speed receivers, and other devices may be used to prevent or utilize unusual channel speeds. Varioplex systems may be repeatered either by subchannel storage or by storage involving several subchannels handled as a unit.

In the time-division multiplex telegraph the channels form fixed component parts of the lane of traffic over which they operate. There is a great convenience in channeling but it is necessary to assign multiplex channels with care because idle channels secure and waste their proportion of lane time, and channels with practical speeds are limited and precious.

The varioplex is a new kind of channel-sequencing system which permits channeling without waste of lane time. It secures this result by allotting the capacity of the lane to working channels only, so long as those channels have anything to send. The application of the new system to the Western Union telegraph plant is described in a companion paper;[1] it is the province of the present treatment to outline the general principles of varioplex theory.

Analogy of Capacity

Since comprehension of the purpose and underlying principles of the varioplex is facilitated by analogy, an examination of the theory of operation of an easily understood form of varioplex will be preceded by reference to two forms of physical transportation.

Figure 1 illustrates analogies for single channel, multichannel, and expanding or variable channel telegraph systems, in the form of paint factories connected to packaging plants by pipe lines. In the first instance it is assumed that the factory manufactures blue paint only. Its single pipe is large enough to carry the entire factory output without congestion. The cross section of the first pipe shown at the right-hand side of figure 1 reveals that the pipe is completely filled, but carries only blue.

Assume that although transmission of one color through one pipe is satisfactory, the factory wishes to diversify the same output among five colors. Under certain conditions the colors might be sequenced through the single pipe, intercolor swabs (corresponding to addresses on telegrams, or machine-switching combinations) being used to remove residues. In the present case, however, assume that ever-open channels are required. Four additional pipes are installed, as shown in the middle figure, each having the same capacity as the original pipe. As the cross sections indicate, the price paid here for the convenience of separate channeling is a tremendous increase in unutilized capacity. Under similar conditions there would be a corresponding increase in unutilized wire capacity if a printer channel capable of handling the traffic of five Chicago branch offices were to be supplemented by four additional similar channels between New York and Chicago in order that the branch offices might be served directly from New York.

The lower part of figure 1 is an analogy for the expanding channel or varioplex system. A single pipe is equipped with five thin flexible partitions which expand as far as they can while in use and collapse when empty. The capacity of the pipe is in this way divided among the channels which are in use, and if we assume that the shell of the pipe is large enough to carry the output of the factory, we automatically rule out all chance of delay at the factory end, or point of dispatch. In similar fashion does the lane of a varioplex operate at full capacity until devoid of load, and if this capacity is not exceeded by the combined load there can be no delay on any channel. This is true even when the traffic is so diverse that all channels are in use at once and the volume handled per channel per unit of time correspondingly low.

Analogy of Sequence

Figure 2 is an analogy for a multiplex in the form of a belt conveyor carrying alphabet cards from three transmitting positions on the right to three receiving positions on the left. The sending dealer (or distributor) works downward, picking up one card from a channel at a time. The receiving dealer distributes the cards as they arrive in a similar manner and in proper sequence. The letters on the belt in figure 2 seem to be badly jumbled but if the reader will substitute himself for the receiving dealer he will find them forming the correct words and sentences as soon as they are put into the proper channels.

If we assume, as in figure 3, that channel 3 has been closed out before its sentence, "PACK MY BOX," had been started through the conveyor, nothing but blank cards would be available at the third channel for the sending dealer to put on the belt. The belt thus carries alphabet cards for channels 1 and 2, and blank cards for channel 3. Numerals have been drawn above the letters in the diagram to indicate their respective channels. The receiving dealer, proceeding in sequence, must lay down blank cards as well as "live" cards in channel order as they arrive. This simple system, corresponding to the multiplex, would at such times waste one-third of the total lane space.

If the belt conveyor were operated on the varioplex principle, as in figure 4, the sending dealer would note the stoppage of transmission on channel 3 and throw a single blank card on the belt to indicate it. Thereafter he would skip channel 3 and would send out cards from channels 1 and 2 exclusively. When the blank card arrives at the receiving end, the dealer there is to be imagined as distributing it in regular sequence to the third channel, as shown in figure 5. The receiving dealer interprets such a card as an indication of the closure of channel 3 and proceeds to skip that channel in the future.

Paper 41-20, recommended by the AIEE committee on communication, and presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941. Manuscript submitted November 13, 1940; made available for preprinting December 2, 1940.

Philo Holcomb, Jr., is general inspector of the traffic department, The Western Union Telegraph Company, New York, N. Y.

[1] For all numbered references, see list at end of paper.

The lane now carries the cards of channels 1 and 2 at a more rapid rate because the third channel's position on the lane is no longer claimed and held by a string of blank cards.

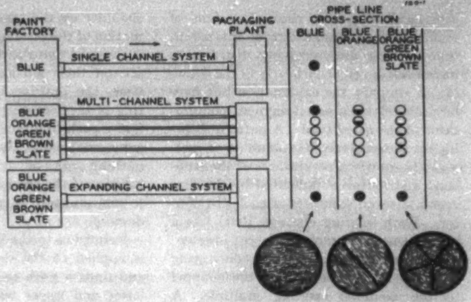

Figure 1. Pipe analogy to compare the efficiencies of single-channel, multichannel, and expanding-channel systems

At this point it is advisable to anticipate the ultimate re-entry of channel 3 because the sending dealer cannot start third channel cards without notice. To this end small numbers may be imagined as painted on the belt below the cards to represent the moments at which channels 1, 2, and 3, can be entered. This is shown in figure 6. These numerals are employed solely for the entry of channels and have no relation to the channel identity of the cards that happen to be above them.

The sending dealer now proceeds to enter channel 3 by putting a card marked "In" on the next space designated by "3" that the belt brings up. The arrival at the receiving station of such a card in such a position is the cue for the receiving dealer to pick up the blank card from the third channel and, having discarded both the blank and "In" cards, include that channel in future distributions.

Channel 3 has been used as an example but obviously the other channels of the varioplex can be entered, mixed, and cut out in similar fashion. The belt numbers in figure 6 can be dispensed with if the rims of the pulleys are numbered correspondingly. The transmission of special signals, corresponding to "In" cards at predetermined times, interspersed among regular signals, is an important feature of the varioplex system because the movement of traffic continues while additional channels are being entered and cut out.

Although the efficiency of a varioplex lane is not impaired by delay in entering it should be understood that entry is not instantaneous. However, on a 68-cycles-per-second varioplex lane 53 characters are transmitted every two seconds. Fifty-three channels could therefore be entered on such a lane in two seconds with an average entry delay of one second.

Methods of Entry and Exit

Another way of entering channels is to show a "pattern" of the channel cut-in situation, i.e., to transmit a group of signals representing the status of a group of channels. "In" channels may be represented by marking pulses and "Out" channels by spacing pulses of the pattern signals. The complete pattern can be shown at a prearranged time, say at the point "50 on the clock," and that point in time always reserved for it at both ends of the lane. This kind of entry will be described in detail when we come to figure 7. Another way of using the pattern is to introduce it into traffic by a special break-in signal, and in this case there is no delay at all in controlling the channels. Patterns may be cascaded by forming them into groups that enter on a time basis; after the group is selected a portion of the pattern is exhibited to reveal the change that is desired in the group. On the same 68-cycle per-second varioplex lane considered above, 55 channels could be entered by cascade in 11 groups with an average entry delay of a quarter of a second. Patterns may be confirmed by repeating them. "Code" entry is effected by following up the special break-in signal with regular Baudot code combinations which indicate the channel being changed. A break-in signal followed by one multiplex letter will immediately control any one of a group of 32 channels. Two kinds of control may be had from the same combination, the first appearance signifying entry, the second exit, the third entry again, and so on.

There are many methods of cutting channels of a varioplex in and out of operation, and sometimes it is expedient to use two methods in the same system. Thus, the periodic transmission of a pattern signal representing the channel situation does not preclude the use of a single exit signal when a particular channel is to be cut out. Double-exit means in such a case would be useful in improving the efficiency of the lane and the second exit would be a check on the first. The signals for altering channel distribution need not be sent on the circuit traversed by the traffic of those channels, in fact added secrecy can be obtained by having such signals sent over another route. The channel distribution can even be altered manually in response to signals or messages sent from one terminal to the other, and in many instances this is an economical and advantageous method of obtaining the benefits of the varioplex.

The selection of combinations for appropriation by the varioplex is a serious problem, because there are only 32 in the Baudot five-unit code and few of them can be spared for the purpose. The place of the one that is appropriated must be filled in such a way that there will be no difficulty when connecting various kinds of keyboards and printers to the varioplex channels. Provision must also be made to keep the traffic channels from sending switching combinations at significant times. A line failure may result in loss of channel synchronism, so the combination should be made difficult to obliterate and easy to check. With these characteristics a good combination will almost always come out of a lane in recognizable form and if it does not meet rigid requirements, alarms are set off or automatic means put into action to resynchronize.

In addition to the safety of special combinations, channels may be installed on a varioplex which have no other function than to open, send test signals, and close again. If such channels open at the proper time and the proper signal is received, it is practically certain that everything is in order. If checking channels are given slightly different periods on different circuits and directions, there will be immediate indication of channel mismating due to crossed or open line wires.

Entry and exit of channels presented difficulties of the first order in the early days of the varioplex, and for this reason the subject has been covered in the foregoing in some detail.

Simple Form of Varioplex

Figure 7 illustrates diagrammatically a simple form of varioplex operating over a seven-unit stop-start channel or lane of traffic. The commutators of the seven-unit sending and receiving distributors have been developed linearly in the drawing to simplify the explanation but may be replaced by a seven-segment commutator of the usual type. A pattern-showing revolution precedes a number of message-transmitting revolutions of the stop-start distributor as indicated by the first group of seven segments of each distributor. Each sending channel (left) has a tape autostop contact arm, a cut-in relay, a tape transmitter, and a sending gang relay for interconnection of the channel to the common sending multiple. A polar relay bank is connected to the sending multiple for storage of characters sent by the various channels. The tongues of the polar sending bank connect to the sending segments of the sending distributor. Pulses for local sending functions are obtained from a local ring on the sending distributor. On the receiving side (right), the pattern channel and message channels correspond to those on the sending side. Message channels on the receiving ring are multiplied to the coils of the receiving polar bank relays, and the tongues of these relays apply battery to the selecting magnets of a particular receiving device when its corresponding gang relay is operated. Both ends of the circuit are equipped with mixers to distribute local ring pulses in the correct order and thereby control the operating channels in rotation, the brush arm of each mixer having three stop positions in the case of three channels, as shown.

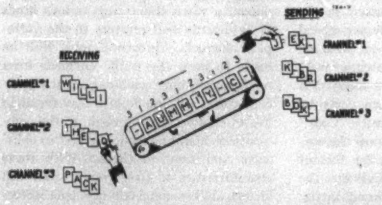

Figure 2. Belt-conveyor analogy for a three-channel time-division multiplex

The sentences under transmission are WILLIAM-JEX-QUICKLY - CAUGHT, THE - QUICK - BROWN-FOX, and PACK-MY-BOX. Dealers move from top to bottom

Let us assume that shortened tape loops have lifted the autostop arms on all sending channels and that the tongues of the sending polar bank are at rest on a certain combination, for example the all positive combination. When the brushes at both terminals are in the positions indicated, a circuit is established between negative and negative via the top sending segment, the line, the top receiving segment, and the receiving start magnet. As the receiving start magnet is not energized under these conditions, its armature is held to the right by its spring and a shoulder on the armature blocks further motion of the receiving brushes. Since it is assumed that the receiving cut-in relays are on their left-hand contacts at this time, the positive battery on the local ring of the receiving distributor does not find a path to ground through any of the gang relay coils, and as a consequence nothing can be transferred from the tongues of the receiving polar relay bank to the magnets of any of the receiving devices.

Returning to the sending end, positive is applied to the sending local segment and finds a path to ground through the lower and upper windings of the three sending cut-in relays. The upper winding of each of these relays is in opposition to its lower winding and overcomes it because of the greater number of turns. The polar relays in the diagram are wound in such a direction that current passing from right to left causes the armature of the relays to move from left to right, and vice versa. When all channels are cut out the tongues of the sending cut-in relays thus assume positions on their left-hand contacts and apply positive battery to the first three sending segments of the pattern channel and positive battery to the three segments of the sending mixer. The arm unit of the mixer tends to rotate at a speed somewhat faster than the speed at the sending distributor but it is frictionally connected to its shaft and can be stopped by the stop armature with the brush engaging any one of the three segments.

Under the assumed condition the sending mixer arm unit rotates freely because whenever the brush touches a segment, positive battery is immediately connected through the brush to the stop magnet and the stop armature is withdrawn from the path of the stop arms. As the sending brush moves downward, a start pulse of positive polarity is sent to the line. This energizes the start magnet at the receiving end, operates the stop armature of the receiving distributor, and permits downward movement of the receiving brushes over the segments of the pattern channel. While the receiving brushes are on their way to the next stopping point, three positive pulses are received and laid down on the three control segments of the pattern channel. This polarity maintains the tongues of the receiving cut-in relays on their left contacts. Positive battery is thus applied to all segments of the receiving mixer and its constantly energized magnet permits its brush arm unit to rotate freely without stopping. The sending brush of the sending distributor continues to advance at a uniform rate, sending rest, start, and all-positive channel pulses throughout its travel, while the receiving brush assembly proceeds through similar stages, laying down positive pulses on each of the channels in turn, which maintain the tongues of the receiving polar bank to the left.

Entry of First Channel

As messages accumulate on the first sending channel, additional tape is punched, and the slackness of the loop permits the autostop arm to fall and ground out the upper coil of the first cut-in relay. When the sending brush of the sending distributor comes again to the pattern channel at the top of the figure, a positive local pulse passes through the lower coil of the first channel cut-in relay, is not neutralized by the upper coil of the relay as before, and now operates the tongues of the relay to the right. This applies negative to the first channel's segment in the pattern channel as an indication to the receiving end that the first channel is prepared for operation. The lower tongue of the cut-in relay removes positive from the first channel's segment on the sending mixer and connects this segment to local operating segments on the sending distributor. These local segments are without battery for the moment, and the unenergized segment on the mixer quickly causes the mixer brush to stop upon it. The negative pattern pulse of the first channel arrives at the receiving end and operates the tongue of the first channel cut-in relay to the right. This removes positive battery from the first channel's segment of the receiving mixer and connects it to local segments of the receiving distributor which are also open at the moment. The brush of the receiving distributor likewise quickly comes to rest on the open first channel's segment. When the brushes of the sending distributor have passed to the next rest and local pulse positions, an operating circuit is completed from the local segment through the magnet of the first channel gang relay, the contacts of the first channel cut-in relay, and the brush and magnet of the sending mixer.

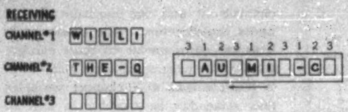

Figure 3. Belt-conveyor analogy for a three-channel time-division multiplex with channel 3 idle and its "turn" wasted

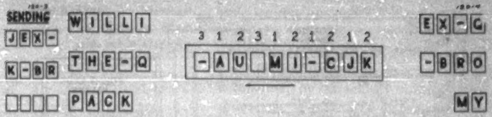

Figure 4. Belt-conveyor-out analogy for a three-channel varioplex in the act of closing out channel 3

Note that distribution changes from three channels to two channels after a blank card denoting exit has been sent by channel 3 on "turn." Established channels can transport their own demolition combinations

This releases the brush of the sending mixer which makes one revolution and comes to rest again in the same spot.

The sending gang relay has six contacts. The lower one opens the magnet circuit of the transmitter, permitting the pins to find their corresponding holes in the tape, and moving the transmitter tongues to negative when they do. The downward operation of contacts 1, 2, 3, 4, and 5 of the gang relay applies the marking and spacing elements of the letter perforated in the tape to the coils of the sending polar bank for transmission to the line by the segments of the sending distributor. At the receiving end, the marking and spacing elements of the received letter cause corresponding movements of the tongues of the receiving polar bank. When this letter has been completely received, a local receiving ring pulse passes through the magnet of the first channel gang relay, the contacts of the first channel cut-in relay, the first channel's segment of the receiving mixer, and through the magnet of the receiving mixer to ground. The operation of the receiving gang relay completes the circuits of the five selecting magnets of the receiving device to the tongues of the receiving polar relay bank. The sixth tongue of the gang relay affords an operating pulse for the receiving device or printer of the first channel. The operation of the receiving mixer stop magnet permits the brush of the receiving mixer to make one revolution and stop again in the same place. At the termination of the local pulse on the sending distributor, the sending gang relay for channel number 1 is de-energized, the tongues of the transmitter disconnect from the sending polar relay bank and the magnet of the transmitter re-energizes. The energization of the magnet of a transmitter of standard design withdraws the pins from the holes and steps the tape. The cycle described above is repeated and the line is completely occupied with transmission from the first channel.

Function of Pattern Channel

At regular intervals, say after 25 letters of traffic, a show of the cut-in situation is made by passage of the brushes over the pattern channel. After transmission from the first channel has continued for a while, assume that additional tape is punched for the third channel, permitting the autostop arm of the channel to descend and bid for entry. When the brushes of the sending distributor next arrive at the position shown in figure 7, local ring positive battery finds its paths to the ground through the lower coil of the first channel cut-in relay, the lower and upper coils of the second channel cut-in relay, and the lower coil of the third channel cut-in relay. This confirms the position of the tongues of the cut-in relays on the first two channels and operates to the right the tongues of the cut-in relay on the third channel. As the sending brush of the sending distributor reaches the pattern channel, it transmits negative from the first control segment to indicate the cut-in condition of the first channel, positive from the second segment to indicate the cut-out condition of the second channel, and negative from the third segment to indicate the cut-in condition of the third channel. At the receiving end the new pattern confirms the operation of the first receiving cut-in relay to the right, the second to the left, and operates the third to the right. The sending and receiving mixers now have two stopping positions without permanent battery, namely, segments for channels 1 and 3. In a manner similar to that explained for channel 1, the gang relay of sending channel 3 now operates in sequence with the gang relay of sending channel 1, and alternate letters from these channels traverse the line and are properly deposited on the printers or receiving devices of channels 1 and 3. In a similar manner, channel 2 can cut in and share proportionately in the capacity of the line. When this occurs, the mixer brushes are stopping at every channel. When a channel cuts out, the local stop arm is lifted, the local sending pulse passes through both coils of the cut-in relay, restoring the tongues to the left and resulting in a skipping of that channel by the sending mixer. The same effect is secured on the receiving mixer by restoring the tongues of the receiving cut-in relays to the left. Thus, it is seen that in accordance with the varioplex principle, the line circuit is loaded to capacity irrespective of the number of operating channels, and the channels are cut in and out automatically as the traffic varies.

Mechanical Type of Mixer

Figure 8 shows a mechanical method of mixing and changing channels, adaptable to the sending and receiving ends of many forms of varioplex systems. It will be

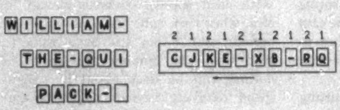

Figure 5. Belt-conveyor analogy of a three-channel varioplex with channel 3 closed out and its "turn" abolished

The lane carries traffic from channels 1 and 2 at a faster rate

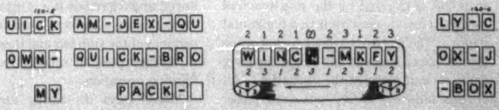

Figure 6. Belt-conveyor analogy of a three-channel varioplex with channel 3 in the act of entering

"Channel time" numerals are painted on the belt and pulleys to add significance to the "In" card. The sending dealer gives channel 3 a "turn" by putting an "In" card on the belt above the number 3. The arrival of this card above the number 3 causes the receiving dealer to include the third channel in future distributions

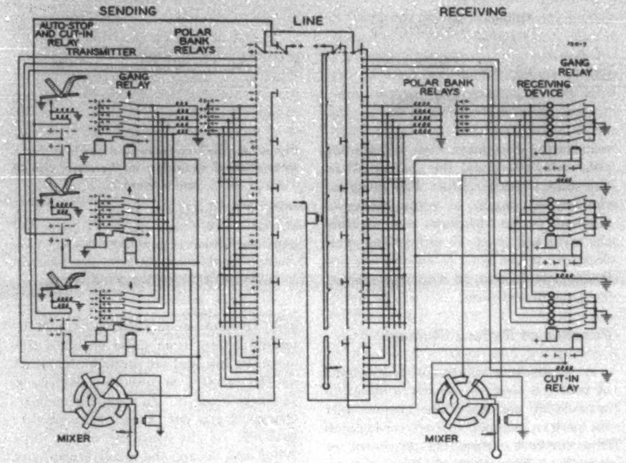

Figure 7. A simple form of varioplex having three subchannels on a start-stop lane of traffic

Entry and exit are accomplished by use of a periodic show of the channel cut-in pattern

fitted into the receiving side of figure 7 to show how it can be substituted for the mixer, the cut-in relays, and the gang relays of that figure.

In figure 8 each varioplex channel is represented on the mechanical unit by a stop bar, a contact lever, and possibly a character counter for telemeter service. The stop bar on the right and the clock above it can be disregarded for the moment.

When all channels are "out" their stop bars are lifted out of the path of the stop arm, which rotates by friction in the space between the stop bars and the contact levers. If channel 1 wishes to enter, a negative pulse from the first segment of the pattern channel energizes the cut-in magnet and lowers the stop bar of that channel into the path of the stop arm. The stop arm quickly comes to rest against it as shown in figure 8. The sixth pulse magnet is soon energized by a pulse, and the stop arm shaft is pulled down against a spring until the stop arm clears the lower edge of the stop bar. The contact lever, which is below and beyond the stop bar, is engaged by the stop arm and rotated a few degrees by it in a horizontal plane. The stop arm comes to rest when the torque of its shaft has closed the gang contacts and metered the character. All of this happens during one-sixth pulse, and at the termination of the pulse the stop arm is lifted by its spring until it again clears the contact lever. It then continues its rotational search for the stop bar of the next cut in channel.

A spring restores the contact lever to its normal position and this removes the ground from the magnets of the receiving device on channel number 1. A simple cut out is employed to keep the stop arm from interfering with the contact levers when all channels are idle.

The varioplex distribution principle is adhered to throughout because the tongue circuits of the polar bank are completed through the receiving devices of operating channels only.

A different method of cutting in and out is applied to the stop bar at the right-hand side of the mechanical unit. The clock assembly is mechanically or electrically geared to the receiving distributor. Since the clock magnet is connected through three condensers to the three pattern segments it is never energized except when a pattern is coming in, and not even then unless changes in the cut-in pattern reverse the charges on the condensers. When such a change does occur the clock arm is so phased that its sword will be above the stop bar of the channel to be changed, and the kick of the sword will result in the stop bar's being raised if it is down, and depressed if it is up. A spring on the sword permits it to follow the cam surfaces of the stop bar and then return to a centered position suitable for the next flip-flop operation.

Many ways of mixing and cutting channels in and out mechanically are under consideration. The design problems are quite similar to those encountered in the telegraph printer field and it is possible that a 50-channel varioplex may some day be mixed in a unit no larger than a printer. By limiting the mixing and entry parts of a subchannel to two small stampings and a contact block, a big step can be taken toward the goal of longer and more lightly loaded subchannels.

Varioplex Speeds and Capacity

Since excessive channel speeds should be utilized or avoided, the reader is referred to figure 7 for a discussion of the subject. It has been assumed heretofore that the whole speed of the lane could be allocated to any of the three channels without undue punishment of the channel apparatus. Transmitters and printers of standard design work very well at 80 words per minute so that the speed of the lane is not restrained by them until that point has been reached. Let it now be assumed that the aggregate load has increased to a point where a lane speed of 150 words per minute is required. Channel speeds in figure 7 are then 0, 50, 75, and 150 words per minute. Since a 150-word speed is impracticably high for standard transmitters and printers, special high-speed apparatus must be employed if it is desired to retain it. For such a speed a special transmitter has been designed, having ten or more pins and stepping two or more letters on every local operation. The receiving unit can be a storing device handling two letters or more on every local operation. The gang contacts shown in figures 7 and 8 is under these conditions also increased in number.

Another way of governing the speed of the figure 7 varioplex is to open additional channels carrying deferred traffic as the regular channels are closed out. Or, dummy channels without transmitters or receivers may be cut in when the speed threatens to be excessive. Such channels may be controlled by increment relays in the autostop multiple connecting to the local segment of the pattern channel on the sending side.

The governor of a varioplex ought not to function until channel printers have attained their maximum practical speeds. With such speeds, channels should be clear when they enter their efficient busy periods, and if they still have traffic to send when the dummies cut in again nothing can be done about it. High-speed receiving devices might be em-

ployed on loaded submarine cables and at varioplex repeaters, but they would be an unnecessary complication on ordinary circuits unless the periods of overload were prolonged and alternated frequently with periods of underload. This does not happen on commercial varioplexes which are supplied with traffic from many places by operators who send at net speeds of considerably less than 65 words per minute.

Varioplex Subchannels on Multiplex Circuits

A start-stop lane of traffic was chosen for the figure 7 varioplex to provide dead time for local operations. If multiplex distributors are substituted for start-stop distributors time for such operations can be furnished by employing overlap storage. A different way is to separate the lane channels, instead of strapping them, and to allow the working subchannels to attach themselves to the lane channels. If unattached lane channels remain idle, the governor problem is solved along with that of local operating time.

Figure 9 shows a separated channel multiplex lane carrying the traffic of nine subchannels. Sixty-five words per minute is assumed to be the speed of the sending and receiving legs, and the speed of each of the four multiplex channels. The subchannel speed varies from 0 to 65 words per minute. As an example, when sending begins on the first leg at Chicago, the distributor-perforator fabricates tape which feeds into the transmitter of the first varioplex subchannel. A relay at the grid junction 1*A* closes and makes a semipermanent connection between the transmitter and the *A* channel of the multiplex. The corresponding grid relay in the New York receiving chain also closes, and traffic begins to move at 65 words per minute. In similar manner multiplex channels *B*, *C*, and *D* are seized by subchannels 3, 4, and 5 which are assumed to open up. When subchannel 9 enters the picture there is no place for it, so the relay chains begin to step and mix the multiplex channels with the varioplex subchannels. Under this condition a certain subchannel makes contact with varying multiplex channels like a tooth of a five-toothed gear making contact with varying teeth of a four-toothed gear that is driving it. This arrangement is illustrated by the analogy at the bottom of figure 9. If more than five subchannels are cut in, the sending opportunity of each is made less frequent, just as the left gear would revolve more slowly if it were larger and had more than five teeth.

The advantages of the varioplex are most apparent when subchannels are extended beyond the system terminal. Repetition of one channel into another channel of higher speed is always a simple matter, but when the reverse condition occurs it is necessary to provide storage of some description. Individual channel storage is not required when several channels are repeatered from one varioplex lane into another because a single storing device can handle the combined traffic of all such channels. The repetition of varioplex subchannels forms an essential part of through channel networks.

Conclusion

While the efficiency of the multiplex system depends upon the proportion of

Powerton-Crawford 220-Kv Line—Design and Construction Features

M. S. OLDACRE
ASSOCIATE AIEE

F. O. WOLLASTON
ASSOCIATE AIEE

THE placing in service of the 220-kv Powerton-Crawford transmission line of the Commonwealth Edison Company marks the completion of a project begun 12 years ago and subsequently dropped during the depression years. When work was suspended in 1932, most of the right-of-way had been secured, tower sites were located, the tower contracts had been let, typical towers had been built and tested, and some of the terminal apparatus was completed.

This line, with a normal rating of 150,000 kva and an emergency rating of approximately 200,000 kva, is to serve as a very important link in the supply to the Chicago area. The plans were carefully reviewed when the project again became active, with the object of incorporating the new ideas that had been developed in the industry for protecting overhead lines from hazards of lightning, sleet, vibration, and galloping conductors. The desired objective was virtually trouble-free operation and this, rather than the lowest cost, was the first consideration. The extent of the advance in the industry is revealed by the present design of the line, which retains only the conductor size of the original designs of 1928 to 1930. Towers, insulators, ground wires, hardware, and all other elements are of present-day design. It is anticipated that the line will have an outstandingly good operating record.

Statistics pertaining to the line are given in the accompanying tables, while the more important elements that affected the design are discussed more generally.

The line is 147 miles long and transverses the rather flat farm region of Illinois between Powerton station near Pekin and Crawford station in Chicago. A right-of-way 250 feet wide was acquired to permit two single-circuit lines for 130 miles from Powerton. The present line is located 75 feet from one edge of the right-of-way to the center of the towers, leaving room for a future circuit 75 feet from the other edge. The remaining 17 miles to Crawford station is through a suburban area dotted with small communities. The only feasible right-of-way was approximately parallel to two main-line railroads in a narrow strip sufficiently wide for only a single tower line capable of carrying two circuits. This comprises the double-circuit section of the line, in which one circuit is installed at present.

Table I. Fair Weather Corona Loss

ACSR Conductor Size		Calculated Corona Loss Kw Per Mile at 240 Kv, Three Phase
Circular Mils	Approximate Diameter (Inches)	
636,000	1.0	0.85
715,000	1.05	0.70
795,000	1.1	0.55
900,000	1.162	0.40

Practically all of the single-circuit right-of-way is an easement from the property owners, about 92 per cent being obtained by agreement and the remainder by condemnation of the land directly under the tower and right of access. A small portion of the single-circuit section and part of the double-circuit section right-of-way are owned outright. The majority of the double-circuit section is on a 25-foot right-of-way. This strip is part of a wider right-of-way that provides space for other transmission lines, high-pressure gas lines, and railroads. A remarkable interchange of ownership and use of the available space was involved in securing this right-of-way for the 220-kv line. The 25-foot strip is just wide enough for the tower base, while the overhanging of the conductors on the adjacent rights-of-way is covered by agreements with the owners.

Basic Considerations of Design

As natural effects of the weather constituted the greatest hazards to trouble-free operation, all the weather information was carefully considered as the basic data in designing the line. Records indicate that an average of about four tornadoes a year may be expected in Illinois. Wind velocities in mild tornadoes are known to be of the order of 100 miles per hour. In the most severe cases the wind may attain a velocity of about 400 miles per hour. It was concluded that the economic limit in the tower design was about reached if the line could withstand wind velocities of 150 miles per hour.

The line route is in the general direction of the Illinois River and DesPlaines River valleys, where frequent and heavy sleet storms occur. Observations in this territory indicate that $^{1}/_{2}$-inch ice may be

channels in operation from moment to moment and may vary from 0 to 100 per cent, the efficiency of the varioplex is 100 per cent so long as there is anything to transmit on any channel, regardless of the number of channels in use or idle. The gain in efficiency obtained in this manner may be employed to give higher speeds and capacities to existing channels, to increase the number of channels having the same loads as existing channels, or to provide an unlimited number of lightly loaded channels. In the last-mentioned use, long, lightly loaded, privately operated channels are for the first time made economically feasible.

encountered once or twice a year, $^3/_4$-inch ice will occur every few years, and $1^1/_2$-inch ice is not beyond the bounds of possibility. The line was designed for trouble-free operation under such loads.

Lightning storms are as frequent and severe as any place in the country with a few exceptions. Extensive investigations by others in recent years have led to the development of methods of making high-voltage lines practically lightning-proof, and full advantage of this information was taken in designing the line.

Conductor

Economic studies for the conductor indicated lowest annual costs for one in the neighborhood of 500,000 to 600,000-circular-mil copper equivalent, although a fairly wide choice of sizes could be used without appreciable effect on annual charges. Studies of corona loss, following recently developed methods, indicated fair weather losses as shown in table I.

A 900,000-circular-mil ACSR conductor of 1.162-inch diameter and 32,300 pounds guaranteed strength was selected because of over-all economy thereby obtained on the conductor and tower installation. The ACSR conductor also had the advantage of a considerable background of satisfactory service, availability of standard splicing and dead-ending equipment, and freedom from corrosion. Actively corrosive conditions due to smoke and fumes are a minor hazard near the terminals and are nonexistent elsewhere along the line.

A minor factor in the choice of the conductor diameter was that the eventual installation of a Petersen coil was seriously considered, although initially the transformer neutrals will be solidly grounded. It was desired to maintain low corona losses at the occasional higher voltages incidental to Petersen coil operation. Laboratory tests in Chicago showed the fair weather corona starting voltage, with insulators and hardware in place, to be at least 150 kv, or the equivalent of a three-phase voltage of 260 kv. In these tests corona appeared only

on hardware, and for the conductor alone the corona voltage was more than 300 kv three-phase.

With this conductor, the sag at 60 degrees Fahrenheit is 38.6 feet in the ruling span of 1,200 feet and the tension is 16.7 per cent of ultimate. Under the assumed worst loading of zero degree Fahrenheit, 1½-inch ice, eight-pound wind, the tension reaches 68 per cent of ultimate, so that the conductor should safely withstand these severe conditions. Similar considerations hold for the double-circuit tower section with shorter spans. The data are given in detail in table II.

Protection Against Sleet

Sleet-prevention and sleet-melting procedures are being used very effectively on the 132-kv lines in the Chicago territory. However, the size of the conductor and the electrical characteristics of the 220-kv line are such that it is impracticable to apply these procedures. Hence it was necessary to design the line for trouble-free operation under heavy ice loading, with its accompanying hazard of galloping conductors.

The envelopes of probable positions of the wires during extreme galloping were determined by an empirical rule developed by A. E. Davison[1] from observations of dancing conductors in the field. The validity and practical value of the procedure were first checked by applying it to all important transmission lines in the Chicago district. It was found that the operating records agreed closely with the findings based on the envelopes of galloping, or sleet clearance diagrams. Where inadequate clearances were indicated, those lines had high rates of outage due to sleet storms. Where clearances were ample, the outage rates were zero or negligible. Figure 1 gives typical examples of sleet clearance diagrams and operating data for the 132-kv lines. It was noted that wire spacings commonly accepted as adequate for 132-kv construction were in reality quite inadequate in several cases from the standpoint of maintaining service with ice on the wires, as is essential with this line.

The most difficult problem in providing adequate spacings is encountered where the wires are in vertical configuration. In single-circuit construction this affects the positioning of the ground wires above the conductors. In double-circuit construction it involves also the positioning of the phase wires one above the other. The difficulty resides in the fact that galloping conductors have been observed to soar up at least as high as the level of their supporting clamps and to drop down

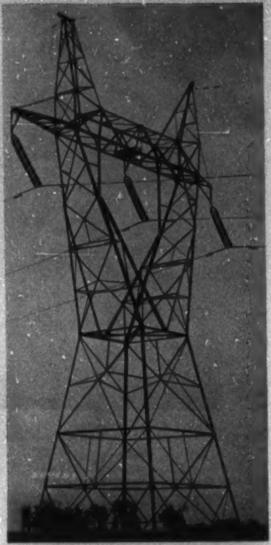

Figure 5b. Typical single-circuit 15-degree-angle tower

somewhat below the normal rest position. This means that the vertical spacing from one wire to the next should be at least as great as the sag in the upper wire. Where the sag is very large, as in unusually long spans, the vertical spacing at the towers should likewise be large and the tower would be correspondingly expensive. For shorter spans the vertical spacings can be smaller and the towers cheaper. In designing towers for adequate wire spacings, it thus becomes necessary to choose one of the following two alternatives: (1) have only one design but the tower must be as large as the longest span requires; (2) have at least two varieties of tower, one for spans of normal length and another for unusually long spans. This point must be studied individually for each class of tower, that is, suspension, angle, transposition, and dead-end.

For the Powerton-Crawford line the second alternative proved to be the most economical and was adopted. Complete data on tower types and wire spacings are given in table III. It should be noted that the tower sites were fixed by prior right-of-way negotiations. If this had not been true, some simplification and economy might have been achieved by shortening some span lengths, thus eliminating some of the types of towers with

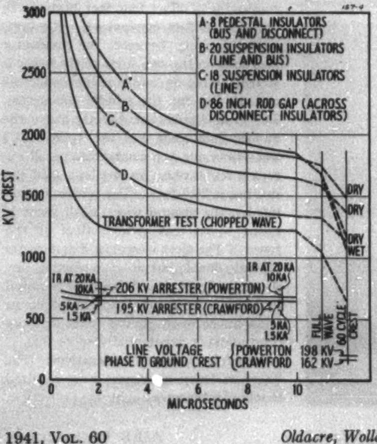

Figure 4. Co-ordination of insulation at terminals of Powerton-Crawford 220-kv line

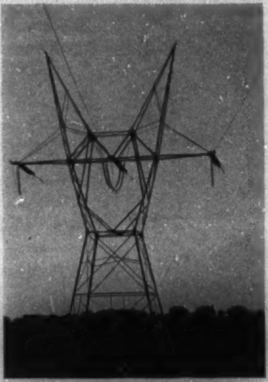

Figure 5c. Typical single-circuit 45-degree-angle and dead-end tower

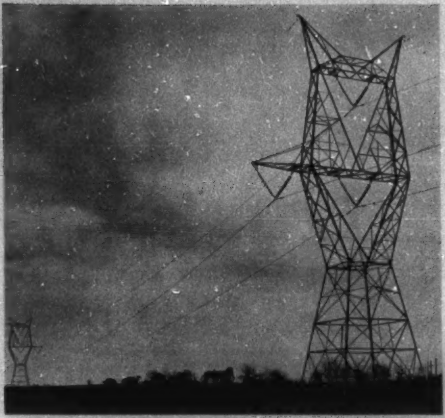

Figure 5d. Typical single-circuit transposition tower

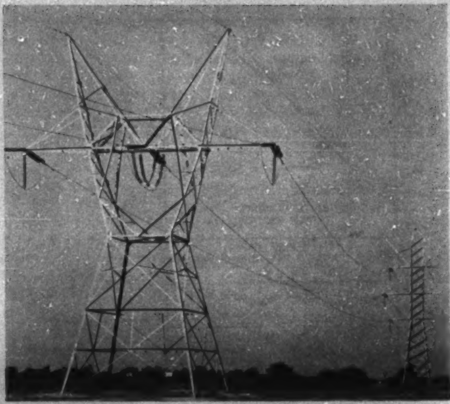

Figure 5e. Transition from single-circuit to double-circuit tower

the larger vertical spacings. On single-circuit towers the ground wires are 29 feet above the phase wires for all spans up to 1,130 feet long, 34 feet for longer spans up to 1,215 feet, and 38.3 feet for the longest spans up to 1,275 feet. These spacings are used not only for the suspension towers but also for the 15-degree-angle towers and dead-end or 45-degree-angle towers. The vertical spacings between the ground and phase wires at midspan are in all cases about ten feet greater than at the tower. This was necessary to provide sufficient clearance and was obtained by stringing the ground wire in a flatter sag than the conductor. The conductors are spaced 33.3 feet apart horizontally, giving ample clearance to tower steel. The two ground wires are inset approximately ten feet from the outer conductors, which helps to maintain galloping clearance. The sleet clearance diagram for typical single-circuit construction is shown in figure 2*a*. Special consideration was given to the transpositions, which are described elsewhere in the paper. The sleet clearance diagram in figure 2*b* shows that ample clearances were provided.

The double-circuit towers have a minimum vertical spacing of 20 feet between conductors for spans up to 800 feet. The longer spans up to 940 feet have 26-foot spacing. One long crossing span of 1,095 feet has $32\frac{1}{2}$-foot spacing. The middle conductor is offset four feet beyond the top and bottom conductors. The horizontal spacing between the conductor positions on the two sides of the tower is 40 feet for the top and bottom conductors and 48 feet for the middle conductors. The ground wires are directly above the middle conductor and are spaced 23.4 feet above the top conductors on all except a few towers; in one long span the spacing is 28.5 feet. The midspan spacing for the ground wire on all spans is about seven feet greater than at the tower. The sleet clearance diagrams for typical double-circuit construction are shown in figure 2*c*. A point to be noted in figure 2*c* is that the vertical spacing at midspan between ground wires and top conductors is substantially more than is required from sleet considerations. The larger midspan clearances were required to secure satisfactory lightning protection,

as is brought out in more detail in the section on lightning protection.

Lightning Protection and Insulation

The degree of shielding of the power conductors from lightning strokes that is effected by the ground wires is usually expressed as a function of the protective angle, which is the angular departure of the conductor from a position vertically below the ground wire. For the vertical position, the protective angle is zero and the shielding is the best obtainable. Larger protective angles mean greater departures from the vertical and reduced efficiency. However, it is generally agreed that the reduction in effectiveness of shielding is negligible for protective angles up to 20 degrees. The towers were therefore designed so that the protective angle would not exceed 20 degrees, and two ground wires were installed on all towers.

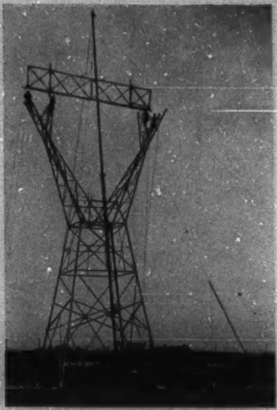

Figure 6. Erecting tower with extensible boom

On the single-circuit section of the line the normal protective angle for tangent and dead-end towers is from 15 to 19 degrees at the tower. At midspan the differential sagging improves the protective angle by about four degrees. The protective angle for transposition towers is about nine degrees at the tower and eight degrees at midspan. On the double-circuit section of the line the protective angle is zero, as the ground wires are directly above the outermost conductors. The location of the ground wires relative to the phase wires on all angle towers, both single- and double-circuit, is the same as on tangent. With these provisions, the chance of a direct stroke hitting a phase wire on any part of the line is exceedingly small.

On the assumption that all direct strokes would terminate on a tower or ground wire, calculations of outage probability were made to determine the effects of line insulation, tower footing resistance, and location of ground wires with respect to the phase wires. The results of these calculations are shown in figure 3.

Based on this study, the line insulation was set at 18 standard 10-inch diameter by $5^3/_4$-inch spacing cap and pin type insulators, having a full-wave flashover voltage of approximately 1,585 kv for a 1.5 by 40-microsecond positive wave. The standard-size insulator was selected following an economic study which showed the cost per kilovolt to be from 10 to 18 per cent less for this insulator than for insulators with 6- or $6^1/_2$-inch spacings, in the string lengths under consideration. For physical reasons double strings

LIGHTING TRANSFORMER WITH DEION PROTECTOR
INSULATED GROUND WIRE

Figure 10. Lighting equipment on tower

of insulators of standard or high strength were used on special towers and special locations, with the number of disks increased to 20 for dead ends.

In order to keep lightning outages down to the desired low level, that is, an average of substantially less than one outage per 100 line-miles per year, figure 3 indicates that tower footing resistances should be held to values below 10 or 15 ohms. However, to provide for the usual uncertainties in measuring ground resistances, seasonal variations, and the departure from true leakage resistances for counterpoises when conducting lightning currents, a value of five ohms was established as the maximum permissible tower footing resistance. The methods of grounding are described later.

Figure 3 shows that a vertical separation between ground wires and phase wires of the order of 35 to 40 feet is indicated to properly co-ordinate midspan insulation with tower insulation on the single-circuit section. As previously discussed in the section on protection against sleet, the prevention of galloping contacts required midspan spacings of 39 feet or more, depending upon span length. Thus, for the single-circuit section of the line, the sleet consideration was the determining factor in setting this separation.

For the double-circuit section, figure 3 indicates that a vertical midspan spacing between ground wire and phase wire of 25 to 30 feet was required from a lightning protection standpoint. This was more than needed to prevent sleet contacts, and was the controlling consideration in determining the vertical spacings for this part of the line.

In both cases, economic studies showed

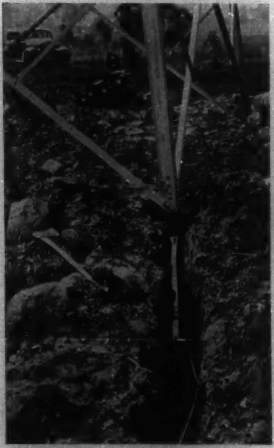

Figure 8. Counterpoise connection to tower leg

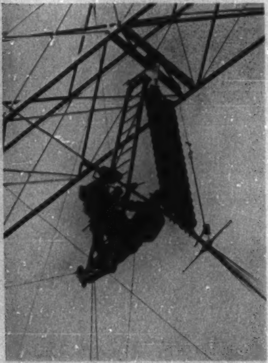

Figure 9. Installing tapered armor rods

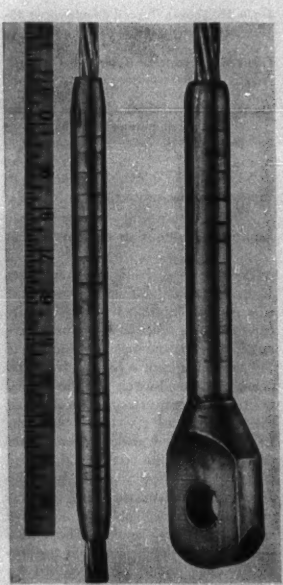

Figure 11. Ground-wire splice and dead end

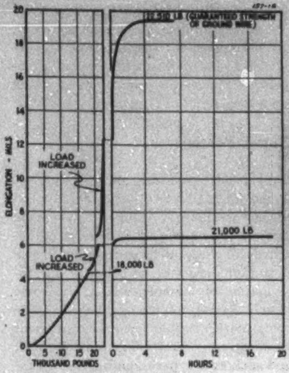

Figure 12. Stress-strain test on dead-end fitting for ground wire

that these large midspan spacings could be most cheaply obtained by employing differential sagging between ground wires and phase wires.

Terminal Insulation

At both the Powerton and Crawford stations the line terminates on steel structures and is conducted over suspended busses, supported from 20-unit insulator strings, to disconnect switches. From the switch to the transformer terminal at Crawford a rigid bus is carried on eight-unit stacks of pedestal-type insulators. These stacks are mechanically graded, with two ten-inch-diameter bolt circle insulators at the bottom, one transition insulator, and five insulators with seven-inch-diameter bolt circle. Eight-unit stacks, rated at 287 kv, were selected to provide additional leakage distance under the atmospheric contamination prevalent at the generating stations.

Similar stacks of insulators are used for the disconnect switches at both terminals. To insure against possible lightning flashover between line side and bus side of the switch when open, the pedestal stacks on each side are provided with rings spaced 86 inches apart. For this spacing the impulse flashover voltage is approximately 20 per cent less than that across the open switch.

At Crawford station, the 230-kv transformer windings are protected by 195-kv station-type arresters installed approximately 50 circuit-feet from the transformer bushings. Because of the higher operating voltage at the generating end of the line, the arresters used at the Powerton end are rated at 206 kv. Figure 4 shows the insulation levels for the various equipment at the terminals.

Figure 13. Stringing wire under tension

To protect the terminals from direct strokes, a network of ground wires is installed above the exposed high- and low-voltage busses. The elevations of these wires above the busses, and their necessary ground resistances, were calculated to give greatest practicable immunity from lightning flashover of the bus insulation.

Ground Wires

The following factors were considered in selecting the ground wire: strength consistent with the flat sagging required, cost, freedom from corrosion and vibration troubles, previous operating record, and availability of splices and hardware. These requirements appeared to be most adequately met by a one-half-inch, 30 per cent conductivity, extra-high-strength Copperweld wire, specially selected for ten per cent increased breaking strength. Complete data on the wire are given in table II. The guaranteed strength is 22,510 pounds. This wire could be sagged approximately ten feet less than the phase wires in the single-circuit section and seven feet less in the double-circuit section with an equally high factor of safety for phase and ground wires. The normal tension at 60 degrees Fahrenheit, no wind, is 15.4 per cent of ultimate for the single-circuit section and 19.6 per cent for the double-circuit section. The maximum design tension at zero degree Fahrenheit, $1^1/_2$-inch ice, eight-pound wind, is 68.7 per cent for the single-circuit section and 60.2 per cent for the double-circuit section. These values are considered to be quite conservative. The permanent set in the unloaded sag will not exceed six feet in any span following this loading, which will occur very rarely if at all.

Tower Design

The lack of means for preventing sleet formation resulted in a rather radical departure from common practice in setting up tower loading schedules. As shown in the loading schedule given in table IV, the towers were designed to withstand $1^1/_2$-inch radial ice of normal density on the conductors combined with the usual transverse wind loading of eight pounds per square foot with all conductors intact. Under this condition the specified margin of safety is 15 per cent. This necessitated unusually heavy construction in certain parts of the towers. In addition, the specification called for the usual 50 per cent safety margin with one ground

Figure 14. Pulling equipment for stringing under tension

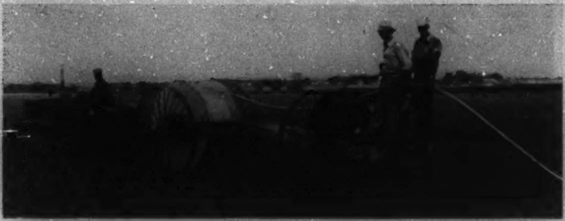

Figure 15. Stringing wire by laying out on ground

wire or one phase wire broken, but in this case the loading was reduced to the customary medium schedule; that is, one-half-inch radial ice and eight-pound wind. The combination of these two requirements resulted in suspension towers and towers for small angles that would almost, but not quite, withstand "any or all" wires broken under the medium loading schedule, instead of the usual "one broken conductor" or "one broken ground wire." The additional steel required to permit these towers to meet the "any or all" condition was so small that it was decided to design the towers to meet it. This results in the unusual situation of having suspension and small-angle towers capable of acting as dead-end towers under all but the most severe sleet and wind loadings. Another consequence is that all towers are heavy enough to withstand very high wind pressures in summer when there is no sleet loading. The calculated maximum steady wind velocity (actual) that can be withstood is about 150 miles per hour, which should enable the towers to withstand all but the most severe tornadoes experienced in this territory. Naturally, the tower strength under storm conditions is expected to be somewhat lower than estimated, because of the effects of dynamic shock produced by gusts of wind or breaking wires.

The double-circuit towers have ten per cent more strength than called for in the specifications. It was decided not to test these towers, due to lack of time and of adequate testing facilities, and so the extra ten per cent strength was included in lieu of testing. The cost of the extra weight of steel required to provide the additional ten per cent margin of strength was about the same as the cost of testing would have been. The same procedure was followed in the case of the single-circuit transposition towers. The single-circuit suspension, 15-degree angle, and dead-end towers were thoroughly tested.

Typical single- and double-circuit towers are shown in figure 5. The towers are of galvanized steel parts bolted together. Heavy lockwashers were used to ensure permanence of the bolted connections, as Chicago tests and experiences indicated heavy lockwashers to be the most reliable device. In addition, the nuts were locked by prick-punching after final tightening.

The erection of most of the single-circuit suspension towers was done very efficiently by using the extensible boom shown in figure 6. The boom had a mobile mounting and was 115 feet long when fully extended. An advance crew assembled the tower into small subsections such as side panels, main section of crossarm, and ground-wire peaks. The assembled sections were laid out on the ground at the tower site in a prearranged pattern. The erecting crew set up the hoisting boom and erected the tower by sections. Suspension towers were often erected in as little as $2^{1}/_{2}$ hours by this method. The erection of the remaining towers was done with a slung gin pole, as has frequently been done before.

Transpositions and Dead Ends

The methods of making transpositions on single- and double-circuit types of construction are thought to have advantages over some other methods that have been commonly used. In the single-circuit transposition, shown in figure 5*d*, there is no crossing of wires in the spans. This materially reduces the chance of wires coming in contact under storm conditions. The double-circuit transposition tower is pictured in figure 5*i*. Only three main crossarms are used, and the tension of each dead-ended conductor is balanced by an equal opposing tension. This makes for a relatively light, neat-looking tower.

The general principle was adopted of having as little dead-end construction on the line as possible. Experience of other utilities indicated that electrical and mechanical troubles were more apt to occur at dead-end towers than elsewhere. Consequently, dead-end towers were installed only where absolutely necessary. In particular, it was considered undesirable to install dead-end towers on tangents for the sole purpose of breaking up a long series of suspension spans.

Tower Footings

Pyramid-type earth anchors were selected for the tower footings. A typical anchor is shown in figure 7. Concrete anchors were not used because of anticipated difficulties with weather and transportation during construction. The installation of anchors was to be done mainly in the winter of 1939–40. The cold weather would have been a great handicap to pouring concrete in the field, and anchors of types requiring that operation were considered unsuitable. This eliminated the Malone type and the grillage-cast-in-concrete type. Precast concrete anchors were ruled out on the grounds of being expensive, difficult to transport from storage yard to tower site, especially over muddy fields, and difficult to set accurately on account of their great weight.

The steel for the earth anchors was designed to have the same safety margins as specified for the towers. The bearing surfaces, however, were designed to have an additional margin of 20 per cent in the case of suspension and 15-degree-angle towers and 33 per cent for dead-end towers. These safety margins apply only to the bearing and uplift pressures in the soil. The maximum allowable

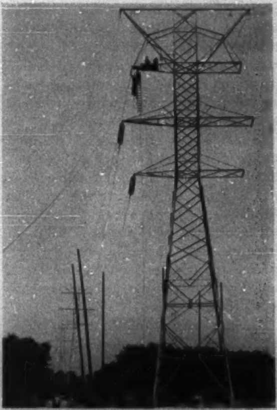

Figure 16. Making compression dead-end on crossarm

Figure 17. Laboratory setup for radio noise and corona tests

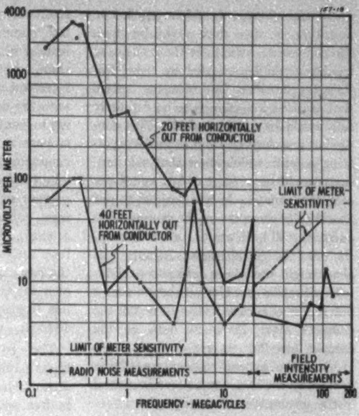

Figure 18. Radio noise under artificial rain—220-kv insulator string and conductor. Conductor energized at 140-kv alternating current to ground

bearing pressure including overloads was specified as 10,000 pounds per square foot. This meant that the maximum actual pressure would be about 5,000 pounds per square foot (10,000/(1.33×1.50)) for the worst condition and the normal pressure would be about 1,200 pounds or less per square foot. Resistance to uplift was figured on the basis of an inverted frustrum of a 30-degree pyramid of earth weighing 100 pounds per cubic foot. A few rock anchors were used, consisting of a post angle carrying crosswise clip angles concreted in rock. The concrete is carried six inches above the ground line and is designed to take the horizontal shear stresses at the ground line.

All anchors are of galvanized steel and are spliced three feet below the ground line to permit replacing any parts that may succumb to ground-line corrosion. As a further precaution, a protective coating of asphalt paint was applied from a point three feet below the ground line to a point six inches above it. Actually no corrosion trouble is anticipated if the galvanizing is intact when the steel is installed, since examinations of some galvanized steel tower footings in this territory which have been in service as long as 33 years show them to be in remarkably good condition.

Tower Grounding

From the standpoint of securing low resistance tower grounds for protection against lightning flashovers, the Powerton-Crawford line is fortunately situated. As shown by Card,[2] Northern and Central Illinois have in general fairly low soil resistivity as compared with most of the United States.

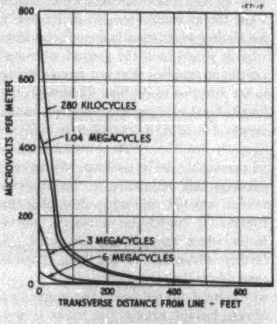

Figure 19. Radio-noise measurements on Powerton-Crawford 220-kv line

The large grillage anchors provide extensive contact area with the soil. At the bottom of each anchor a ten-foot galvanized steel rod was driven and connected to the footing, as shown in figure 7. This procedure resulted in bringing 92 per cent of the towers to the desired resistance of five ohms or less. For 57 towers, some of which were in rocky soil where rods could not be driven, the measured ground resistance averaged 12.2 ohms and had a maximum value of 47 ohms. Footing resistances of these towers were reduced in a few cases by deep ground rods and in the remainder by counterpoises. An average of 1,420 feet of counterpoise per tower resulted in an average final footing resistance for these towers of four ohms. Special precautions were taken to assure permanence of the grounds. Ground rods, counterpoise wire, and connections have extra heavy galvanizing. Galvanized steel was used throughout to avoid having contacts between dissimilar metals that might cause galvanic action.

Counterpoises are of the discontinuous type parallel to the line. Half-inch stranded galvanized steel wire was used, buried 18 inches in the ground and connected to the tower legs with galvanized steel straps as shown in figure 8. Wires 300 feet long were installed successively on the four tower legs until the resistance had reached the specified value. Where necessary, additional wires of the same length were installed parallel to the first wires. Except in a few instances, where interference with the counterpoise wires was encountered, they were spaced 50 feet apart. The maximum amount of counterpoise used on any one tower was 3,600 feet.

When the grounding work was completed, all towers on the line had footing resistances below five ohms. The average for the 761 towers on the line was 1.8 ohms.

Vibration Protection

The available information on vibration troubles on overhead wires covers a wide range of causes of vibration such as tension, material, and construction of the cable. It was concluded after studying this information that any overhead wire might be subject to vibration and that preventive devices should be applied to any type of wire that might be used. There is some indication that vibration trouble could be avoided by using low stringing tensions, but it seems certain that tensions low enough to be definitely safe would be uneconomical. This conclusion was derived from extensive operating records which show that safe tensions would be at least as low as ten per cent of ultimate. It was decided to put Stockbridge dampers on the ground wires and to install both armor rods and dampers on the conductors. Armor rods alone might have been sufficient to eliminate vibration troubles on the conductor but it was considered safer to install the dampers also. Pertinent data on the damper installations are given in table II, and the general appearance of the devices on the line is to be seen in several of the accompanying photographs.

A view of the armor rods being installed is shown in figure 9. Besides vibration protection, they will provide protection for the conductor against flashover burns and mechanical damage in the region of the clamp. Protection against flashover burns could have been obtained by using grading shields, but only at the expense of reduced clearances to tower steel or of larger towers. Grading shields were not used, as they would have no function beyond protecting the insulators against flashover damage. This seemed unnecessary, in view of the general experience that modern insulators do not shatter badly enough to come apart because of flashovers. Any lesser damages such as loss of insulating value would probably be confined to a few units in the string. This would be of little consequence because several units could be short-circuited in the string without affecting normal operation of the line. This results from the fact that the string length was selected on the basis of impulse strength and its 60-cycle strength happens to be considerably higher than necessary.

Insulator and Hardware Assemblies

The selection of the hardware assemblies presented several points of interest. Double strings as illustrated in figure 5*b* were used at all crossings of important highways for conductors in suspension. The double clamp arrangement shown in the photograph was preferred to the more usual yoke-plate and single clamp because the total length worked out about the same as for the single string. Consequently, the clearance to the tower steel was not affected by the inevitable last minute decisions to install double instead of single strings at certain locations. Longer armor rods to match the increased clamping length were installed with the double strings. It was surprising to learn from tests that even the single suspension clamp would not permit the conductor to slip through it under broken-wire tensions. This is desirable as it will prevent spans adjacent to a broken span from coming down all the way to the ground. The slip is not needed to relieve the tension. If a conductor breaks, the suspension insulator strings will pull over far enough in the direction of the line to slack off the tension as much as 40 to 70 per cent.

The ground-wire suspension assemblies, figure 9, were made flexible and about 18 inches long. This puts the wire in free suspension, so that the tension will be equalized between the spans. Thus the maximum tension under heavy ice loading is substantially reduced from what it would be if the ground-wire supporting assemblies were not free to swing in the direction of the line. Likewise, the longitudinal swing of the assembly in the event of a broken ground wire will reduce the loading on the tower by 15 to 50 per cent. As in the case of the conductors, this reduction in broken-wire tension was not utilized in designing the towers. It constitutes a reserve safety factor which was cheaply obtained. A further advantage of the long, flexible assembly is that the chance of the ground wire being damaged due to the supporting clamps locking against the tower is negligible.

The hardware for all suspension assemblies was selected on the basis that the elastic limit of the weakest piece should be at least equal to the maximum design load on the assembly. In general, the ultimate strength of each item making up the assembly is at least $2^1/_2$ times the design load. The insulators were selected so that the maximum continuous loading would not exceed 40 per cent of the M&E rating. However, it was deemed permissible[3] to go to 60 per cent of M&E rating for the maximum design load. The maximum loading is for the condition of very heavy sleet on the wires, and is expected to have a duration of not more than about 48 hours. On the basis of these considerations, the standard ten-inch insulators having an M&E rating of 15,000 pounds were selected for suspension duty.

The insulators in the conductor dead-end assemblies were selected on the same basis as the suspension insulators. Because of the heavier design loadings, double strings of standard ten-inch insulators with an M&E rating of 25,000 pounds were required. The hardware for all dead-end assemblies was selected on the basis that the ultimate strength of the weakest item would be at least equal to the breaking strength of the wire. The splices and dead-end fittings for the ground wire had to meet these requirements and, in addition, it was desired to take no chances on galvanic corrosion at the point where the fittings contacted the copper-covered steel strands. A new splice and dead-end fitting, figure 11, were developed to meet these needs. They are pressed on the wire with the same press and dies used for splicing and dead-ending ACSR wire. The material is a special bronze, to avoid corrosion and season cracking troubles. The weight is extremely low, to avoid vibration troubles. Results of accelerated loading tests with and without severe heat cycles were very satisfactory. Some typical test data are shown in figure 12. The compression sleeve of the dead-end fitting is identical to the splice, which is a bronze sleeve with a sprayed coating of Nichrome on the interior of the bore. When the sleeve is pressed on the wire, the hard particles of Nichrome are embedded in the softer metals of the sleeve and wire coating and form a bond between them.

Wire Installation

The conductor is the largest of the ACSR type that has ever been installed by pulling out under tension. The setup at the feeding end is shown in figure 13 and the pulling rig is shown in figure 14. In figure 13 the conductor is being paid off the three reels in the foreground and the ground wire from the other two reels. The braking drums for applying enough tension to keep the wire from dragging on the ground are directly in front of the cable reels. In part of the work, all five wires were pulled out simultaneously with the two tractor-mounted rigs shown in figure 14. Another method of pulling out under tension which was used extensively was to hitch the pulling lines to three tractors and drive them forward. One tractor pulled the middle conductor; the other two each pulled one outer conductor and ground wire. The tractor crews were directed by radio telephone. The pulls were about 3,600 feet long for both the conductor and ground wire. The pulling lines were attached to the wires with woven-wire basket grips.

Another method of stringing was to lay out the wire on the ground and then raise it into position on the towers. This scheme was used for the outer conductors and ground wires wherever the ground was smooth enough to ensure that the wire would not be damaged. The reels were mounted as shown in figure 15 and the wire was paid out as the tractor moved forward. The middle conductor on the single-circuit towers was always pulled out under tension, since it had to pass through the center of the tower.

It was found necessary to watch closely the surface of the stringing blocks, particularly the steel block used for the ground wire. The steel pulling line tended to wear grooves in the surface which could cut the copper coating of the wire. The ground wire tended to twist as it was being pulled through the blocks under tension, which made the cutting action worse. A little trouble was experienced from this cause but was largely avoided by close inspection.

The wires were temporarily dead-ended during installation at anchors set in the ground near midspan. Permanent dead ends and splices were usually made up on the ground. However, at some crossings it was not feasible to lower the wires again for the compressing of the dead ends after the wires had once been raised into position. In these cases a platform was set up on the crossarm and the dead ends were made on the tower, figure 16. Sagging was done by transit, and occasional checks were made with a dynamometer. The observer at the span being sagged directed the adjustment of the tension over a field telephone set connected to the conductor. All the wires were installed without prestretching.

Tower Lighting

The towers for the first ten miles from Crawford station are located in the general vicinity of the Chicago Municipal Airport and its associated airways and are to be provided with red warning lights in accordance with an agreement with the Civil Aeronautics Board. The usual method of providing a supply line to the towers by a distribution line would have been quite expensive, as an entirely new line would have been required throughout most of the ten miles. Instead, resort has been made to the unusual arrangement of insulating one of the ground wires and using it to supply distribution-type transformers on each tower. The return circuit is through the earth and the other ground wire. The insulation of the energized ground wire, figure 10, is sufficient for its normal potential of 2,160 volts alternating current, 60 cycle, but the impulse strength is only about 80 kv. De-ion protectors are shunted across this insulation so that a lightning stroke will go to ground through the protectors, except possibly for very steep-front strokes. Thus the energized wire will also function as a ground wire.

A distribution-type transformer of the CSP design is installed on each tower and supplies a standard 120-volt, 150-watt lamp. The fixtures are the standard Civil Aeronautics Board duplex obstruction lights, which have a throwover relay to place the second lamp in use after failure of the first one. The lamp sockets are mounted in specially developed spring supports to protect the filaments against vibration. The normal load current in the ground wire has been kept very low, about three amperes average, by using the 2,160-volt feed. The maximum current that would occur due to a fault has been limited to ten amperes by a reactor in the supply circuit. These limitations of current were necessary to secure inductive co-ordination, as discussed in the following section. Protective devices are provided in the circuit to open it in case of a fault anywhere external to the transformers on the towers. If a tower transformer becomes faulted, it will be automatically disconnected without interrupting the circuit.

Inductive Co-ordination

Some difficult problems in inductive co-ordination were encountered in the 17-mile section of double-circuit towers at the Chicago end of the line. The route throughout this section parallels three main trunk telegraph leads operated by two large telegraph companies. The separations originally varied from 50 feet to 3,000 feet. About 57 telegraph circuits are involved. Many of them are varioplex and four-channel multiplex circuits operating at signaling speeds of about 66 words per minute and their sensitivity to disturbing voltages is quite high. In addition, the telephone, telegraph, and signal wires of two important railroads are carried on the same poles with the commercial telegraph circuits. Some carrier telegraph and telephone circuits are now being superposed on the existing wires and there is an increasing trend toward this type of plant.

Co-ordination was secured by a variety of methods. The pole lines for the signal plant were relocated to eliminate physical conflict, but it was not possible to obtain wide separations. About $4^1/_2$ miles of parallel has only about 200-foot spacing. The induction on the sensitive high-speed signal circuits due to normal operation of the power line is nullified by neutralizing amplifiers[4] connected to the telegraph circuits. A pilot wire on the signal lead picks up the same voltage as is induced on the signal wires. This voltage is then applied in opposite phase to each affected signal wire, thus virtually canceling the induction. The signal circuits other than high-speed telegraph, for example telephone and Morse telegraph, are not provided with neutralizing equipment. For the benefit of such circuits, the mitigative measures included the retransposition of telephone circuits where necessary and the provision of resonant reactors for some of the telegraph circuits. A co-ordination measure of general benefit to all signal plant was to lay out the transpositions of the power line in such a way as to minimize the disturbing effect of earth currents induced in the ground wires by balanced current in the phase wires. The line was transposed at five points in the 17-mile section for this purpose.

The induction due to power line abnormals was calculated to be several thousand volts. This is far beyond the capacity of the neutralizing equipment, which has an efficient working limit of about 100 volts. However, it was seen that abnormals would very seldom occur since the construction used on the power line is of very high grade. On this basis, arrester relays to drain the 60-cycle induced current from the signal wires during power line abnormals were deemed adequate.

The supply circuit for the obstruction lights on the towers presented a difficult co-ordination problem, since it is essentially a multigrounded circuit with earth return and parallels the signal leads for ten miles. Co-ordination was accomplished by specially designing the circuit and its feeding equipment to hold the normal load current and the maximum fault current to the very low values previously mentioned. The induced voltages due to these currents are well within the capacity of the neutralizing amplifiers to nullify and in fact would have very little disturbing effect if the neutralizing amplifiers were out of service.

The only co-ordination problem of any consequence encountered on the 130 miles of single-circuit construction was solved by specially locating one of the transposition points. Only four transpositions were made, as the main purpose was merely to balance the impedances of the three phases. The four transpositions gave two complete barrels, one about 80 miles long and the other about 50 miles.

The progress of co-ordination engineering in the last ten years is well illustrated by the work done in connection with this line. When the project was started in 1930, the co-ordination measures then proposed were the best that were available. The present measures, however, are very much more effective and satisfactory to all the interested parties. This improvement in results did not entail increased costs. On the contrary, the present cost is more than 30 per cent less than the cost of the measures proposed in 1930. Another striking feature was the simplicity of the negotiations from an engineering standpoint. Due to the work of various committees in developing and publishing data on co-ordination problems, it was surprisingly simple to arrive at agreements between the many interests involved.

Radio Noise

Because of the proximity of the line to the Chicago Municipal Airport and its relationship to the Chicago radio range beacon, some questions arose as to possible interference with aviation radio communication which might be caused by the line. An investigation was conducted by three methods: (1) measurement of radio noise from a typical insulator string and section of conductor in the laboratory, (2) determination of radio noise at selected locations near the line and airport before and after the line was placed in service, and (3) checks on existing 220-kv lines in Pennsylvania and New Jersey.

In the laboratory investigation, an 18-unit string of insulators, supporting a 50-foot length of 900,000-circular-mil ACSR conductor, including the armor rods and vibration dampers, was arranged for test as shown in figure 17. Voltages up to 185 kv to ground, or equivalent 320 kv three phase, were applied to the conductor and measurements of radio noise-influence voltages made, using the EEI-NEMA-RMA circuit.[5] A frequency range of 150 kilocycles to 20 megacycles was covered.

The laboratory tests also included measurements made with an antenna placed at various distances from the conductor and insulator string. These measurements covered a frequency range of 150 kilocycles to 125 megacycles with special emphasis on the frequencies in common use in aviation radio. Radio noise at the lower frequencies and up to 20 megacycles was explored by means of a meter having the recommended EEI-NEMA-RMA circuit; the higher frequencies with an RCA high-frequency field intensity meter. This latter meter was applicable only for the measurement of radio-frequency field strengths; consequently, the lower and higher frequency measurements were not strictly comparable.

With the insulators dry, radio noise was practically negligible, even directly underneath the conductor. Results for an artificial rain falling on the insulators are shown in figure 18. At the closest point of measurement, an actual distance of 28 feet from the suspension clamp, field strengths as high as about 3,000 rms microvolts per meter (quasi-peak voltage of radio-frequency wave) were measured around 300 kilocycles. There was a marked decrease in radio noise for the higher frequencies, until at 20 megacycles and above no field strengths that exceeded the meter sensitivity were noted. Attenuation normal to the conductor was very rapid; the highest value measured 45 feet from the suspension clamp was only 100 microvolts per meter. As shown in the graph of test results, figure 18, much lower values were measured over most of the frequency range between 300 kilocycles and 125 megacycles. It appeared from these laboratory tests that the interference of the line with radio services would be negligible.

This tentative conclusion was supported by field measurements made during a co-operative investigation this year by several organizations on operating 220-kv lines. Data from this investigation are to be published. It was found that the attenuation of radio noise normal to the lines was quite high. At a few hundred feet the radio noise was negligible even at the lower frequencies, which included the radio range beacon services.

The general conclusions drawn from the foregoing tests were confirmed by measurements on the Powerton-Crawford 220-kv line. Figure 19 shows the characteristic rapid attenuation normal to the line and decrease in noise at the higher frequencies, for fair weather conditions. There has been no opportunity as yet to obtain corresponding data for wet weather conditions. It is anticipated, however, that the line will not be a source of radio interference, during any weather conditions, to receiving stations located a few hundred feet or more from the line. A careful check has shown that the line has had no detectable effect on the radio range beacon.

Short-Circuit Calculating Procedure for Low-Voltage A-C Systems

A. G. DARLING[*]
NONMEMBER AIEE

Introduction

FAULT currents in electrical systems depend upon the impedance of the circuit for their intensity. Stresses, both thermal and mechanical, occur due to such currents and at various time intervals following initiation of the fault. Such stresses are of primary interest in system and equipment design. The possible amount of short-circuit current in any system equals the quotient of the voltage divided by the impedance. The latter term usually includes certain elements which formerly were indeterminate but now can be estimated with reasonable accuracy. Short-circuit currents measured in present-day (600 volts and less) types of equipment were found to check closely with currents calculated from the impedance of the circuit and the applied voltage.[1] It is, therefore, advisable to discard "rule-of-thumb" or "discounting" procedures for predetermining fault currents.

In the discussion which follows, a method is given whereby the symmetrical current may be calculated from the E/Z relation; the amount of d-c component is shown to decrease from a theoretical maximum at zero time at various rates according to the relation of the circuit reactance to its resistance; a simplified and convenient step-by-step procedure is given for the determination of balanced three-phase short-circuit currents using the foregoing relationships; the time is shown at which currents that determine the interrupting and short-time duties of circuit interrupting devices are identified in order that the corresponding value of reactance and d-c component can be used for calculation of the imposed current.

Impedance values of apparatus, conductors, devices, etc., generally in the metallic circuit, also arc drop and contact resistance have been assembled in sufficient variety for most cases accompanied by explanations, where necessary, of their uses.

The material presented, while not entirely complete, will, it is expected, give the reader a fairly comprehensive view of short-circuit calculations and supply him with a procedure and essential impedance data.

Scope

The procedure suggested is a fairly rigorous method and applies in particular to a-c systems of 600 volts and less. It applies specifically to "bolted faults" in which the values of impedance are known. Data, however, are listed in the appendixes which indicate possible arc drop in certain types of arc faults. The procedure does not attempt to discuss the limitation of currents when affected by interrupter action.

The procedure outlined gives a method of calculation which is of high accuracy, permitting the application of apparatus on a reasonably sound basis. Involving, as it does, a degree of technical knowledge, the need is indicated for a simplified approach which may be agreed upon as being capable of reasonable accuracy and which can be applied by industry at large. Certain efforts are now being made to simplify the determination of short-circuit current during transient conditions, but until such methods have been developed and agreed upon the procedure outlined herein, will, it is expected, be of definite assistance to those interested in predicting short-circuit currents. These methods, however, will not obviate the necessity for taking into account all the impedance elements in low-voltage circuits.

Objective

The object of a short-circuit calculating procedure is to obtain that value of current which occurs at a particular time, as required by the characteristics of the equipment upon which the duty is imposed. The duty imposed by the short-circuit current may result in mechanical or thermal stresses or stresses due to the function of circuit interruption, relay operation, or system disturbance.

Principles Underlying the Calculation of Short-Circuit Currents in Low-Voltage A-C Circuits

1. Short-circuit currents should be determined by calculation from the impedance constants and the voltage of the circuit, that is

$$I = \frac{E}{Z}$$

The accuracy of the calculation depends upon the completeness and the accuracy of the impedance values used.

2. In the calculation, the impedance of all apparatus, devices, busses, and conductors up to the point of fault, should be considered, assigning the proper numerical values available for each item. Although impedance values of individual devices or parts of the circuit may appear negligible, the sum of a number of small impedances may be of appreciable magnitude in the total impedance. Missing circuit impedances should be estimated as well as possible using good judgment based on experience with similar types of circuits.

3. Values of impedance (resistance and reactance) for the principal devices and conductors in distribution circuits have been established by recent studies and added to available information. These data together with the constants of apparatus are given in the appendixes. Data given in appendix A, pertaining to apparatus, is general in nature but may be used in the majority of cases for "estimating" purposes. For specific apparatus, specific data should be obtained from the manufacturer when accuracy of such degree is warranted.

(NOTE: While it is expected that specific information concerning equipment and apparatus given herein will be repre-

sentative of that manufactured by other concerns, the data included have been obtained from apparatus and equipment manufactured by the company which the authors represent.)

4. Arbitrary reduction factors should not be applied to calculated short-circuit currents. Likewise, the practice of using a fixed short-circuit current value, arbitrarily established regardless of circuit constants, should be discontinued.

Short-Circuit Characteristics of Systems

GENERAL

Short-circuiting a system at any point permits an abnormal current to flow immediately in that system. The amount and persistence of this current rush depend upon the characteristics of the synchronous and induction motors and generators connected to the system at the time, and upon the impedance in the circuit between the sources and the point of short circuit.

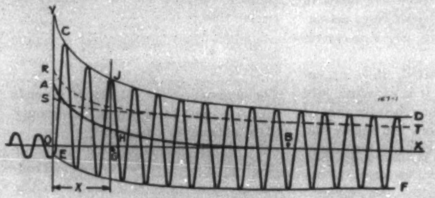

Figure 1. Short-circuit current flowing in one phase of a three-phase system

The greatest transient disturbance of the system that can occur at the point of application of the interrupting device, bus-bar supports, current transformers, etc., when the system is short-circuited governs the selection of those parts. The rms value of current is the unit in which the strength or ability of those parts is defined. A diagram showing the current flowing in one phase of the external circuit, when a system is short-circuited under ordinary conditions, is shown in figure 1. In this diagram, representing a current-time curve, the origin *O* is located at the instant fault occurs. The axis of abscissas, *OX*, represents time and the axis of ordinates, *OY*, represents current. The wave to the left of *O* represents the current during normal operation while that to the right represents the current from the start of the short circuit to the time it has become constant or sustained. It will be noted that the current wave at the instant of short circuit for the condition shown is initially unsymmetrical in respect to the *OX* axis, but that the wave gradually approaches the axis during the increasing increments of time, until it again assumes a position of symmetry. This phenomenon is dependent upon the point of the voltage wave at which the short circuit is established. It is possible by short-circuiting at different points on the normal voltage wave to secure short-circuit current waves ranging anywhere from those symmetrical about the *OX* axis to those totally unsymmetrical. Referring again to figure 1 showing short-circuit current based on an unsymmetrical wave, *CD* is a curve passing through the maxima of the wave of the total current, and *EF* is a curve passing through the minima. *AB* is a curve which cuts the vertical everywhere midway between *CD* and *EF*.

The wave of total current whose crests lie along curves *CD* and *EF* and whose ordinates are measured from the axis *OX* may be regarded as having two components, namely:

1. A direct component.
2. An alternating component.

The direct component is represented at any time by the ordinate to the curve *AB* or at the time *X* by the ordinate *GH*.

The alternating component is a wave whose crest value at any time is the difference between the ordinates to the curves *CD* and *AB*. This difference at the time *X* has the value *HJ*. The rms values of this alternating component are shown on curve *ST*. At any instant, this component is considered to have the same rms value as an alternating wave of constant amplitude whose crest value is represented by one-half the distance between curves *CD* and *EF* at that instant.

The effective total current at any instant is the square root of the sum of the squares of the value of the d-c component and the effective value of the a-c component. The quantity, so obtained, is the rms value of a steady-state current having the same magnitudes of a-c and d-c components as those which existed at the instant under investigation. The rms values of the waves whose peaks are defined by curve *CD* (major peaks) are shown on the curve *R-T*.

The rms current at any point of a system under short-circuit conditions is affected by the following factors:

1. Synchronous and induction rotating machine voltage, reactance, and resistance.
2. Circuit arrangement, voltage, reactance, and resistance.
3. Contact or arc resistance at the short circuit.
4. The nature of the short circuit, whether single-phase, multiphase, or phase-to-neutral.
5. The kilovolt-amperes and power factor of the load being carried at the time of the short circuit.
6. The point of the voltage wave at which the short circuit is established.
7. The effect of automatic voltage regulators is not considered herein as it is usually not noticeable until approximately 0.2 second after the short circuit.

SOURCES OF SHORT-CIRCUIT CURRENT AND THEIR BEHAVIOR

Practically all the rotating machines represent sources of short-circuit current, including induction as well as synchronous machines, whether applied as generators, motors, or converters. The short-circuit characteristics of the principal classes of machines differ in some respects as follows.

Synchronous Machines

A Steady-State Portion (I_s) controlled by the synchronous reactance x_d and field excitation which persists as long as speed and excitation are maintained, providing the circuit remains closed.

Plus a Transient Portion ($I'-I_s$) whose initial magnitude is controlled by the transient reactance (x_d') and which diminishes exponentially with a time constant generally between the limit of one-fourth and eight seconds, depending upon specific machine constants and electrical proximity to the fault.

Plus a Subtransient Portion ($I''-I'$) whose initial magnitude is controlled by the subtransient reactance (x_d'') which also diminishes exponentially but at a much faster rate with the time constant in the order of $^1/_{30}$ second.

It is to be noted that a quantity which is diminishing at an exponential rate is reduced to approximately one-third of its original value in a time interval equal to the time constant.

Induction Machines

The short-circuit current contribution from an induction motor or generator consists essentially of a single a-c component which diminishes exponentially.

No steady-state component is present due to the absence of separate excitation. The time constant of decay is of the same order as the subtransient component in synchronous machines, which permits common treatment of the two.

Synchronous Converters

Considering only the case of synchronous converters, singly or, if in multiple, supplied as a group from a common bus and paralleled on the d-c side, the reactance of the armature circuit and its resistance, together with the impedance of the converter's transformer, will limit the a-c current fed by the converter to a source-side fault.

If separate sources of supply feed converters operated in multiple on the d-c side, the impedance of the converter circuit is materially changed. This case deserves separate consideration.

Large Systems Feeding Small Systems

When giving consideration to a small system, fed in part or in whole by a large system, the large system should be carefully analyzed in order to be fairly accurate. The total impedance of the large system to the small system, incorporating the subtransient reactance, should be calculated from accurate data. It is inadvisable to assume that the voltage of the large system will be maintained during a fault on the smaller system or that the effect of the subtransient reactance of the sources in the large system can be neglected until a careful review of the large system diagram and its constants has been made and compared with the impedance of the transformers connecting the two systems.

If the necessary information required for the foregoing procedure is not available, the most accurate impedance data that are available should be used. Generally, these will be in the form of transient reactance and an incomplete knowledge of the system from which an approximation of the large system subtransient reactance can be obtained.

The effect of motors, generators, and converters on the secondary side of the transformer should also be taken into account.

RESISTANCE

Resistance of the circuit has two effects:

First, it limits the flow of current in the circuit by creating a voltage drop. Except that the drop is at a 90-degree phase angle with respect to the drop due to reactance the two are similar. To obtain the impedance to point of fault, it is necessary to obtain the total resistance and total reactance and combine them in the relation:

$$Z=\sqrt{R^2+X^2}$$

substituting either ohmic or per unit values and obtaining results in the same unit. If resistances of arcs are to be taken into account, they should be added directly to the resistance of the metallic circuit. Appendix *F* suggests values of arc resistance for specific types of faults. The effect of an arc varies from practically no effect to that of a current-limiting effect by which the arc is self-extinguishing.

Second, the d-c component of total short-circuit current decays more rapidly as resistance increases. The effect will be seen in the d-c decrement factor, plate *B*, figure 2.

COMPLETE SHORT-CIRCUIT STUDY

For a three-phase system, a complete short-circuit study involves various types of faults:

1. Three phases
2. Phase-to-phase
3. Phase-to-neutral
4. Multiple phases and neutral

Many low-voltage a-c systems do not use a grounded neutral and, for the remainder, the three-phase fault practically always develops maximum initial current. Where other than three-phase faults are to be considered, it will be advisable for the investigator to use the symmetrical component or other like procedure.

The general procedure suggested herein should be used for three-phase and other types of faults up to the point of calculating the particular fault. From this point on, the procedure pertains only to three-phase faults on three-phase systems. For other types of fault, additional impedance data will be required.

Specific Procedure for Calculating Three-Phase Short-Circuit Currents in a Three-Phase System

Step 1. Prepare a one-line system diagram on which the reactance and resistance of component parts, referred to a common base, will be noted.

Step 2. Determine the resistance and the reactance of all equipments, devices, and conductors and the transient and subtransient reactance of synchronous machines, the reactance of induction machines which is equivalent to the subtransient reactance of synchronous machines, and the resistance of synchronous and induction machines.

Step 3. Express all resistance and reactance values in terms of "per unit" (pu) on a convenient size, common base, and insert these values on the system diagram—step 1.

To express a pu value, referred to one base, such as the rating of a definite piece of apparatus, on a different base use the relation:

$$\text{pu value base}_2=\text{pu value base}_1\times\frac{\text{base}_2}{\text{base}_1}$$

The value of any resistance, reactance, or impedance in ohms may be expressed in pu terms by:

$$\text{pu value on base kva}=\frac{\text{base kva}\times\text{ohms}}{\text{kv}^2\times 1{,}000}$$

Step 4. Calculate, by conventional methods or by the use of a calculating board, the total pu reactance and resistance (expressed on the common base) to the point of fault.

NOTE: A method of combining parallel impedances into an equivalent single circuit is given in appendix J.

Step 5. Calculate the impedances and rms value of symmetrical short-circuit current by the relations:

$$Z_d'=\sqrt{x_d'^2+r^2}$$

corresponding to transient reactance.

$$Z_d''=\sqrt{x_d''^2+r^2}$$

corresponding to subtransient reactance. Z_d', Z_d'', x_d', x_d'', and r should be expressed in pu values.

The total subtransient reactance (x_d'') is obtained by adding the subtransient reactance of the synchronous machines or the reactance of induction machines directly (in series circuits) to the fixed reactance of connections, devices, transformers, induction regulators, etc. Similarly, the total transient reactance is obtained by adding the transient reactance of rotating machines directly (in series circuits) to the aforementioned fixed reactances.

$$\frac{I_B}{Z_d'}=I' \text{ (rms amperes)}$$

corresponding to transient reactance.

$$\frac{I_B}{Z_d''}=I'' \text{ (rms amperes)}$$

corresponding to subtransient reactance. I_B should be expressed in amperes of the base kilovolt-amperes at the voltage of the point for which calculations are being made.

Step 6, Symmetrical Current at Time t_1. The quantitative relation between values of x_d'' and x_d' varies for different sources of short-circuit current. To be exact for a number of different sources would involve considerable investigation.[3] The characteristics of various types of sources have been consolidated into a single set of characteristics and are used in the following procedure which determines the symmetrical current due to the decrease in subtransient reactance effect at time (t_1) by the relation

$$I_{(\text{rms sym.})t_1}=I_B\left[\frac{1}{Z'}+C\left(\frac{1}{Z''}-\frac{1}{Z'}\right)\right]$$

which is the same as

$$I_{(\text{rms sym.})t_1}=I'+C(I''-I')$$

Factor (C) is obtained from plate A, figure 2. It represents the rate at which the subtransient reactance decreases in relation to the transient reactance as time progresses. The time (t_1) at which C is selected may be taken from table A which specifies the time (t_1) needed for general uses. Obtain factor C at time (t_1) and calculate $I_{\text{rms}_{t_1}}$ from formula above.

Step 7, Unsymmetrical Currents. Select step 7*a* or step 7*b* according to results desired; see table A.

Step 7a, Maximum Unsymmetrical Current in One Phase at Time (t_1). Select the curve from the d-c decrement factor, plate B, figure 2 corresponding to $\dfrac{\text{pu } x_d'}{\text{pu } r}$ and obtain the factor K for the time (t_1) at which current is to be determined. The total rms unsymmetrical current at time (t_1) including the effects of subtransient reactance and d-c component is obtained by

$$I_{(\text{total rms unsym.})t_1}=KI_{(\text{rms sym.})t_1}$$

Step 7b, Unsymmetrical Current, Maximum Average of Three-Phase Currents at Time (t_1). Multiply the symmetrical current at time $t_1={}^1/_2$ cycle obtained in step 6 by a factor ($K_{\text{avg 3 ph}}$) selected from figure 3, according to the x''/r ratio of the system to the point at which current is to be obtained.

$$I_{\text{avg 3 ph}}=I_{(\text{rms sym.})t1}\times K_{\text{avg 3 ph}}$$

General Factors to Obtain Total Current From Symmetrical Current

By the foregoing fairly rigorous procedure, the total unsymmetrical current may be calculated for any particular time desired. The particular time for which current is to be calculated depends upon the purpose under consideration. For the practical purpose of determining the duties on devices and equipment in circuit, the standards to which they are built must be consulted. It will be found that there is no general agreement among existing standards and in some instances no standards exist. Suggestions of duties to use pending adoption of standards are offered later in the text.

Certain efforts are now being made to simplify the procedure by nomination of multiplying factors by means of which total current may be obtained from symmetrical current in order to put the calculation of total current on a common basis for specified equipment or devices and to eliminate the necessity for use of the x''/r ratio. Attention is called to a factor for three-phase low-voltage air circuit breakers which is the only one for low-voltage equipment that has come into somewhat general use and is explained in a footnote under table A. As other factors are agreed upon, they may be used within the limitations of their definition.

For determination of total currents under specified conditions of x''/r and elapsed time from initiation of current, table A synopsizes existing standards of current as a variable with time which should be calculated or suggests elapsed times in lieu of such standards.

In lieu of the determination of the specific average of the three unsymmetrical, available currents for a specific x''/r ratio, the factor 1.25 may be used to increase the symmetrical current calculated in step 6 to obtain the average of the three un-

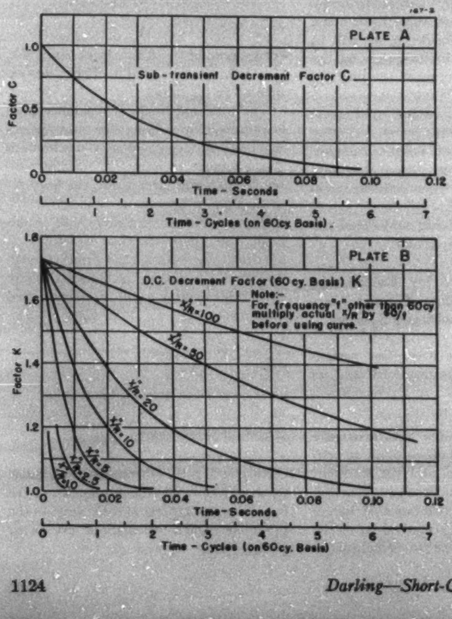

Figure 2. Short-circuit current decrement curves for subtransient and direct currents

I total rms $=K[I'+C(I''-I')]$

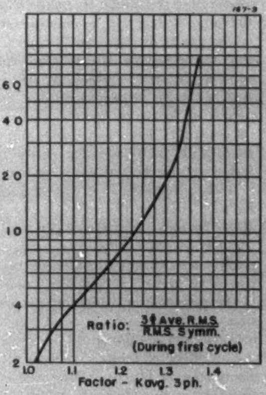

Figure 3. Short-circuit current decrement curve for three-phase average d-c decrement

Ratio of three-phase average rms total current to rms symmetrical during first cycle of fault-current flow

Curve represents maximum ratio for a simultaneous three-phase fault with initial components of:

Phase	A	B	C
A-c sym.	1.0	1.0	1.0
D-c	1.42	0.71	0.71

Table A. Short-Circuit Currents for Establishing Mechanical, Thermal, and Interrupting Duties on Devices and Equipment

Device or Equipment	Mechanical	Thermal	Interrupting
A. Stationary equipment, e.g., current transformers, bus bars, and supports, etc.	Step 7*a* ($t_1 = {}^1/_2$ cycle)	$I_{\text{therm.}}$*	
B. Interrupting devices, e.g.			
1. Air circuit breakers, 3 phase, 600 volts and less**	Available current Step 7*b* ($t_1 = {}^1/_2$ cycle)		Available current Step 7*b* ($t_1 = {}^1/_2$ cycle)
Air circuit breakers, 1 phase, 600 volts and less	Available current Step 6 ($t_1 = {}^1/_2$ cycle) × 1.25		Available current Step 6 ($t_1 = {}^1/_2$ cycle) × 1.25
Cartridge and plug fuses, 600 volts and less, and current-limiting fuses, all voltages			Available current Step 7*a* ($t_1 = {}^1/_2$ cycle)
2. Power circuit breakers	Step 7*a* ($t_1 = {}^1/_2$ cycle)	$I_{\text{therm.}}$*	Step 7*a* (t_1 = minimum relay time + minimum contact separation time)
3. Industrial controllers			
a. Those whose circuit opening and closing ability = 10 × current at hp rating	Available current Step 7*a* ($t_1 = {}^1/_2$ cycle)		Available current Step 7*a* ($t_1 = {}^1/_2$ cycle)
b. Those incorporating in a manufactured assembly, hp rated contactors and short-circuit protective devices such as fuses and instantaneous trip air breakers	Available current Step 7*a* ($t_1 = {}^1/_2$ cycle)		Available current Step 7*a* ($t_1 = {}^1/_2$ cycle)
c. Those which comprise a single switching element having published hp and short-circuit ratings	Available current Step 7*a* ($t_1 = {}^1/_2$ cycle)		Step 7*a* (t_1 = minimum relay time + minimum contact separation time)

*$I_{\text{therm.}}$ In selecting a current for this designation, the object is to choose a current which, if sustained, would produce the same heating as is created by the actual thermal duty cycle under consideration. The times at which currents are to be calculated are partially indicated in existing standards.

**In lieu of the determination of the specific average of the three unsymmetrical, available currents for a specific x''/r ratio, the factor 1.25 may be used to increase the symmetrical current calculated in step 6 to obtain the average of the three unsymmetrical, available currents in a three-phase low-voltage air circuit breaker when the x''/r ratio is less than 12:1.

symmetrical, available currents in a three-phase low-voltage air circuit breaker when the x''/r ratio is less than 12:1.

For a clearer understanding of table A, the comments which follow should be noted.

Mechanical stresses, such as determine momentary ratings of breakers, current transformers, and bus rigidity,[3,4] are calculated from the highest total rms current (including the d-c component) during the first half cycle.

Thermal stresses occur as an integration of current, squared, over a time interval. Present thermal ratings are determined from currents at selected periods or assume that currents are held at a constant value. The standards for the equipment or device under consideration should be used to obtain a guide to calculating the thermal duty.

The ability of interrupting devices is, at the present time, defined by either of two conventional methods. In one instance the duty is expressed as to current (termed "available current") which would flow in the circuit if the interrupting device is considered to have negligible impedance—measured in testing by substituting a short-circuiting bar of negligible impedance for the interrupting device.

NOTE: Where the term "available current" is used in this procedure, it is intended to mean maximum available current. In the other instance the duty is expressed as the current which exists at the moment the contacts of the interrupting device part or arcing begins. Since the construction and adjustment of the devices determine the time element from inception of short circuit to contact separation, the current must be calculated at a suitable increment of time after short circuit. In the interests of simplification, a common method of expressing interrupting device ability would be very helpful.

Short-circuit duty standards have not been adopted for industrial controllers. In general, the varieties of controllers can be classified into three groups. Suggested means to calculate the duties of these groups are as follows:

Group A. Controllers rated only in horsepower. In general, such controllers are capable of switching the current corresponding to ten times the horsepower rating of the controller. Available current might be used to express the duty on this group of controllers.

Group B. Controllers consisting of horsepower rated contactors and short-circuit protective devices, such as fuses and instantaneous trip air circuit breakers, all assembled by the manufacturer in a unified structure in such a manner as to practically preclude the possibility of a fault short-circuiting the impedance of any portion of the combination. Current that is available on the source side of the combination might then be used to express the duty on the controller.

Group C. Controllers comprising a single switching element which have a published horsepower rating as a controller and a published short-circuit rating as an interrupting device. In this case the short-circuit duty might be expressed in terms of the short-circuit rating of the switching element which will generally be found to be in terms of the current existing when the switching element is in circuit and at the time its contacts part.

Interrupting Devices Classified

CLASS I

Class I includes those interrupting devices whose duty is expressed in terms of available current.

Fuses for 600 Volts and Less. Some conventional cartridge fuses will, on heavy currents, open the circuit before the peak of the first half cycle. It is believed that, when a-c ratings are assigned, they will be in terms of available current. Until standards for a-c interrupting ratings are established, it is suggested that the duty be calculated as of the maximum rms current during the first cycle.

Fuses—Current Limiting for All Voltages. Domestic and foreign current-limiting fuses for 2,500 and higher voltage circuits are available and some foreign makes of low-voltage current-limiting fuses are made. Since these operate before the peak of the first half cycle, their duty is expressed in available current and therefore it should be expressed in terms of the maximum rms current during the first cycle.

Circuit Breakers—Air (600 Volts and Less). The interrupting rating of an air circuit breaker of 600 volts or less is expressed in total available rms amperes, which occur during the first cycle following inception of the short-circuit current. (This rating in amperes remains constant for any circuit voltage within the rating of the breaker.) The momentary rating of an instantaneous trip air circuit breaker is numerically equal to its interrupting rating.

In the case of three-phase breakers, the three-phase duty is taken as the average of the three-phase short-circuit currents. A convenient means of determining the average as a function of the ratio of subtransient reactance to resistance in the circuit is given in figure 3. These data are derived from that relation of currents in the three phases which gives the highest average of the three currents. In the case of phase-phase duty followed by three-phase duty, such as might occur with nonsimultaneous short-circuiting of the three phases, it is possible to calculate higher average currents than given in figure 3. This case appears to be sufficiently improbable to allow it to be discarded from normal calculated circuit breaker duty and instead to depend upon the ability of the air breaker to interrupt the slight additional expected current which can occur under these remote circumstances. When the more exact method, indicated above, of obtaining the average of the three phase currents is not required, the factor 1.25 may be used to increase the symmetrical current calculated in step 6 to obtain the average of the three unsymmetrical available currents when the x''/r ratio is less than 12:1.

In the application of breakers, in single-phase circuits, a factor of 1.25 times the symmetrical rms current in the first cycle is suggested as representative of the average total unsymmetrical rms current likely to be encountered in actual cases. The maximum unsymmetrical current can, if desired, be obtained from step 7*a* ($t_1 = 1/2$ cycle).

Class II

Class II includes those devices whose duty is expressed in terms of the current existing at the instant arcing begins in the interrupting device. This definition requires the interrupting device to be in circuit at the time a performance test is made.

Power Circuit Breakers. Beside momentary and five-second current ratings, the duty is calculated for this group of circuit breakers functioning without purposely delayed action at a certain inherent time delay after inception of short circuit, i.e.—time required for breaker, tripping and protective relays—sufficient to cause separation of the contacts. The time taken to cause contact separation is generally expressed in terms of whole cycles on a 60-cycle basis. The current to be calculated is the maximum rms value, one phase, that occurs at the instant of contact separation, regardless of the number of poles for which the breaker is built.

Inverse time overcurrent relays operate on the integration of current over the period of time elapsing during short circuit. For purposes of preliminary setting, it is safe to use transient reactance (x_d') since the first settings are generally modified by trial after installation. Minimum tripping current exists under maximum impedance conditions instead of minimum impedance needed for maximum current.

System arrangement and operating characteristics depend upon momentary current, current after a few cycles, and sometimes current after a longer period of time.

MISCELLANEOUS

J. Combining parallel impedances into a single equivalent circuit.

Appendix A. Rotating Machines

Impedance data for rotating machines is being subjected to analysis from the standpoints of calculating methods, tests, and technique of making tests. For close calculations, specific data for specific apparatus should be obtained until greater refinement in general form can be issued.

Where ranges of data are given, it is expected that the reader will select values within the range which will exemplify the case in hand. Only when very little is known of the particular machine should the mean value be used.

The values given in the following tabulations are only approximate and are intended merely to indicate the order of magnitude of the machine reactance and of the time constant. The designers may deviate from these average values quite appreciably in order to obtain other desired characteristics of the machines.

A-1. Synchronous Machines

See tables I and II.

A-2. Synchronous Converters

See figure 4.

A-3. Induction Generators and Motors

The short-circuit reactance of induction machines (in per unit on its own kilovolt-ampere base) may be taken as the reciprocal of the times normal stalled rotor current under conditions of rated impressed voltage and frequency. Induction generators, generally, will have the same reactance as induction motors of like rating.

Appendix B. Transformers

B-1. Distribution Transformers

See table III.

B-2. Power Transformers

See table IV.

Appendix C. A-C Reactors and Feeder Regulators

C-1. Reactors

The reactance is a portion of the rating.

The voltage drop through the reactor at rated current and frequency divided by the line-to-neutral voltage of the circuit gives the per unit reactance on the current rating of the reactor. (This will also be the per unit reactance on the kilovolt-ampere rating of the circuit, if the rated reactor current is the same as the rated current of the circuit.)

The effective a-c resistance may be obtained from the losses (I^2R) of the reactor. The d-c resistance is about 60 per cent of the effective resistance.

C-2. Feeder Regulators

See table V.

Appendix D. Conductors

D-1. Rectangular Bars and Channels

Resistance of Flat Copper Bars. See table VI.

Resistance of Channels. The resistance of channel conductors will generally be negligible when compared to their reactance.

Reactance of Bars and Channels. All reactance values given apply to 60 cycles. Reactance values at any other frequency f multiply the 60-cycle value by $f/60$.

The reactance of rectangular bars used for busses and connections depends on their length, size, grouping arrangement, and

NOTE: Refer to ASA standards, group 10, sec. 35 for definitions of:

T_a—Short-circuit time constant of armature winding.

T'_{d0}—Direct axis transient open circuit time constant.

spacing. The order of reactance magnitude at 60 cycles is from, say, 0.030 to 0.100 ohm per 1,000 feet of each conductor. While a reactance of 0.00006 ohm representing, say, the reactance of one foot of conductor, will not ordinarily be of serious importance in limiting short-circuit currents, a 50-foot length of conductor in a circuit, that is, 50 conductor feet at, say, 60 microhms per foot will represent 3,000 microhms reactance, or 0.003 ohm. At a current of 40,000 amperes, for example, the voltage drop across this reactance would be 120 volts, which is a sizeable voltage magnitude in a circuit of 600 volts or below.

The reactance at 60 cycles of rectangular bars used for busses and connections depends on their length, size, grouping arrangement, and spacing. Figures 5, 6, 7, and 8 give data for the more usual constructions. These values are primarily for long lengths but will be only slightly less for short lengths. In the case of joints between conductors of different sizes or spacings, the reactances for the various portions of the circuit are calculated separately and then added together. For general purposes of short-circuit calculations, the effect of angles and bends in the bus runs may be neglected and the reactance obtained from the total lineal distance.

D-2. CABLES IN DUCTS

Cables of particular interest in the calculation of short-circuit currents in low-voltage circuits include rubber, varnished cambric, and paper insulated types designed with insulation for 600, 3,000, and 5,000 volts.

Basic data are given in table VII for three-conductor and three single-conductor cables in a duct for the following basic conditions:

Standard-strand conductors.
Nonmagnetic binder construction.
Nonshielded design.
Operation in nonmagnetic ducts.

Note that the lead sheath increases the effective a-c resistance approximately five per cent above the a-c resistance shown. The lead sheath also tends to decrease the reactance from the values shown. The figures given are estimated to be within five to ten per cent. The impedance values shown do not include the increase in resistance and decrease in reactance mentioned.

Tables of resistance include the skin and proximity effects of three-conductor cables at 60 cycles. Tables of reactance for different types of insulation of any one voltage rating have been combined when the calculated values were within five per cent. This has also been done for cable impedances to reduce the number of columns.

Multiplying Factors

For conditions other than those specified, the following multiplying factors may be used to obtain *approximate* values.

(*1*) *Sector Conductor Cable* (*Compact*):

Size in MCM	Ratio = $\frac{\text{Round Cond. Reactance}}{\text{Sector Cond. (Av.) Reactance}}$
300	1.03
400	1.04
500	1.05
600	1.07
700	1.075
850	1.08

[†] For three-phase transformers of 500 kva and less, use the data of single-phase distribution transformers at one-third the kva rating of the three-phase transformer.

Obtain data for three-phase transformers over 500 kva from table IV.

* Data are given for specific designs. To allow for variations in manufacture, it is suggested that the resistance, reactance, and impedance data be rounded off to two significant figures.

D-c resistance may be derived from the 60-cycle resistance values by dividing them by factors varying from 1.0 to 1.2 using the larger factors for the higher normal ampere ratings.

(2) *Three-Conductor Cable With Magnetic Binder.* Multiply X by 1.25.

(3) *Cable in Magnetic Duct:*

Three-conductor cable—multiply X by 1.12
Three single-conductor braid-covered cables { multiply X by 1.25; multiply R by 1.12
Three single-conductor lead-sheath cables { multiply X by 1.12; multiply R by 1.30

(4) *Balanced Three-Phase, Four-Wire Circuits.* Use same values as three-phase, three-wire circuits as the increased spacing is small in comparison to the random arrangement of conductors.

As a result of field test data,[5] the spacing of the three single-conductor, braid-covered cables was increased 45 per cent to allow for the random arrangement of the cables in the duct. The test data also indicate that the reactance of lead-sheath cables for the lower voltage ratings is nearly the same as that for braid-covered cables. The data in table VII have, therefore, been made accordingly.

Since the tables for three single-conductor cables give line-to-neutral values, the resistance, reactance, and impedance of single-conductor cables on isolated single-phase circuits may also be determined by assuming the same spacing and proximity effect. Test data on the spacing of two single-conductor cables in a duct are not available but it is known that there will be some "snaking" of the conductors and the spacing, thereby, increased.

D-3. Stranded Conductors in Air

By means of table VIII, the resistance and diameter of various conductors may be obtained, and by means of the curves, figures 10 and 11, the reactance in ohms per mile at 60 cycles at various spacings of conductors may be obtained.

For frequencies other than 60 cycles, ohms at frequency

$$F=\frac{\text{ohms at 60 cycles}}{60}\times f \text{ cycles per second;}$$

i.e., for 25 cycles, ohms = ohms at 60 cycles × 25/60.

For three-phase circuits in which the conductors are not symmetrically arranged, at equal spacings, the reactive voltage drops in the three conductors are unequal, even for the case of balanced currents.

For approximate calculations in three-phase circuit with balanced currents and with unequal spacings, s_1, s_2 and s_3 between conductors, the mean spacing $s=\sqrt{s_1s_2s_3}$ may be used for calculation of average reactance per phase to neutral.

Appendix E. Current Transformers

The impedance of current transformers, though generally of a low order of magnitude in ohms, should be considered in short-circuit current calculations in low-voltage circuits because it may have an effect on the magnitude of the short-circuit current for heavy current short circuits, that is, of the order of 25,000 amperes or larger.

The impedance of the current transformers depends on the current rating and on their design, and varies over a wide range. Therefore, a single value of impedance applicable to a variety of current transformers, cannot be given.

With Primary Circuits of the Wound Type

Approximate data on resistance and reactance at 60 cycles for current transformers of type *W*, covering current ratings from 100 to 800 amperes, based on tests at short-circuit currents, are given in table IX. The values in table IX apply to transformers with a secondary burden of one volt ampere or less at five amperes or at normal current. For higher burdens, the impedance referred to the primary side will be somewhat increased, but the increase is far less than that occurring at normal currents, on account of the reduced mutual inductance between primary and secondary windings. The impedance values based on low burden are conservative for calculations of maximum short-circuit current.

Having Bar-Type Primary Conductor

For bar-type current transformers with current ratings from 1,000 to 4,000 amperes, such as the following types:

JS2—600 volts
WC15—5,000 volts
KC50—7,500 volts

the resistance and reactance have the following approximate order of magnitude:

Resistance—0.000025 ohm
Reactance—0.000070 ohm

at currents within the range from 10,000 to over 80,000 rms symmetrical amperes, with or without d-c component.

The reactance depends on the spacing between phases, since a considerable amount of air flux links the primary bar conductor. The value given is that for nine-inch phase spacing with the transformers side by side, representing an average value for the three phases for three-phase short circuits. Strictly speaking, the reactance in the three phases will be unequal in a side-by-side assembly of current transformers, but for short-circuit current calculations an average value can ordinarily be used without serious error.

It is a fair approximation to say that the reactance for bar-type transformers is equal to the air reactance of the primary conductor, considering its length, size and shape, and the spacing between phases. (See appendix D on reactance of bar conductors.)

Appendix F. Contact Drop and Fault-Voltage Drop Including Current-Limiting Effects

Contact Drop

Contact resistance drop in permanent joints is generally negligible in comparison with the impedance of the apparatus, conductors and devices in the circuit. In practical calculations, the resistance of permanent joints may be considered equal to the resistance of a length of conductor equal to the length of the joint.

Fault-Voltage Drop Including Current-Limiting Effects

The effect of the impedance at the point of fault on the magnitude of the short-circuit current in low-voltage distribution circuits varies widely, depending on the type of fault, that is, whether of the bolted type as in the case of a faulty connection, or of the arc type in which the member causing the short circuit is quickly repelled. A single value for impedance or resistance or current-limiting effect of the fault itself, can therefore not be given.

The current-limiting effect of an arc fault is due to its resistance. The procedure recommended for allowing for the effect of arc resistance in short-circuit current calculations is to use representative values of arc voltage in the calculating method outlined below. Though the arc voltage for many kinds of faults is relatively large, and may reach, or even exceed 50 per cent of the available voltage in the circuit, a correspondingly large current reduction due to the arc voltage is not obtained because the arc drop is a resistance drop and is therefore in quadrature with the reactance drop of the circuit. This caution is important, since short-cut methods of calculation using large reduction factors to take account of arc resistance have been erroneously used in the past.

Faults may be classified into the following groups from the point of view of their effects upon the magnitude of short-circuit current, as indicated by the magnitude of the arc voltages given in table X, to which the following groups of comments also apply.

1. *Short Circuits of the Bolted Type* are treated in the class with those in which the conductors are held in contact by other means, or in which a highly conducting member is firmly held or wedged against the conductors short-circuited.

The voltage drop at the fault will be that due to the contact resistance (or resistances) and will be less than, say, ten volts in most cases. The current-limiting effect of this type of fault will be negligible.

Should the contact at the fault become slightly loosened so as to produce a small arc, across a small gap of the order of, say,

†For three-phase transformers, use the data of single-phase transformers of one-third the kva rating of the three-phase transformer.

*Data are given for specific designs. To allow for variations in manufacture, it is suggested that the resistance, reactance, and impedance data be rounded off to two significant figures.

D-c resistance may be derived from the 60-cycle resistance values by dividing them by factors varying from 1.0 to 1.2 using the larger factors for the higher normal ampere ratings.

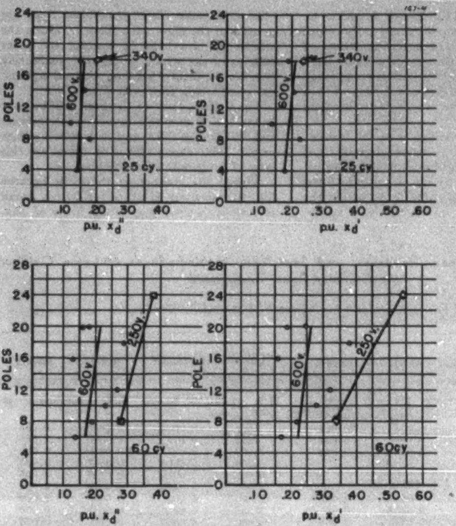

Figure 4. Synchronous converter reactance for use in isolated converter or when converters are paralleled on d-c side and fed from same a-c source

Add transformer reactance:

For compound wound converters 12 pu

For shunt wound converters 0.7 pu

General note: converter resistance 0.003 pu; transformer resistance 0.008 pu for small sizes to 0.005 pu for large sizes

$^1/_8$ inch, arc voltages of the order of 40 volts may be obtained, according to Slepian and Strom, who found arc voltages ranging from 40 to 100 volts at currents from 2,500 to 6,400 amperes between bare copper bars one-fourth inch apart.

Since arc voltages of the order of 40 volts instantaneous will generally not have an appreciable current-limiting effect, and since faults produced by firmly held conducting members may not form arcs at all in the initial stage of a short circuit, the faults of the group classified as "bolted faults or their equivalent" will develop the highest short-circuit current. Their magnitude is to be calculated on the basis of the impedance of the metallic circuit up to the point of fault, neglecting the fault resistance as in the case of a bolted fault resulting from a faulty connection.

2. The Current-Limiting Effect of Accidental Arc Faults formed by objects readily repelled or destroyed by the arc in enclosed, congested structures may be of a minor order. Arc-fault currents as high as 100 per cent (average three-phase value) of the rms symmetrical bolted fault short-circuit current may be expected in circuits up to 600 volts line-to-line open-circuit voltage.

Fault arcs in these structures may not be self-clearing within normal protective device clearing time.

Three-phase short-circuit currents for arc faults of this class as high as 99,000 amperes rms average value for the three phases, have been obtained in tests at 600 volts line-to-line voltage.

The arc voltage drop for faults of this type for conductor clearances of the order of two inches between phases and between circuits (case 2*a* in table X) was found to be as low as 80 volts crest, line-to-neutral value at circuit voltages within the range from 300 to 600 volts line-to-line voltage in three-phase circuits.

Arc faults between bare conductors with two-inch phase spacing in a metallic enclosure in the absence of other circuits within the same enclosure (case 2*b* in table X) gave arc voltages from 150 volts crest, line-to-neutral value.

Faults started as single-phase, line-to-line faults developed into three-phase short circuits within one-half cycle, in both cases 2*a* and 2*b*.

3. Arc Faults Between Isolated Bare Conductors away from enclosing walls will often have substantial current-limiting effects when the member initiating the fault is readily repelled or destroyed by the short-circuit current. In tests of faults of this kind, maximum peak currents have often been limited to values below 25,000 amperes, and the faults have cleared themselves within the first half cycle, but a limitation of current to this order of magnitude cannot be depended on.

4. Arc Faults Observed in Insulated Cables initiated by piercing the insulation with conducting members capable of being repelled gave currents as high as 80 per cent (approximate rms value) of the rms symmetrical bolted fault short-circuit current indicating that large current-limiting effects, in excess of 20 per cent with respect to the rms symmetrical bolted fault current, cannot be depended on.

Short circuit caused by piercing cable insulation with light metallic members such as a $^1/_8$-inch diameter drill, short-circuiting the line conductors, resulted in currents limited to values well below half of the rms symmetrical bolted fault short-circuit current.

Faults of the above character in exposed cables (not enclosed in ducts) were self-clearing within one or two half cycles.

Table V. Short-Circuit Impedance of Feeder Regulators of 60-Cycle Design

Range—Plus 10 Per Cent, Minus 10 Per Cent Volts

Type	No. of Phases	No. of Cores	Circ. Volts	Kva of Regulator	Per Cent Impedance (on Base of Circ. Kva) Min.	Avg.	Max.	Ratio of Reactance to Resistance
Induc.	1 or 3		2,400 to 4,800	12 to 96	0.65	0.85	1.00	10:1
				Amp. of Regulator				
Step	1	1	2,400 to 13,800	All ratings	0.0+		0.6	4:1
Step	3	1		to 160	0.0+		0.7	4:1
Step	3	3		over 160	0.15		1.0	4:1

Note: The impedance of a given step regulator is modified by the position of the tap changer, and becomes a maximum at maximum voltage boost. It is minimum at neutral position, while at the maximum buck the impedance is higher than at neutral.

Table VI. Resistance of Flat Copper Bars

4 bars 4"x$^1/_4$", in groups with 2" clearance between groups	0.0021	0.0027	0.0038

Calculating Procedure for Estimating Short-Circuit Currents in Circuits With Arc Faults

The arc voltages for different kinds of faults in low-voltage circuits will vary depending on

The conductor spacing between phases,
The spacing between adjacent circuits,
The type of construction, whether open or enclosed,
The clearances to ground and to enclosing walls,
The type of conductors, whether bare or insulated,
The manner in which the fault is initiated,
The character of the enclosing walls, etc.

It will not be attempted to consider all of these in detail. Some of the fault conditions of particular interest in low-voltage switchgear construction are those caused by conductors dropping across phases in the following types of structures:

(*a*). Heavy current bar-conductor assemblies with low to minimum spacings, metal enclosed, with two or more bar-conductor circuits in close proximity to each other.

(*b*). Bar-conductor circuits, remote from other live conductors, metal enclosed.

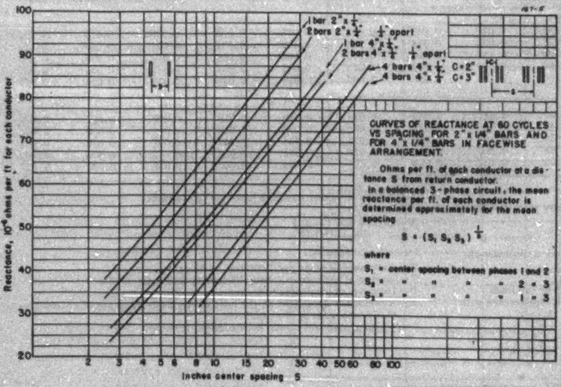

Figure 5

Less severe types of faults than those for (*a*) and (*b*) above may occur in open bar-conductor circuits remote from live conductors, and may give rise to short-circuit currents with more pronounced current-limiting effects.

When low to minimum clearances are used in structures of types (*a*) and (*b*), short-circuit currents due to objects (which are capable of being repelled or destroyed) bridging across phases may be roughly estimated from the values suggested in table X.

Basis of Formulas. As a first approximation, the vector voltage equation 1 for three-phase short-circuit including arc may be written assuming sine-wave voltages and currents:

$$\mathbf{E}-\mathbf{V}-r\mathbf{I}-j\mathbf{I}x=0 \text{ rms volts to neutral} \qquad (1)$$

where **E**, **V**, and **I** are vectors representing impressed voltage, arc voltage (line-to-neutral value) and line current respectively.

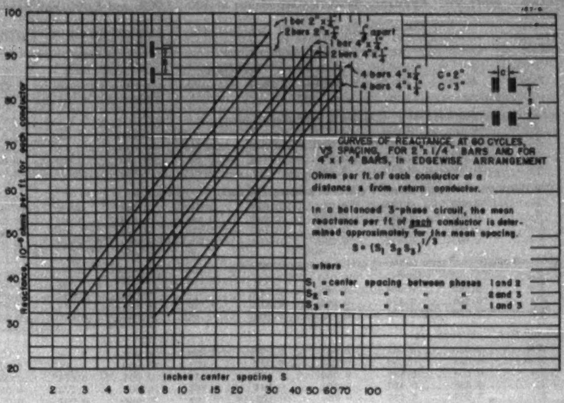

Figure 6

Numerically, the values are defined as follows:

E = scalar value of $\mathbf{E}=0.58x$ (line-to-line voltage of circuit)
V = scalar value of $\mathbf{V}=0.71x$ (crest value of arc voltage to neutral from figure 7 or 8, as required)
i = scalar value of $\mathbf{I}$ = rms symmetrical short-circuit current, amperes
$j=\sqrt{-1}$
r = resistance and reactance, respectively, of metallic circuit, ohms per phase, to the point of fault

The scalar value of current in rms amperes per phase, derived from equation 1 is:

$$i=-\frac{rV}{(r^2+x^2)}\times\left(1-\sqrt{1+\frac{(r^2+x^2)(E^2-V^2)}{r^2V^2}}\right) \qquad (2)$$

Figure 7

*Cable insulation and finish types:

X-a—Reactance of V.C. with braid cover or V.C. or paper with lead sheath.
X-b—Reactance of paper or V.C.
X-c—Reactance of rubber with braid cover or lead sheath.
X-d—Reactance of rubber.
Z-a—Impedance of rubber, V.C. or paper with braid cover or lead sheath.
Z-b—Impedance of rubber.
Z-c—Impedance of paper or varnished cambric.
R-a[6]—Resistance of single-conductor cable with braid cover (no lead).
R-a-c[7]—Resistance of three-conductor cable (no appreciable difference with braid cover or lead sheath).

NOTE: The reactance data are based on the formula:

$$X=0.023\left(\log_e\frac{2S}{D}+K\right)$$

$\log_e=\log_{10}\times 2.3025851$

X = Reactance in ohms per 1,000 feet at 60 cycles.
S = Spacing of conductors (center to center) in inches.
D = Diameter of conductor in inches.
K = A coefficient dependent on the ratio of the inside diameter of a conductor to outside diameter of the conductor.
For cables of standard-strand construction, $K=0.25$.

The general formula (2) reduces to the simpler formula (3) when the resistance r of the metallic circuit is negligible.

$$i=\sqrt{\frac{E^2-V^2}{x}}\text{ amperes, when } r \text{ is negligible} \quad (3)$$

For simplified calculations, the current i in equation 2 may be expressed in terms of the bolted-fault short-circuit current, multiplied by a factor p which is a function of the ratio of V/E and the power factor $\cos\theta$ of the metallic impedance. With the aid of curves of the factor p for particular values of the voltage ratio V/E and of $\cos\theta$, the calculation of short-circuit currents for arc faults becomes a simple procedure.

Results of calculations are given in table XI. In these calculations the arc voltages observed in the tests were used together with the metallic circuit reactance based on bolted-fault tests. Calculated and observed short-circuit current values for the arc faults are in good agreement, considering that the test values include at least a small amount of d-c component. The calculated values obtained with the assumed

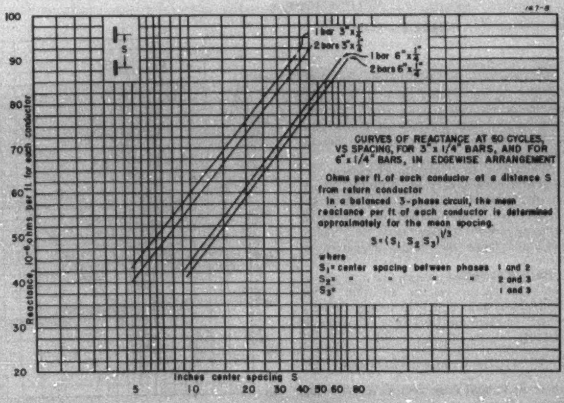

Figure 8

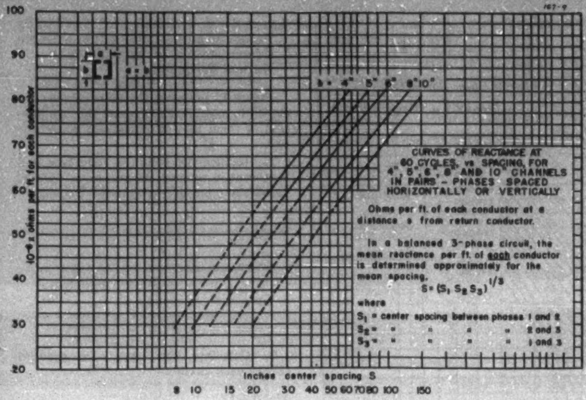

Figure 9

sinusoidal form factor of 0.71 for the arc voltage are probably somewhat high since the arc voltage is generally flat topped. Possibly a form factor of 0.8 or 0.85 for the arc voltages would be more nearly correct. The calculations of the table were made with a form factor of 0.71.

Appendix G. Switching and Control Equipment

G-1. OIL CIRCUIT BREAKERS

The reactance of certain oil circuit breakers with their contacts closed is indicated by the approximate values in table XII.

The data are given in ohms per pole at 60 cycles. The reactance values are based on calculations considering the size of the loop and the spacing between poles, and have been checked by test data for about one-third of the cases. The data do not apply after the contacts have begun to open; i.e., the resistance due to arc voltage during short-circuit interruption is not included. Obviously, the reactance per pole will not be the same for the three phases for three-phase balanced current flow. Approximate average figures have been given, since the unbalance of voltage drops in the different phases will almost always be negligible in the over-all impedance of the circuit.

The order of magnitude of the a-c resistance of oil circuit breakers of the above-mentioned types is from, say 0.00040 ohm per pole for a 200-ampere breaker to 0.000030 ohm for a 2,000-ampere breaker.

G-2. AIR CIRCUIT BREAKERS AND NETWORK PROTECTORS (600 VOLTS AND LESS)

The reactance of air circuit breakers with their contacts closed is indicated by the following:

	AE-1B-600 A. Coil Rating, Amps.		
	15	225	600
Resistance in ohms	0.033	0.00022	0.00010
Reactance in ohms	0.110	0.00085	0.00020

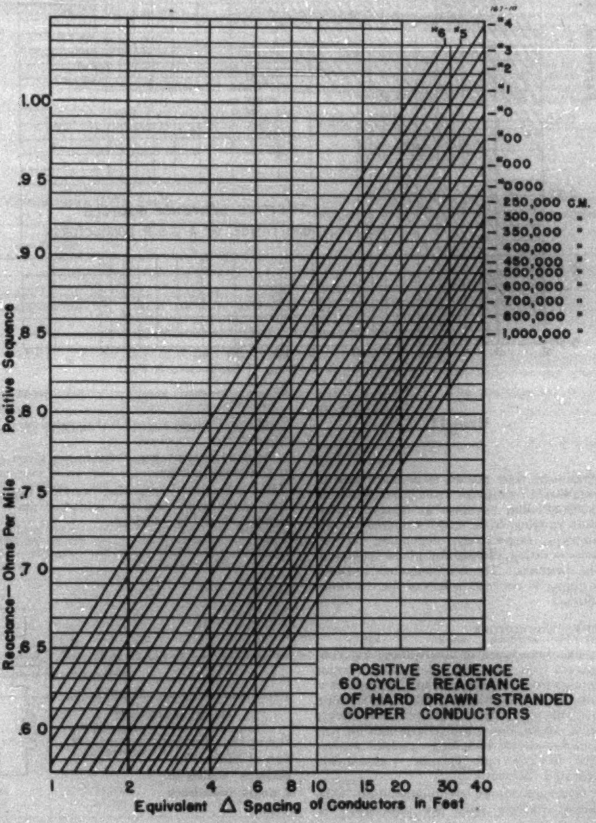
For air circuit breakers and network protectors of representative designs in rating above 200 amperes, the reactance in ohms is approximately 0.2/continuous rating in amperes. The a-c resistance of such breakers and protectors is in the order of 25–50 per cent of the reactance.

This does not include the impedance due to arc drop when a circuit breaker is in the presence of interrupting a short circuit. However, arc drop in interrupting devices need not enter into short circuit current calculations when circuit breakers are rated and selected on the basis of the prospective short circuit current, i.e., the current obtainable in the circuit when the breaker is replaced by a conductor of negligible impedance.

G-3. LEVER SWITCHES AND DISCONNECTING SWITCHES

The reactance of lever switches and disconnecting switches for low-voltage circuits

Figure 10



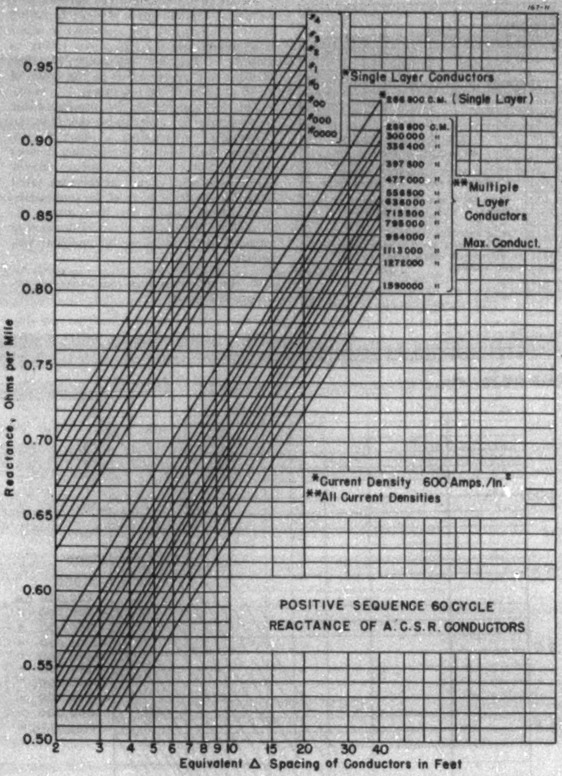


Figure 11

(600 volts and below) is of the order of magnitude ranging from 0.000050 to 0.000080 ohm per pole at 60 cycles, for sizes ranging from 4,000 amperes to 400 amperes, respectively, depending on the ampere rating, design, and phase spacing of the switches. The a-c resistance in ohms is about 30 per cent or less of the reactance ohms.

G-4. Contactors

The impedance of low-voltage a-c contactors (600 volts and below) with current ratings from 600 amperes to 150 amperes is roughly of the order of 0.001 to 0.003 ohm per pole at 60 cycles, the resistance being from about one-third to one-half of the impedance, not including overload protective devices and current transformers operated therewith.

Overload relays commonly used with motor starters have an impedance of roughly $5/I^2$ ohms where I is their rated current.

Data on current transformers are given in a separate section.

For calculations requiring accurate figures, additional data on contactor impedance should be obtained.

Appendix J. Solution of Combining Paralleling Impedances Into a Single Equivalent-Circuit Impedance at Normal Frequency

Figure 12 indicates the nomenclature assigned to multiple circuits and the combination of them into an equivalent single circuit.

1. Reduce the values of resistance and reactance in each of the two given parallel circuits to a per unit (pu) basis. Example:

	r	X
Branch *A*	0.05	0.15
Branch *B*	0.008	0.108

2. Calculate the impedance squared (Z^2) of each circuit

$Z^2 = r^2 + X^2$

Branch *A*: $r_a^2 + X_a^2 = Z_a^2$,
e.g., $-\overline{0.05^2} + \overline{0.15^2} = 0.025$

Branch *B*: $r_b^2 + X_b^2 = Z_b^2$,
e.g., $-\overline{0.008^2} + \overline{0.108^2} = 0.0117$

3. Obtain the ratios of r/Z^2 for each circuit

Branch *A*: r_a/Z_a^2, e.g., $\dfrac{0.05}{0.025} =$ 2.0

Branch *B*: r_a/Z_b^2, e.g., $\dfrac{0.08}{0.0117} =$ 0.683

4. Add the foregoing $r/Z^2 = G_0 =$ $\overline{2.683}$

5. Obtain the ratios of X/Z^2 for each circuit

Branch *A*: X_a/Z_a^2, e.g., $\dfrac{0.15}{0.025} =$ 6

Branch *B*: X_b/Z_b^2, e.g., $\dfrac{0.108}{0.0117} =$ 9.2

6. Add the foregoing $X/Z^2 = B_0 =$ $\overline{15.2}$

7. $Y_0^2 = G_0^2 + B_0^2$, e.g., $= \overline{2.683^2} + \overline{15.2^2} =$ 238.2

8. $r_0 = G_0/Y_0^2$, e.g., $\dfrac{2.683}{238.2} = 0.0112$

9. $X_0 = B_0/Y_0^2$, e. g., $\dfrac{15.2}{238.2} = 0.0642$

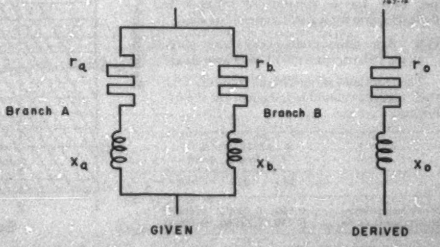

Figure 12. Resolution of multiple impedance circuits to a single impedance circuit

Table X. Arc Voltages for Various Types of Arc Faults

Type of Fault	Arc Voltage Instantaneous Volts	Current-Limiting Effect
1. Short circuits of the bolted type and their equivalent	Less than 50 volts and generally less than 10*	Not appreciable. Current to be calculated from impedance of metallic circuit, neglecting fault resistance
2. Arc faults in enclosed congested structures typical of modern switchgear and station design, formed by objects readily repelled or destroyed by the arc		
a. Highly congested construction with a multiplicity of closely spaced bare conductors	From 80 volts up*	Not of a large order; may be determined by calculation
b. Less congested structures	From 150 volts up*	Higher than 2*a*, may be determined by calculation
3. Arc faults between bare conductors in the absence of nearby live conductors and away from enclosing walls; arc voltages highly variable depending on the circumstances	May be of the order of magnitude of the circuit voltage and higher*	Highly variable, calculation not recommended
4. Arc faults in cables produced by piercing the insulation with conducting members capable of being repelled; arc voltages may vary widely	May be of the order of magnitude of the circuit voltage and higher*	Highly variable; large current-limiting action cannot be depended on; calculation not recommended

*Line-to-neutral values for three-phase short circuits.

Table XI. Comparison of Calculated and Measured Values of Short-Circuit Currents for Arc Faults in Enclosed Double-Bus Assembly

500	0.00010	0.00022
600	0.00008	0.00019
800	0.00004	0.00012

*Approximate values at short-circuit currents with d-c component; rms symmetrical component ranging from 15,000 to 55,000 amperes.

Notes: These values are also representative of the order of magnitude of the impedance for current transformers of the following types, rated at 5,000 volts: *JW*1, *JW*4, *JW*6, *JW*14, *WC*12, *WF*1, *WF*6, and *WF*12.

Impedances for other designs of current transformers of the wound primary type may be estimated by applying the following approximate factors to the values of table IX:

Type of Current Transformer	Factor to Be Applied to Resistance and Reactance Values in Table IX
*KF*85—7,500 volts	1.8
*JS*1—15,000 volts	0.4

The foregoing may be tabulated for convenience in solving a number of parallel pairs of circuits:

	r	X	$Z^2=r^2+X^2$	r/Z^2	X/Z^2
Branch *A*	( )	( )	( )	( )	( )
Branch *B*	( )	( )	( )	( )	( )
Branch *C*, etc.					

Addition of the last two columns gives $\overline{G_0=(\ \ )\ B_0=(\ \ )}$. The combination of the circuits results in:

$$r_0=\frac{G_0}{Y_0^2}, \qquad x_0=\frac{B_0}{Y_0^2}, \qquad Y_0^2=G_0^2+B_0^2$$

Any number of parallel circuits may be accommodated by additional horizontal columns same as branch *A* and branch *B*,

Surge Characteristics of Two-Winding Transformers

REINHOLD RÜDENBERG
MEMBER AIEE

1. Introduction

THE object of this paper is to show the performance of transformers with two windings in the rapid-transient state when surges develop in their conductors. On the one hand, we will determine the characteristic constants for traveling waves, as surge-impedance and wave velocity, from the data of the transformer. On the other hand, we will consider the rapid interaction of the primary and secondary windings, with different numbers of turns, which for travelling waves is very different from the coupling under quasi-steady-state conditions.[1,2,3]

In a previous paper[11] it is shown that the propagation of traveling waves of moderate frequency in coils and windings is similar to the propagation in smooth lines and that the values of surge-impedance and traveling-velocity of such waves can be derived from the total self-inductance and the total ground-capacitance of the windings under steady state conditions. Furthermore, very steep parts of incident waves, corresponding to the highest frequencies, are cut off and converted within the winding into a flattened front, the length of which depends on the internal capacitance between the turns or coils. In this paper these results for moderate frequencies will be used but the influence of internal capacitances for very high frequencies will not be considered, as this would only obscure the principal objective of the paper.

2. Characteristics of Ideal Transformer Coils

Consider a single-layer tubular coil as represented in figure 1. The axial length and the diameter may be large compared with the insulating distance b to the inner core. However, the wall thickness of the coil may be small compared with the distance b, while the outer tank may be at any distance from the coil. The surfaces of the core and the tank are considered as being smooth, and concentric to the winding and it is assumed that both are electrically perfect conductors. Then no rapid-transient flux can penetrate their interior, so that the magnetic field is parallel and the electric field perpendicular to their surfaces. The core and the tank are assumed to be grounded.

First we derive the steady-state values of capacitance and self-inductance of the coil since these are basic for the surge characteristics. We use the electromagnetic system of units and shall add conversion factors for the practical system where it is useful.

A uniform voltage E in the winding produces over the internal breadth b and the external distance d electric gradients which are represented in figure 1 as E_i and E_e. If w is the wire length of one turn, equal to the circumference of the coil, and h is the axial length of the winding, the electric charge of the entire winding under the influence of E is given by the total electric displacement over the areas on both sides of the coil as

$$Q=\frac{wh}{4\pi v_0^2}\left(\epsilon\frac{E}{b}+\epsilon\frac{E}{d}\right)=\frac{\epsilon wh}{4\pi v_0^2}E\left(\frac{1}{b}+\frac{1}{d}\right) \tag{1}$$

where ϵ is the dielectric constant of the insulating spaces on both sides and v_0 is the velocity of light in vacuum. Hence the total ground-capacitance of the coil, as the quotient of charge and voltage, is

$$C=\frac{Q}{E}=\frac{\epsilon wh}{4\pi v_0^2}\,\frac{b+d}{bd}\;(\times 10^9 \text{ in farads}) \tag{2}$$

A steady-state current I in the coil produces a magnetic flux which is entirely in the axial direction, and is equal in magnitude and opposite in direction within the insulating spaces on both sides of the coil. The flux densities B_i and B_e in the internal and external gaps are shown in figure 1. If N denotes the total number of turns of the coil, the flux in the gaps on either side of the coil is

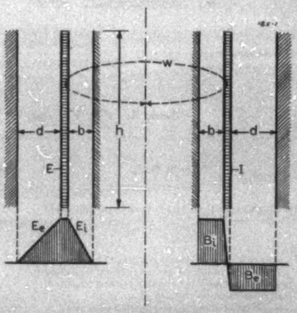

Figure 1. Ideal transformer winding with distribution of radial electric field and axial magnetic flux

$$\Phi=\frac{4\pi\mu wNI}{h/b+h/d} \tag{3}$$

where μ is the magnetic permeability on both sides of the winding. Hence the self-inductance of the entire coil is

$$L=\frac{N\Phi}{I}=4\pi\mu\frac{w}{h}N^2\frac{bd}{b+d}\;(\times 10^{-9} \text{ in henrys}) \tag{4}$$

It contains the physical dimensions h, d, b of the transformer in the same mutual arrangement as in equation 2 for the capacitance.

Paper 41-85, recommended by the AIEE committee on electrical machinery, and presented at the AIEE North Eastern District meeting, Rochester, N. Y., April 30–May 2, 1941. Manuscript submitted October 26, 1940; made available for preprinting March 6, 1941.

REINHOLD RÜDENBERG is professor of electrical engineering, Harvard University, Cambridge, Mass.

If we denote the total wire length of the winding by

$$a=wN \tag{5}$$

the velocity of traveling waves within the coil is determined by total self-inductance and total ground-capacitance as

$$v=\frac{1}{\sqrt{lc}}=\frac{a}{\sqrt{LC}} \tag{6}$$

l and c being the respective values per unit length of the wire. If we insert herein the values of C and L from equations 2 and 4, we see that all physical dimensions cancel and there remains the relation

$$v=\frac{v_0}{\sqrt{\epsilon\mu}} \tag{7}$$

This shows that the velocity of waves along the wire of such transformer coils is always equal to the universal velocity of light, 300 m/μsec. divided by the square root of dielectric constant and magnetic permeability.

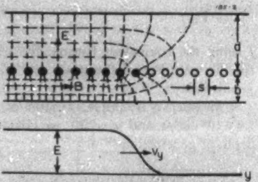

Figure 2. Electromagnetic field of a steep-front wave traveling through a coil

This fundamental law was found empirically[11] as a result of measurements on many actual transformers as a limiting case for small internal capacitance. We see now this law is well founded theoretically and that electromagnetic waves on conductors wound into coils with negligible internal capacitance travel with the same velocity as in straight wires. Hence the increase in self-inductance by winding the wire in a cylindrical coil is exactly compensated by the decrease in ground-capacitance caused by the crowded arrangement of the turns.

The surge impedance of the coil, which determines the ratio of voltage and current of travelling waves, is also determined by equations 2 and 4 as

$$Z=\sqrt{\frac{l}{c}}=\sqrt{\frac{L}{C}}=4\pi v_0\sqrt{\frac{\mu}{\epsilon}}\frac{N}{h}\frac{bd}{b+d}$$
$$(\times 10^{-9}\text{ in ohms}) \tag{8}$$

As the value of v_0 is universally given, we can simplify the numerical magnitudes and obtain, in practical units,

$$Z=120\pi\sqrt{\frac{\mu}{\epsilon}}\frac{N}{h}\frac{b}{1+b/d}\text{ (in ohms)} \tag{9}$$

Thus we see that in addition to ϵ and μ the surge impedance of transformer windings[13] is dependent mainly on the number of turns per unit length N/h and on the internal insulating distance b, the larger external distance d entering only in a correction term.

A model oil transformer[6] with grounded core, the latter consisting of a cylindrical steel sheet, had a single-layer winding of flat copper wire 1.2×7 mm in cross-section and $a=59$ m long. The wire was wound with $N=52$ turns on an insulation tube of 36.3 cm diameter and an axial length $h=65$ cm. The inner distance from coil to core was $b=5.4$ cm and there was no outer metal tank. From the shape of the switching-on voltage curves, measured with a cathode-ray oscillograph, in comparison with those of a known smooth line, the propagation velocity through the turns of the winding was determined as $v=155$ m/μsec, and the surge-impedance as $Z=920$ ohms approximately.

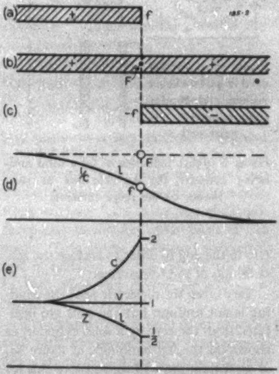

Figure 3. Finite end of a coil and its electromagnetic characteristics

With an average $\epsilon=3.5$ and $\mu=1$, equations 7 and 9 give

$$v=\frac{300}{\sqrt{3.5\cdot 1}}=160m/\mu s$$

$$Z=120\pi\sqrt{\frac{1}{3.5}}\cdot\frac{52}{65}5.4=870\Omega$$

Thus our conceptions have enabled us to derive proper values of the coil characteristics.

Average transformer-windings in oil with $\epsilon=3.5$ and $\mu=1$, having a winding density of $N/h=10$ turns/cm and insulating distances $b=3$ cm to the core and $d=30$ cm to the tank, may have a surge-impedance

$$Z=120\pi\sqrt{\frac{1}{3.5}}\cdot 10\cdot\frac{3}{1+3/30}=5{,}500\Omega$$

This is about ten times the value of the surge-impedance of ordinary overhead lines.

A study of many power transformers of various types shows that

For rated sizes of 5 to 500 to 50,000 kva
The winding density varies from 100 to 10 to 1 turns/cm

These values refer to the high voltage side; for the low voltage side the values of winding density are about $^1/_3$ to $^1/_{10}$ of the foregoing figures. Since the insulating distance b varies only from 1 cm for low voltages to 5 cm for high voltages, while the tank distance d is always relatively large, we can expect that the windings of oil transformers of the sizes just considered will have surge impedances of the order of

Z_{HV} = 20,000 to 5,000 to 1,000 ohms
Z_{LV} = 4,000 to 600 to 100 ohms

for the high voltage and low voltage sides respectively. These figures agree well with sporadic measurements published in the literature.[1]

If a wave of any form travels with high velocity v along the wire of a helical winding, the axial velocity of propagation of the electromagnetic state will be much smaller than v. The shape of the circumferential wave remains preserved in axial direction; however, it is condensed in the ratio of wire length w to pitch s of a turn. Thus the axial velocity of the wave is only

$$v_y=\frac{s}{w}v=\frac{h}{a}v \tag{10}$$

expressed also in terms of axial coil length h and total wire length a.

If an impact wave E of a form shown in figure 2 travels through the coil, the turns ahead of the front are still without voltage and current while the turns behind the front have full voltage and current. The electric and magnetic lines of force therefore follow curves as shown in figure 2. The wave front travels circumferentially along the helical wire with the velocity of light in the dielectric medium. The entire electromagnetic excitation of the coil, however, propagates in the axial direction of the coil with much lower velocity, as given by equation 10. Because of this slow axial propagation, the electromagnetic field in the longitudinal cross-section shown in figure 2, is nearly static, so that it is easy to trace the lines of force. Thus the structure of the electromagnetic field of the transformer coil is wave-like in the circumferential direction but quasi-stationary in the axial direction.

3. Approximation to Actual Windings

Until now we have assumed that the coil is infinitely long. In order to consider the effect of a finite end, as shown in figure 3*a*, the electromagnetic field of this end may be conceived as being composed of the field of an infinite coil, as in figure 3*b*, and the field of a finite coil, as in figure 3*c*, extending to the other side and having the opposite sign from the infinite coil. A superposition of the two coils of figure 3*b* and 3*c* gives exactly the coil of figure 3*a* with a finite end. If F is the well-known electromagnetic field of the infinite coil, and f the unknown field at the end of the finite coil in figure 3*a*, the field at the end of the auxiliary coil in figure 3*c* is $-f$. The superposition gives

$$F-f=f \text{ or } f=F/2 \tag{11}$$

Hence the electromagnetic field and therefore the specific properties, such as electromagnetic and electrostatic inductance, both per unit length, decrease towards the end of a coil to exactly half the value which they have in an infinite coil or at the center parts of a long finite coil. This is represented in figure 3*d*, while figure 3*e* shows that the specific capacitance c, the reciprocal of the static inductance, is doubled at the end.

The velocity of the waves, determined by the product of l and c, as in equation 6, remains spatially constant up to the end of the coil. The surge impedance, however, determined by the quotient of l and c, as in equation 8, decreases towards the end to one-half its original value. This is shown in figure 3*e*. The axial distance up to which these changes in v and Z extend into the coil depends entirely on the breadth b of the dielectric gap and actually is only a small multiple of the distance b. As a whole, a finite end of the coil acts as if it were loaded with some additional capacitance and some inductance were removed. Those properties of the coil which are determined by the wave velocity, as for example the natural frequencies, are not changed by the alterations near a finite end. The surge impedance on the other hand, comes into effect mainly with transmission of the waves, coming from or going to adjacent lines, which for the most part have much smaller surge impedance than the coil. Halving of the surge-impedance near the coil end produces therefore only moderate alterations in the transmitted voltage.

In actual transformers, as in figure 4, neither the coren or the tank have a smooth surface as in our idealized picture, but the insulating distances vary around the circumference. However, since we will not determine the variation of voltage around a single turn, we may replace, without actual loss of accuracy, the irregular surfaces of both core and tank by concentric circles which give an equivalent interior and exterior insulating distance. As the distance d to the tank is comparatively large and its influence, according to equation 9, is small, it does not matter whether or not the tank is eccentric to the coil in order to enclose the second limb of the transformer.

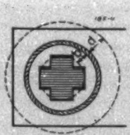

Figure 4. Actual and equivalent ground electrodes surrounding a circular coil

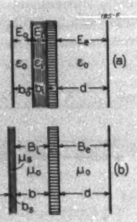

Figure 5 (right). Influence of (a) a solid insulating cylinder, (b) the skin flux in steel sheets, on the surge constants

Very often the dielectric near the winding is not uniform but the coils are insulated from the core by a solid cylinder, as shown on the left-hand side of figure 5*a*. If we denote the wall thickness of this insulating tube by b_i and its dielectric constant by ϵ_i, while the remainder of the distance to the core is b_0 with the constant ϵ_0, we have instead of equation 1 for the electric charge of the coil under the voltage E

$$Q=\frac{wh}{4\pi v_0^2}E\left(\frac{\epsilon_0}{d}+\frac{1}{b_i/\epsilon_i+b_0/\epsilon_0}\right) \tag{12}$$

By comparison with equation 1 we obtain therefore as mean dielectric constant for the whole transformer

$$\epsilon=\epsilon_0\frac{\dfrac{1}{\epsilon_0/\epsilon_i\cdot b_i/b+b_0/b}+\dfrac{b}{d}}{1+b/d} \tag{13}$$

With actual figures this gives for oil transformers resultant values of about $\epsilon=3.5$, which may be used for the wave-velocity in equation 7 as well as for the surge-impedance in equations 8 and 9.

The interior and exterior boundaries of the electromagnetic field of actual transformers do not consist, as in our idealized picture, of material with perfect electric conductivity but are built up of iron with finite electric conductivity and high magnetic permeability. Figure 4 shows that the surface consists partly of rolled steel sheets, partly of magnetic or anti-magnetic constructional steel plates, and partly of the edges of the steel sheets which form the active magnetic core. High frequency magnetic oscillations, of which every travelling wave is composed, penetrate only into a thin layer of these materials, the equivalent depth of which is

$$b_s=\frac{1}{4\pi}\sqrt{\frac{s}{\mu_s f}} \tag{14}$$

f being the equivalent frequency, s the specific resistance of the steel, and μ_s its permeability.

If we put, for example, $f=10^4 c/s$, $s=1.5\times10^4\text{ cm}^2/s$, and $\mu_s=200$, we obtain a depth of penetration

$$b_s=\frac{1}{4\pi}\sqrt{\frac{1.5\cdot10^4}{200\cdot10^4}}=6.9\times10^{-3}\text{ cm}$$

The magnetic flux within this skin supplements the air flux and, since the flux density in steel is μ_s times that in air, we have an additional equivalent air breadth for the internal magnetic flux as $\mu_s\cdot b_s=1.39$ cm in our example.

For several reasons it is difficult to decide without further experiments which value of the permeability actually comes into effect. The edges of the highly magnetic steel sheets are deteriorated magnetically by the cutting process, the magnetization by the travelling waves is superposed on the steady state magnetization, the magnetic circuit for the wave flux is not iron closed, and the hysteresis in steel parts of poorer magnetic quality gives an additional screening effect.

If the effective permeability μ_s of the steel surfaces were known, we could compute the additional effect on the permeability μ_0 of the insulating space as in figure 5*b*. In confining ourselves to the effect of the more important core surface, we can derive the resultant surge permeability for a steel core winding as

$$\mu=\mu_0\frac{1+b/d}{\dfrac{1}{\mu_s/\mu_0\cdot b_s/b+1}+\dfrac{b}{d}} \tag{15}$$

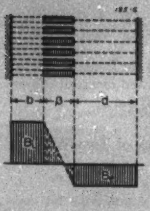

Figure 6. Influence of the magnetic field within the winding space on the surge constants

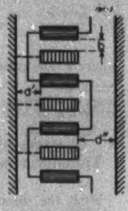

Figure 7. Effective distances for pancake windings with grounded secondary

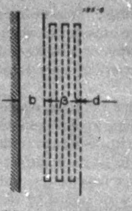

Figure 8. Effective distances for concentric layer windings

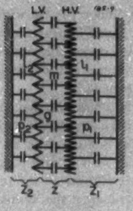

Figure 9. General linkage diagram for two-winding transformers

an expression which in its structure is similar to equation 13. If the value of μ exceeds considerably that of μ_0, it decreases the wave velocity given by equation 7 and increases the surge-impedance given by equations 8 and 9. Since b_s, according to equation 14, is dependent on frequency, we then obtain a variation of the characteristics of the winding with frequency.

With the values of the last example and insulating distances $b=3$ cm and $d=30$ cm, we obtain a resultant permeability

$$\mu=1\frac{1+3/30}{\dfrac{1}{200/1\cdot 6.9\cdot 10^{-2}/3+1}+\dfrac{3}{30}}=1.43$$

For smaller frequencies this magnitude may become considerably larger.

The copper winding also permits some penetration of the magnetic flux since it is not perfectly conducting. As its permeability μ_c is always equal to 1, then according to equation 14 the skin depth becomes with $s=2\times 10^3$ cm$^2/s$ and $f=10^4 c/s$,

$$b_e=\frac{1}{4\pi}\sqrt{\frac{2.10^3}{1.10^4}}=3.56\cdot 10^{-2}\text{ cm}$$

This value is so small compared with the insulating distances that one is almost always justified in neglecting it.

We have assumed that the wall thickness of the coil in figure 1 is very small. Actual transformers, however, have a considerable coil thickness β, as in figure 6, where the variation of the flux density between the interior and exterior insulating spaces is indicated by an inclined dotted line. The intermediate flux within the cross section of the winding is only partially linked with the turns and gives therefore, as is well known, only an additional breadth $\beta/3$. However, as transformer coils are usually wound with solid copper wire with high skin-effect as mentioned above, the transient flux penetrates only the insulation of the wires and not the copper. With β' as the total internal radial insulation between the turns of figure 6, we thus obtain a correction factor

$$\mu'=1+\frac{1}{3}\frac{\beta'}{b} \qquad (16)$$

which may be used as an additional permeability for the electromagnetic space.

As figure 6 indicates, the capacitance of the winding to ground is not noticeably altered by a finite wall-thickness of the coil even if the winding consists of single sections, with small distances between. Since neither the total self-inductance nor the total ground-capacitance is materially influenced by subdivision of the winding into single discs, sectionalized cylindrical coils as in figure 6 can also be treated by the method already outlined. However, the last discs at the ends of the entire coil-stack will have some extra ground-capacitance due to the flat outer faces of the stack. This can be considered as lumped end-capacitance of the coil in addition to the other end effects already mentioned.

If the transformer is built up of pancake coils with interleaved primary and secondary sections as in figure 7, it is still possible to compute the total self-inductance and ground-capacitance in a manner similar to that already described, when the secondary winding is short-circuited and grounded, thus forming a part of the entire ground. We have only to consider, according to familiar rules, the formation of the electric and magnetic fields within all interspaces of the primary and secondary coils with distances b, d', and d'' as in figure 7. Also the multiple concentric layer winding of figure 8 can be treated likewise, except that in this case the internal capacitance between adjacent layers far outweighs the ground capacitance, so that wave velocity and surge-impedance may become dependent on frequency.[11]

4. Interaction of Primary and Secondary Coils

In real transformers there are always two windings acting together and influencing each other.[2,3] Whether or not the windings have different numbers of turns, their interaction can be analyzed by consideration of the voltages induced magnetically and statically by the currents. We again consider surge waves of such lengths that the mutual inductances of neighboring elements, in the winding under consideration as well as in the other winding, can be combined to give equivalent self- and mutual-inductances, as indicated in a previous paper.[11]

Then the spatial variation of voltages in each of the windings, distinguished by the subscripts 1 and 2, is

$$\left.\begin{aligned}-\frac{\partial e_1}{\partial x_1}&=l_1\frac{\partial i_1}{\partial t}+m\frac{\partial i_2}{\partial t}\\ -\frac{\partial e_2}{\partial x_2}&=l_2\frac{\partial i_2}{\partial t}+m\frac{\partial i_1}{\partial t}\end{aligned}\right\} \qquad (17)$$

The effective self- and mutual-inductances l and m per unit length of the conductors are related to the constants L and M of the entire windings under steady state conditions, as

$$l_1=L_1/a_1 \quad l_2=L_2/a_2 \quad m=M/\sqrt{a_1a_2} \qquad (18)$$

a_1 and a_2 being the lengths of the windings.

Since the mutual inductance m is the same in both equations 17, it must be formed symmetrically with respect to both windings. Furthermore, it must be derived from the mutual inductance M between the entire windings by dividing by a length. These dimensional conditions are satisfied by the last expression in equation 18.

The variation of voltage with time for each winding is determined by the spatial variation of both currents

$$\left.\begin{aligned}-\frac{\partial e_1}{\partial t}&=p_1\frac{\partial i_1}{\partial x_1}+g\frac{\partial i_2}{\partial x_1}\\ -\frac{\partial e_2}{\partial t}&=p_2\frac{\partial i_2}{\partial x_2}+g\frac{\partial i_1}{\partial x_2}\end{aligned}\right\} \qquad (19)$$

where p and g are Maxwell's self- and mutual-potential coefficients. These are reciprocal values of capacitances and thus are determined by the potential coefficients P and G of the entire winding as

$$p_1=P_1a_1 \quad p_2=P_2a_2 \quad g=G\sqrt{a_1a_2} \qquad (20)$$

The last expression again satisfies the dimensional considerations.

Figure 9 shows the self-constants l and p and the mutual-constants m and g for the high-voltage and the low-voltage windings of a transformer, both situated between the internal and external ground electrodes. In addition to these parameters actual transformers have internal capacitances between adjacent turns of each winding which produce, however, no coupling interaction between the two windings. Therefore we will not consider them and will thus obtain the interaction of the transformer coils in the purest form.

The differential equations 17 and 19 can be solved by linear dependences between voltage and currents in both windings, as

$$e_1 = Z_1 i_1 + z i_2 \qquad e_2 = Z_2 i_2 + z i_1 \tag{21}$$

Herein Z_1 and Z_2 denote the self-surge impedances of the two coils while z is a mutual surge-impedance between both coils as indicated in figure 9.

In order to determine these constants, we insert equations 21 in the left-hand sides of equations 17 and 19. For their first lines, expressing e_1, we obtain

$$\left.\begin{aligned} -\frac{\partial}{\partial x_1}(Z_1 i_1 + z i_2) &= \frac{\partial}{\partial t}(l_1 i_1 + m i_2) \\ -\frac{\partial}{\partial x_1}(p_1 i_1 + g i_2) &= \frac{\partial}{\partial t}(Z_1 i_1 + z i_2) \end{aligned}\right\} \tag{22}$$

For waves travelling with constant shape, differentiation in time and in space is proportional. We can then divide the first equation 22 by the second and obtain

$$(Z_1 i_1 + z i_2)^2 = (l_1 i_1 + m i_2)\cdot(p_1 i_1 + g i_2) \tag{23}$$

Since this is valid for any currents i_1 and i_2, the coefficients of the respective currents on both sides must be equal. We have, thus, the three conditions

$$Z_1^2 = l_1 p_1 \quad z^2 = mg \quad 2Z_1 z = l_1 g + p_1 m \tag{24}$$

The first two conditions give the surge impedances

$$Z_1 = \sqrt{l_1 p_1} \qquad z = \sqrt{mg} \tag{25}$$

and substituting these surge impedances into the third condition, we find

$$p_1/l_1 = g/m \tag{26}$$

If we insert the last equation of (21) into the last lines of equations 17 and 19 we obtain from the corresponding conditions the surge impedances

$$Z_2 = \sqrt{l_2 p_2} \qquad z = \sqrt{mg} \tag{27}$$

and the additional condition

$$p_2/l_2 = g/m \tag{28}$$

The second equations in (25) and (27) are identical and the coincident equations 26 and 28 indicate certain qualities of symmetry in the windings. Thus we have defined the three surge impedances which determine the interaction of currents and voltages in the coils according to our statement (21).

In order to determine the wave velocities in the two windings, we differentiate the first equation 22 with respect to t and the second with respect to x_1. Subtracting eliminates the surge impedances, and arranging the terms with regard to the currents gives

$$l_1 \frac{\partial^2 i_1}{\partial t^2} - p_1 \frac{\partial^2 i_1}{\partial x_1^2} = -m \frac{\partial^2 i_2}{\partial t_2} + g \frac{\partial^2 i_2}{\partial x_1^2} \tag{29}$$

Since this relation is valid for any value of i_1 and i_2, both the sides must disappear independently of each other. Therefore each side forms the well-known wave equation, and thus the wave velocities along the wire length x_1 of the winding 1 are

$$v_1 = \sqrt{p_1/l_1} \qquad v_1' = \sqrt{g/m} \tag{30}$$

The first expression 30 gives the velocity of the self-induced waves, the second gives that of the mutually-induced waves, and by inserting condition 26 in the second expression, we see that both velocities coincide.

By subjecting the second lines of equations 17, 19, 21 to the same operations as performed in the first lines, we obtain the wave velocities in the wires of winding 2 as

$$v_2 = \sqrt{p_2/l_2} \qquad v_2' = \sqrt{g/m} \tag{31}$$

Consideration of equation 28 shows that also in winding 2 there exists only one well-defined wave velocity along the wires. Furthermore, we see by comparison of v_1' and v_2' in equations 30 and 31 that all the velocities along the wires of both windings are exactly the same.

These conditions show that the primary as well as the secondary winding of any transformer possesses one and only one wave velocity which, furthermore, is the same in both windings, measured along the conductors of each winding. The presence of the other winding and the flow of currents therein does not alter this electromagnetic property of every coil. This does not mean, as we see later, that the windings do not interact with each other. However, it has the result that along the axis of the winding an electromagnetic field will travel only with a velocity corresponding to the pitch of the winding under consideration, independent of the presence of the other winding. Therefore we have to distinguish two different axial velocities, namely those of the H.V. and of the L.V. windings. Corresponding to equation 10 these velocities are

$$v_H = \frac{s_1}{w} v = \frac{h}{a_1} v \qquad v_L = \frac{s_2}{w} v = \frac{h}{a_2} v \tag{32}$$

where v now means the fundamental velocity given by all the identical expressions in equations 30 and 31.

5. Characteristics of Two-Winding Transformers

With the same assumptions for coils and insulating spaces as previously made, figure 10 represents the cross-section of a two-winding transformer. Now b_1 and d_1 are the internal and external distances to ground of the H.V. coil 1, while b_2 and d_2 are those of the L.V. coil 2. The self-potential coefficients are then reciprocal to equation 2

$$\left.\begin{aligned} P_1 &= E_1/Q_1 = (4\pi v_0^2/ewh) b_1 d_1/(b_1 + d_1) \\ P_2 &= E_2/Q_2 = (4\pi v_0^2/ewh) b_2 d_2/(b_2 + d_2) \end{aligned}\right\} \quad (\times 10^{-9} \text{ in } 1/\text{farad}) \tag{33}$$

As shown in figure 10*b*, the potential of winding 1 drops linearly from its own voltage E_1 to zero at the ground electrodes. If we introduce into this field a secondary winding at position 2 in figure 10*a*, it takes up by static induction a voltage

$$E_2 = \frac{b_2}{b_1} E_1 = \frac{4\pi v_0^2}{ewh} \; \frac{b_2/b_1}{1/b_1 + 1/d_1} Q_1 \tag{34}$$

where the value of the voltage E_1 is inserted from equation 33. The mutual potential coefficient between the windings 1 and 2 is, therefore,

$$G = \frac{E_2}{Q_1} = \frac{4\pi v_0^2}{ewh} \; \frac{b_2 d_1}{b_1 + d_1} \quad (\times 10^{-9} \text{ in } 1/\text{farad}) \tag{35}$$

The form of this expression is symmetrical to both coils, as we see from figure 10, since all the denominators of equations 33 and 35 have the common value

$$b_1 + d_1 = b_2 + d_2 = D \tag{36}$$

giving the distance between both ground electrodes, independent of the positions of the coils.

The self-inductance of each of the windings follows from the previous equation 4, as

$$\left.\begin{aligned} L_1 &= 4\pi\mu \frac{w}{h} N_1^2 \frac{b_1 d_1}{b_1 + d_1} \\ L_2 &= 4\pi\mu \frac{w}{h} N_2^2 \frac{b_2 d_2}{b_2 + d_2} \end{aligned}\right\} \quad (\times 10^{-9} \text{ in henrys}) \tag{37}$$

N_1 and N_2 denoting the number of turns of the two windings.

The distribution of the primary magnetic flux over the insulating spaces is shown in figure 10*c*. The secondary coil is linked with only a part of this flux within the inner space, namely

$$\Phi_2 = \frac{b_2}{b_1}\Phi_1 = 4\pi\mu w \, \frac{N_1 I_1}{h} \, \frac{b_2/b_1}{1/b_1+1/d_1} \tag{38}$$

where the value of the flux Φ_1 is inserted from equation 3. Thus the mutual inductance between the coils becomes

$$M = \frac{N_2\Phi_2}{I_1} = 4\pi\mu \, \frac{w}{h} \, N_1 N_2 \, \frac{b_2 d_1}{b_1+d_1} \quad (\times 10^{-9} \text{ in henrys}) \tag{39}$$

This expression is also geometrically symmetrical to both coils, as we see from figure 10.

Now we can determine the specific constants per unit length according to equations 18 and 20, by dividing or multiplying the total values by the wire lengths

$$a_1 = N_1 w \quad a_2 = N_2 w \tag{40}$$

We see immediately that all these constants, inserted in equations 30 and 31, give only a single value for the wave velocity along the wires, namely,

$$v = v_0/\sqrt{\epsilon\mu} \tag{41}$$

which again is identical with the universal velocity of light, adapted to the electromagnetic constants of the transformer space.

On the other hand, insertion of the constants in equations 25 and 27 gives the three surge impedances

$$\left.\begin{aligned} Z_1 &= 4\pi v_0 \cdot \sqrt{\mu/\epsilon} \cdot N_1/h \cdot b_1 d_1/D \\ Z_2 &= 4\pi v_0 \cdot \sqrt{\mu/\epsilon} \cdot N_2/h \cdot b_2 d_2/D \\ z &= 4\pi v_0 \cdot \sqrt{\mu/\epsilon} \cdot \sqrt{N_1 N_2}/h \cdot b_2 d_1/D \end{aligned}\right\} \quad (\times 10^{-9} \text{ in ohms}) \tag{42}$$

dependent on winding density and insulating distances. We derive from the last expressions the ratio of the mutual-surge-impedance to both of the self-surge-impedances, which will often be used, as

$$\frac{z}{Z_1} = \sqrt{N_2/N_1}\,\frac{b_2}{b_1} \qquad \frac{z}{Z_2} = \sqrt{N_1/N_2}\,\frac{d_1}{d_2} \tag{43}$$

If ϵ and μ are heterogeneously distributed with respect to both windings, equivalent distances b and d can be determined easily, with ratios frequently increasing towards unity.

From equation 21 we can derive that the ratio of voltages is determined directly by the ratio of surge impedances. The coupling ratio for travelling waves in a transformer is given therefore, according to equation 43, by the square root of the turn ratio, in contrast to the steady state coupling which is given directly by the ratio of turns. This is advantageous when a wave is transmitted from the L.V. to the H.V. side, but very unfavorable for the transmission of waves from the H.V. to the L.V. side of a transformer.

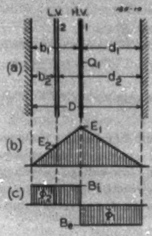

Figure 10 (left). Mutual inductive and capacitive interaction of two concentric windings

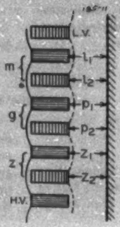

Figure 11 (right). Coupling coefficients for pancake coils

The coupling ratios in equation 43 are determined further by a geometric factor given simply by the distances. The ratio of the inner distances b is always materially smaller than one, while the ratio of the outer distances d for the most part is slightly smaller than one. In order to avoid high transmitted surges from the H.V. to the L.V. winding, it is thus preferable to arrange the L.V. winding as the inner coil and the H.V. winding as the outer coil, which actually is the usual practice with transformers having only two coils.

Pancake windings, as in figure 11, satisfy also the general coupling diagram of figure 9 and can therefore be treated in the same way as concentric windings. However, the mutual interactions appear here as more intensive and the subdivision into sectional coils is more pronounced.[13]

6. Wave Transmission Between Two Windings

The electromagnetic field propagates axially through the H.V. winding with the moderate velocity v_H, and through the L.V. winding with the higher velocity v_L, both determined by equation 32 and being much slower than the velocity of light. We call these the natural velocities of the windings. The complete electromagnetic state of the transformer is composed of both these slow and fast moving fields. Each of them cuts the helical wires of its own winding with a velocity of light. The wires of the other winding, however, are cut with a velocity different from that of light. The problem therefore arises as to the manner in which a winding responds if a wave is impressed on it, the velocity of which does not coincide with its natural velocity.

Let us investigate this performance of windings by means of a method which is easy to visualize. We perceive, as in figure 12, a coil with a definite natural axial wave velocity v_N, and along which an electric charge Q is moved with a given velocity V. Then three different cases are possible:

(a) The Velocity of the Charge Is Equal to the Natural Velocity of the Coil

In this case the electromagnetic induction of the moving charge produces voltage and current in the coil which move in synchronism with the charge. For an observer moving with the charge, the waves of current and voltage represented in figure 12 seem to be at rest. They form electromagnetic energy which travels along the coil always in parallel to the charge. This case is present in transformers with a turn ratio 1:1, which, however, is quite rare. The waves on both windings here interact in the same way as waves on parallel smooth lines, the performance of which is well known.

(b) The Velocity of the Charge Is Higher Than the Natural Velocity of the Coil

In this case, represented by figure 13, the moving charge Q is not able to bind any opposite charge on the coil for such charge can move only with a smaller natural velocity v_N and thus cannot follow the high velocity V of the charge Q. If no charge on the coil can be bound, then no current can flow in its turns, and if no current exists in the wires, the coil performs exactly like an insulator, having no conductivity for waves moving with higher

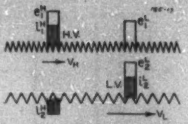

Figure 17 (above). Voltages and currents in high-voltage and low-voltage windings produced by fast-moving and slow-moving waves of natural velocity

velocity than the natural velocity of the coil.

On account of the low natural velocity, any voltage on the coil produced by a faster moving charge is therefore merely a statically induced voltage which cannot flow away from the zone of influence of the charge Q. The coil performs therefore in interaction with a fast-moving charge as if it consisted only of conducting rings not connected with one another, instead of turns of a helical wire. The coil thus appears transparent for the electromagnetic excitation of a fast-moving charge.

These results are transferred to our transformer coils in figure 14. Any wave consisting of voltage e_2 and current i_2 on the L.V. winding and moving with higher velocity v_L than the natural velocity v_H of the H.V. winding can induce within the latter only a static voltage wave e_1 but no current i_1. The H.V. winding is therefore subjected merely to a capacitive voltage division. This winding does not absorb any energy; the entire energy of the wave is rather conducted by the L.V. winding with its high natural velocity. As, under these circumstances, there is no reaction from the H.V. winding back to the L.V. winding, the H.V. winding appears nonexistent from the viewpoint of the L.V. winding and its waves.

(c) THE VELOCITY OF THE CHARGE IS LOWER THAN THE NATURAL VELOCITY OF THE COIL

In this case, as represented by figure 15, the charge Q can bind opposite charges on the coil, as it would do even at rest. However, no voltage can be formed opposite the moving charge since every voltage immediately flows away in both directions with the higher natural velocity v_N of the coil. The winding performs therefore like a metallic layer, conducting in the axial direction. From the viewpoint of the slowly moving charge the coil appears opaque and acts as a perfectly conducting screen. The counter-charges moving with the low velocity V of the charge Q produce currents varying in space and time in the coil. Here exists therefore an intensive magnetic interaction between the slow-moving charge and the coil.

Figure 16 represents this interaction within transformer coils if a low velocity wave propagates with v_H on the H.V. winding. Its voltage e_1 and current i_1 induce only current i_2 at the L.V. winding but not voltage e_2. The L.V. winding appears therefore, from the viewpoint of the H.V. winding and its waves, as perfectly conducting in every direction or as a complete metallic screen. The induced current i_2 is carried along the L.V. winding directly opposite the slow-moving H.V. wave. The entire energy of the electromagnetic field is conducted by the H.V. winding with its low natural velocity.

In order to determine the consequences of this different performance of the windings in transformers, we go back now to our analytical expressions. Figure 17 shows in a comprehensive manner by means of short rectangular waves the voltages and currents which can flow in the windings. Both types of wave, the fast one with the energy concentrated on the L.V. winding and the slow one with the energy concentrated on the H.V. winding, travel independently of each other and form by superposition the entire electromagnetic state of the transformer. We distinguish both wave systems by superscripts L and H on all currents and voltages, and consider first the fast L.V. waves.

With reference to figure 17 we have in the transparent H.V. winding

$$i_1^L = 0 \tag{44}$$

and therefore equation 21 simplifies to

$$e_2^L = Z_2 \cdot i_2^L \qquad e_1^L = z/Z_2 \cdot e_2^L \tag{45}$$

We see that for the L.V. winding there remains effective only the self-surge impedance Z_2, while in the H.V. winding a transmitted voltage appears, the magnitude of which is determined by the ratio of surge impedances given by the second equation 43. The H.V. winding thus has no influence on the performance of the L.V. waves; it suffers only a voltage division according to the coupling factor z/Z_2. From the standpoint of the L.V. winding the H.V. winding appears as air.

For the slow H.V. waves, on the other hand, we have, as in figure 17, within the opaque L.V. winding

$$e_2^H = 0 \tag{46}$$

The second line of equation 21 therefore gives

$$i_2^H / i_1^H = -z/Z_2 \tag{47}$$

by which the current in the secondary winding is determined. If we insert this in the first equation 21, we obtain the primary voltage

$$e_1^H = Z_1 i_1^H - z^2/Z_2 \cdot i_1^H = Z_1^H i_1^H \tag{48}$$

Thus we can define an effective surge impedance of the H.V. winding,

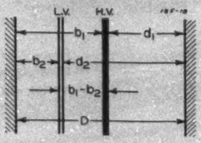
$$Z_1^H = Z_1(1 - z^2/Z_1 Z_2) \tag{49}$$

We see that this is considerably diminished by the reaction of the L.V. winding with respect to the slow-moving H.V. waves.

By introducing into equation 49 the values of equations 42 and 43, we can determine the effective H.V. surge impedance by the dimensions of the windings as

$$Z_1^H = 4\pi v_0 \sqrt{\mu/\epsilon} \cdot N_1/h \cdot d_1(b_1 - b_2)/d_2 \quad (\times 10^{-9} \text{ in ohms}) \tag{50}$$

Figure 18. Distances deciding the effective surge-impedance of the high-voltage winding



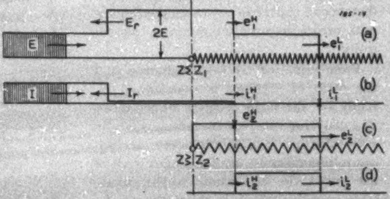


Figure 19 (right). Fast- and slow-moving traveling waves released by an incident high-voltage surge in the two windings of a transformer with open low-voltage terminal

If in figure 18 we examine the distances given in the last fraction of equation 50 and compare them with equation 8 and figure 1, we see that Z_1^H is constituted exactly as if the L.V. winding were replaced by a ground electrode. The L.V. winding therefore reacts intensively on waves in the H.V. winding, in screening their rapid electromagnetic field completely. The effective surge impedance of the H.V. winding is therefore given by the leakage flux of both windings, as indicated already by the form of equation 49. Any influence of the magnetic steel core disappears here completely.

For verification of these results we consider measurements made by H. Norinder[8] with a 450-kva oil transformer for 20 kv/112 v with $b_1-b_2=1.4$ cm insulating distance between the windings. The H. V. winding consisted of 80 sectional coils each with 20 turns, each coil covering an axial length of 0.865 cm. The secondary winding was grounded at the neutral. The dielectric constant can be taken as $\epsilon=3.5$, the permeability as $\mu=1$, and the tank wall was far away. We compute by equation 50 an effective H.V. surge impedance

$$Z_1^H=120\pi/\sqrt{3.5}\cdot 20/0.865\cdot 1.4= 6{,}530 \text{ ohms}$$

This magnitude was measured by cathode-ray oscillograms and was found to be 6,600 ohms, a very close agreement indeed. The wave velocity in the wires was $148m/\mu s$ in accordance with equations 7 and 41. Since the L.V. winding had a distance to the core $b_2=1.4$ cm, the unreduced H.V. surge impedance would be, with $b_1=2.8$ cm, $Z_1=13{,}060$ ohms, which is much higher than the effective as well as the measured value.

The fact that the slow wave within the H.V. winding cannot transmit voltage to the L.V. winding does not mean that no voltage at all appears on the L.V. winding. This would occur only if the L.V. winding were grounded throughout. In many actual cases, however, an incident H.V. surge produces both wave systems at the terminals of the winding, the slow and the fast one, in the primary as well as in the secondary winding and these waves travel further through the windings.

Figure 19 shows the performance of a terminal in a special but important case, to which we will confine ourselves for the sake of simplicity: the surge impedance of the incident H.V. line may be small compared with that of the H.V. winding, while the L.V. winding may be open at the terminal. Then the H.V. terminal voltage, doubled by reflection as in figure 19*a*, is composed of both voltages

$$e_1^L+e_1^H=2E \tag{51}$$

and the L.V. terminal current is, as in figure 19*d*,

$$i_1^L+i_1^H=0 \tag{52}$$

By using equation 45 we can transfer e_1^L into e_2^L and by successive application of equations 48, 47, 52, 45, we can also transfer e_1^H into e_2^L. This gives, with use of equation 49,

$$2E=e_2^L(z/Z_2+Z_1^H/z)=Z_1/z\cdot e_2^L \tag{53}$$

and thus we obtain for the most interesting voltage at the open L.V. terminal

$$e_2^L=z/Z_1\cdot 2E=2\cdot b_2/b_1\cdot\sqrt{N_2/N_1}\cdot E \tag{54}$$

Hence this voltage, transmitted by the travelling wave interaction of the windings, is given by twice the value of the surge coupling ratio and therefore is determined by the square root of the turn ratio and by the ratio of the insulating distances between windings and core. For actual transformers both distances b_1 and b_2 may be corrected with respect to the heterogeneous distribution of ϵ and μ in accordance with the method of section 3.

On account of the importance of the secondary surge voltage, many investigations have been published on transmitted voltages. However, only a few of them are made under such well-determined conditions that they can be compared with equation 54. The table gives results of three experiments[3,5,9] in which a short-front wave impinging on the H.V. winding was transmitted to an open L.V. winding, primary and secondary waves being measured by cathode-ray oscillograms. The characteristics of the transformers are given in the table, so far as they have been published, and estimated values for the distances are added, appropriate to power and voltage. The measured secondary surge voltages are all only slightly smaller than the theoretical values computed by equation 54, and thus the main conceptions underlying our calculations are verified.

The influence of loading the secondary terminals and the consideration of other terminal conditions, as well as the further behavior of the waves after their production at the terminals, remains to be investigated.

7. Summary and Conclusions

In transformer windings with coils which are large as compared with their insulating distances, the velocity of travelling waves along the conductors of both windings is equal to the velocity of light adapted to the magneto-dielectric constant of the adjacent space. The surge impedance of the windings is determined by the turn density of the coils and the distances of insulation and is in the range of 100 up to 20,000 ohms for power transformers of low voltage and high power up to high voltage and low power.

On the arrival of a surge at the terminals, two different wave fields travel axially through the windings, a slow one coupled with the H.V. coils and a fast one coupled with the L.V. coils, both propagating with light-velocity helically in their respective windings. The H.V. winding appears transparent, or nonexistent, for the axially fast-running

Table I. Comparison of Computed and Measured Secondary Surge Voltages in Transformers

Investigator	Palueff and Hagenguth[3]	Rebhan[5]	Elsner[9]
Connecting diagram at test			Rated high voltage	220 kv	15 kv	110 kv

Distances b_2/b_1, estimated	1:2.5	1:2	1:3
Transmitted voltage, e/E, computed	30.1%	16.3%	28.8%
Transmitted voltage, e/E, measured	30%	15%	26%

waves; the L.V. winding appears opaque, or perfectly screening, for the axially slow-running waves.

This mechanism effects a transmission of surge voltages between the two windings entirely different from any steady state transformation. The surge-coupling factors of the primary and secondary windings are determined by the ratio of the insulating distances and by the square root of the turn ratio. For transmission from the H.V. to the L.V. side this coupling factor is larger than the turn ratio.

All the principal results of this paper capable of numerical examination are verified by experiments collected from the previous literature.

Special Symbols

a = wire length of the winding
b = internal insulating distance
d = external insulating distance
f = field at the end of a finite coil
g = mutual potential coefficient per unit length
h = axial length of the entire coil
p = self-potential coefficient per unit length
s = pitch of the helical coil
s = specific resistance
v = velocity of waves
w = wire length of a turn
z = mutual surge impedance
D = distance between core and tank
F = field of an infinite coil
G = mutual potential coefficient
N = number of turns of the winding
P = self-potential coefficient
Z = surge impedance
β = insulating distance across a multi-layer coil

Synopsis: A knowledge of the natural frequencies of transformer, reactor, and generator windings is essential for the determination of the transient response of such coils to lightning waves and switching surges, as well as for the calculation of the recovery characteristics of circuit breakers and expulsion gaps. Different testing methods have been employed to determine these natural frequencies, and it has usually been taken for granted that each of these different testing procedures gives results in substantial agreement. Recently, however, in a study of transformer transients it was found that several different methods of test failed to agree, and an investigation as to the cause of the discrepancies disclosed that all of these usual methods are not equally valid or reliable.

It is, therefore, the object of this paper to discuss various testing procedures, and to point out their theoretical limitations toward yielding the supposed information.

The voltage distribution along the winding of a grounded neutral transformer is discussed analytically and the basic equations are developed.

Results of voltage distribution tests made by several methods are reported and compared. The various methods of testing are discussed and compared with the conclusion that the method of free oscillation is, in general, preferable.

Introduction

THERE are four general methods for ascertaining the natural frequencies of windings or distributed circuits:

1. Cathode ray oscillograms of free oscillations excited by an impulse generator.
2. Resonance frequency determined by varying the applied frequency so as to cause a maximum or minimum voltage at a selected point of the winding. The applied frequency may be a sustained alternating voltage supplied, for example, from a vacuum tube oscillator, or it may be a damped oscillatory wave furnished by an impulse generator. The voltage may be measured by a vacuum tube voltmeter, a cathode ray oscillograph, or a spark gap.
3. Voltage-current ellipses on the screen of a cathode ray oscillograph as a sinusoidal applied voltage is varied in frequency.
4. Impedance-frequency curves calculated from corresponding voltage and current readings for sustained sinusoidal applied voltages covering a sufficiently wide range of frequencies.

In order that the limitations of each method of test may be examined critically from a theoretical point of view, consider the case of an idealized uniformly distributed circuit having self inductance, capacitance to ground, capacitance between adjacent turns, and energy losses; such that its transient response to an infinite rectangular applied voltage wave (a "unit function") consists of a set of space harmonics, each oscillating at its own natural frequency about a final distribution as an axis of oscillation, and decaying exponentially, as given in equation 1 of appendix I.

It is immaterial whether such an idealized circuit actually exists or not in practice (although it is known to be closely approximated by transformer windings, transmission lines, generator coils, etc.), because if it can be shown that this theoretical circuit cannot yield unquestionable results to a given method of test, then it can hardly be expected that circuits which are not ideal (with respect to pure harmonics) will do so.

Appendix I gives the solution, through an application of Duhamel's theorem, to this same idealized circuit when the applied surge is a damped oscillatory wave, and as a special case thereof for a sustained alternating voltage (zero decrement factor for the applied wave), particularly when in resonance with one of the natural frequencies.

I—Free Oscillations Excited by an Impulse

One method of testing for the transient voltage distribution along the winding of a transformer subjected to an impulse is to apply a surge of the desired shape from an impulse generator and take oscillograms of the voltage to ground at different points along the winding with a cathode ray oscillograph. Figure 1 shows a set of such oscillograms (tracings from the images on the screen of a transient analyzer), taken on a 66 Kv, 3,000 Kva high voltage concentric disk-type coil stack of a transformer from which the low voltage winding had been removed. The applied wave in this case had a very steep front and a long tail (0.2×275).

The voltage from the 50% point shows a predominant fundamental of 41,000 cycles, distorted during the first cycle by higher harmonics. The decrement factor for the fundamental is approximately $\gamma_1 = 0.022$ (where time is measured in microseconds). Assuming that the transient consists of pure sinusoidal space harmonics, the distortion is due to those of odd order—the 3rd, 5th, 7th, etc., and theory shows that their amplitudes rapidly decrease in size as their order increases. The segregation of a higher harmonic, which is not at all pronounced, from a decaying oscillation is not very certain or satisfactory, and considerable error may be involved.

The second space harmonic is a maximum at the 25% and 75% points of the winding, and passes through zero at the midpoint. By connecting the oscillograph between the 25% and 75% points, the second harmonic is doubled in amplitude, the fourth harmonic is zero at both these points, and all odd harmonics cancel out. Thus, this is a strategic connection for the segregation of the second harmonic. The oscillogram of figure 1 shows this harmonic to have a frequency of 105,000 cycles (2.5 times that of the fundamental), and a decrement factor of 0.035. There is very little distortion shown in this oscillogram, but in many transformer tests the 6th harmonic is sufficiently pronounced to be segregated.

If oscillograms are taken from the 25% and 75% points to ground, then the distortion due to the odd harmonics is quite pronounced, as shown in the two bottom oscillograms of figure 1. It is difficult to match these two separate oscillograms with sufficient accuracy to yield, by subtraction, the preceding oscillogram, and, therefore, it is always best to measure between the 25% and 75% points. There are no other strategic points along the winding which will permit a definite segregation of any of the other harmonics. Thus, this method of test does not ordinarily yield good results for other than the fundamental and the second harmonic, but for these two the data are definite and reliable.

The advantages and limitations of this method of test are as follows:

(*a*). *The natural frequencies* of the fundamental and second harmonic are definite and reliable, and their decrement factors can be obtained with reasonable accuracy.

Paper 41-84, recommended by the AIEE committee on electrical machinery, and presented at the AIEE North Eastern District meeting, Rochester, N. Y., April 30–May 2, 1941. Manuscript submitted November 2, 1940; made available for preprinting March 4, 1941.

L. V. BEWLEY is head of the department of electrical engineering, Lehigh University, Bethlehem, Pa. J. H. HAGENGUTH and F. R. JACKSON, JR. are both with the General Electric Company, Pittsfield, Mass.

(*b*). The natural frequencies and decrement factors of some of the remaining harmonics can be roughly obtained, but only in cases where they are pronounced.

(*c*). From oscillograms of the voltages to ground all along the coil stack, the envelope of oscillations, as well as the initial and final distributions, can be obtained as in figure 2. The difference between the initial and final distributions can be analyzed by Fourier's method to determine the amplitudes of all of the space harmonics, and these values may be checked against the amplitudes of the fundamental and second harmonic as determined directly from the oscillograms of figure 1. If an oscillograph is not available these distributions can be obtained by means of a spark gap.

(*d*). The effect of applied wave shape—steepness of front, length of tail, etc.—in reducing or amplifying the oscillations can be studied experimentally, and, therefore, the effects of these factors on voltage stresses throughout the winding can be studied in detail.

II—Resonance With Damped Oscillatory Waves

If a damped oscillatory wave is applied to a winding, and the frequency varied so as to cause the voltage at a selected point of the winding to become a maximum, a condition of resonance is indicated. Figure 3 shows this condition in the neighborhood of the resonance frequencies for the fundamental and second harmonic. The oscillograms for the fundamental and second harmonic at resonance are shown in figure 4. The selected connection for the fundamental was the 50% point to ground, and for the second harmonic between the 25% and 75% points of the winding.

As a check, the envelopes of the oscillations shown in figure 4 can be calculated with fair accuracy from the data of figures 1 and 2. The solution for a damped oscillatory applied wave is given by equation 4 of appendix I. If the applied frequency is equal to one of the natural frequencies, $b=\omega_s$, and, if the decrement factor γ_s is small compared to ω_s, as is the case in practice, then the *dominant* term of the transient is

$$A_s \sin\frac{s\pi x}{l}\,\frac{E}{2}\sqrt{\frac{b^2}{\gamma_s^2}+1}\times\left(\frac{\epsilon^{-at}-\epsilon^{-\gamma_s t}}{a/\gamma_s-1}\right)\sin(bt-\lambda_s)$$

and this has a maximum occurring at

$$t=\frac{\log\ (\gamma_s/a)}{\gamma_s-a}$$

The fundamental has an amplitude, as determined from the oscillogram taken at the 50% point of figure 1, of

$$A_1=y\epsilon^{\gamma_1 t}=0.13\epsilon^{0.022\times 60}=0.49$$

and this agrees reasonably well with the Fourier analysis of figure 2.

The decrement of the applied wave of figure 4 is $a=0.014$. Then

$$\frac{a}{\gamma_s}=\frac{0.014}{0.022}=0.635 \qquad \frac{b}{\gamma_s}=\frac{2\pi\,41{,}000}{22{,}000}=11.7$$

The time at which the envelope of the oscillation reaches maximum is

$$t=\frac{\log 1.575}{0.008}=57$$

and the maximum itself is

$$\frac{0.49}{2}\sqrt{11.7^2+1}\left(\frac{\epsilon^{-0.014\times 57}-\epsilon^{-0.022\times 57}}{0.635-1}\right)=1.27$$

The maximum value of 1.27 at 57 microseconds has been plotted as a "calculated point" on figure 4, and is seen to agree well with the tested value.

The corresponding values for the second harmonic are:

$$A_2=0.22 \qquad \gamma_2=0.035 \qquad a_2=0.035$$

and the calculated maximum is 0.77 occurring at $t=26\mu s$. Between the 25% and 75% points of the winding the maximum is twice as much, or 1.54, which is in fair agreement with the value shown on figure 4.

This method of determining the natural frequency appears to give reasonably accurate results for the first few harmonics. But, as can be seen from equation 4 of appendix I, it is not an exact method because many other terms are present in addition to the "dominant" term. In circuits with high decrement factors the error may be appreciable, particularly for the higher harmonics.

IIb—Resonance With Sustained Oscillations

Instead of applying a damped oscillatory wave, it is usually easier to apply a sustained sinusoidal voltage by means of an oscillator. The frequency can then be varied in the neighborhood of a resonance frequency until a maximum voltage is obtained at some selected point of the winding; or better, complete distributions can be taken along the winding, as in figures 5 and 6, so as to obtain the maximum both in space and in time. Thus, in figure 5 the distribution for an applied frequency of 42 Kc (the frequency giving the maximum envelope), and partial distributions for 40 and 44 Kc are shown. Likewise in figure 6, the distributions for applied frequencies of 100, 112, 117, and 120 Kc are shown.

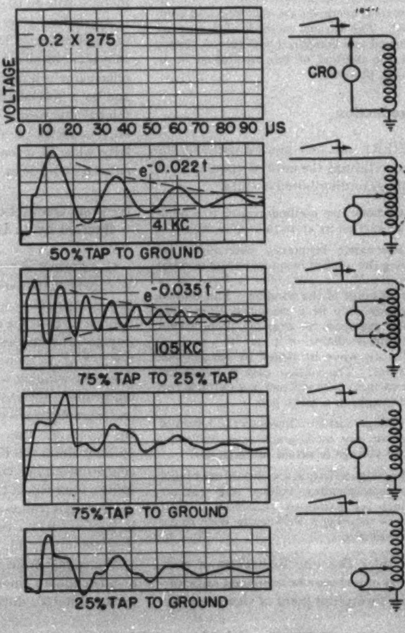

Figure 1. Free oscillations excited by impulse generator

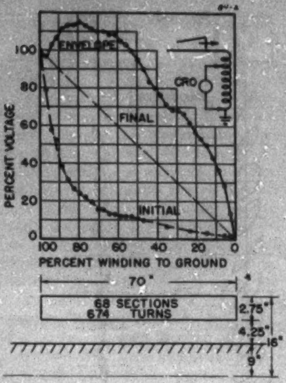

Figure 2. Envelope of oscillations and initial distribution

It is seen that a small departure from resonance causes a very great reduction in the maximum voltage distribution, and the maximum is very sensitive to frequency in the neighborhood of a resonance point.

Equation 8 of appendix I gives the solution for a sustained sinusoidal applied wave, after steady state conditions prevail. Under resonance conditions $b=\omega$, and for the usual conditions of decrement factors small compared to the angular velocities, the solution reduces to equation 10, from which it is seen that the phenomenon consists essentially of an oscillating axis and a dominant harmonic, although all the other space harmonics are present. In transformer windings the contribution of harmonics, other than that under resonance excitation, is practically negligible.

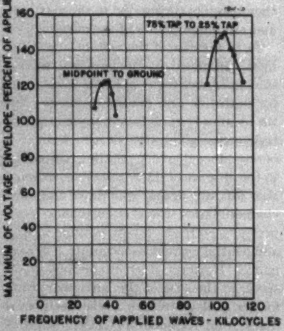

Figure 3. Resonance with damped oscillatory waves

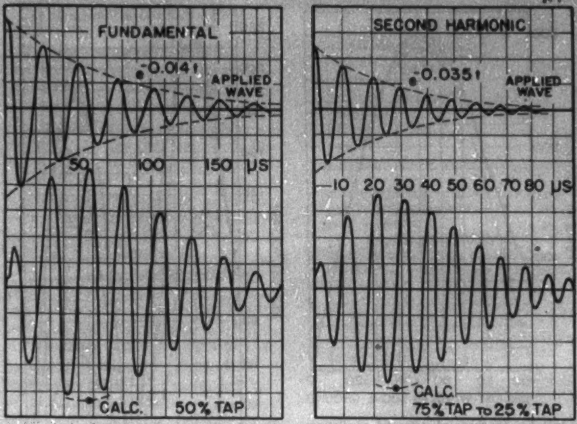

Figure 4. Resonance with damped oscillatory waves

Thus, it is impossible for the circuit to oscillate in a single space harmonic to the exclusion of all other space harmonics, when it is excited in this manner. The other space harmonics contribute to the total voltage and current, and, therefore, it cannot be concluded that a maximum at a point on the winding is an exact condition for true resonance.

It will be seen also from equation 10 that the harmonic oscillations take place about an oscillating axis, and in space this axis is the initial distribution curve. The total maximum voltage to ground at any point, therefore, is composed of two parts: the initial voltage to ground and the harmonic voltage. The amplitude of the latter depends considerably on the decrement factors of the harmonic oscillations. For high decrement factors the amplitude of the harmonic voltage will be low and the initial voltage component will be an appreciable part of the total amplitude.

The equations show that the nodal points of harmonic oscillations are located along a curve represented by the initial voltage distribution. This is indicated in figure 6 where the nodal point for the second harmonic at the midpoint of the winding lies on the initial voltage distribution curve. Also, in figure 5 the envelope of voltages to ground produced by the first harmonic when in resonance is shown by the dashed line. This line is obtained by subtracting the initial voltage distribution curve, figure 1, from the test points obtained for an applied sustained oscillation of 42 Kc.

For the winding here considered:

$$\frac{b_1}{\gamma_1}=\frac{2\pi\,41{,}000}{22{,}000}=11.7$$

$$\frac{b_2}{\gamma_2}=\frac{2\pi\,105{,}000}{35{,}000}=18.9$$

Equation 10 then gives for the amplitudes of the fundamental and second harmonic, respectively:

$$e_1=e(0,x)\cdot\sin b_1t-0.49E\ \sin\frac{\pi x}{l}\times$$
$$(-0.75\sin b_1t+5.85\cos b_1t)+\ldots\ldots$$

$$e_2=e(0,x)\cdot\sin b_2t+0.22E\sin\frac{2\pi x}{l}\times$$
$$(-0.75\sin b_2t+9.45\cos b_2t)+\ldots\ldots$$

The calculated maximum values for these resonant conditions are then

$e_1=2.91$, and $e_2=2.11$

as compared with test values from figures 5 and 6 of 3.00 and 2.20, respectively.

The first term of the equations gives the initial voltage, and as seen in the above equations, this may be an appreciable part of the maximum voltage.

III—Voltage-Current Ellipses

A method sometimes used to determine resonance conditions is to apply a sinusoidal voltage, which is connected to one axis (pair of plates) of a cathode ray oscillograph, and measure the corresponding terminal current on the other axis of the oscillograph. The oscillograph then records the instantaneous voltage-current relationship at the line terminal. According to equations 12 and 13 of appendix I the

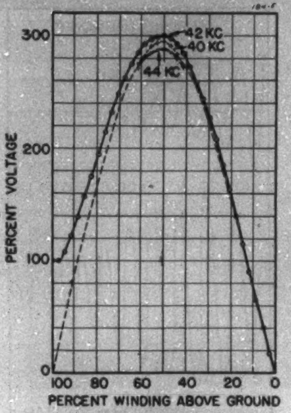

Figure 5. Envelope of sustained oscillations near fundamental resonance

Dashed line = contribution of harmonic oscillations to envelope of maximum voltage at 42 kc

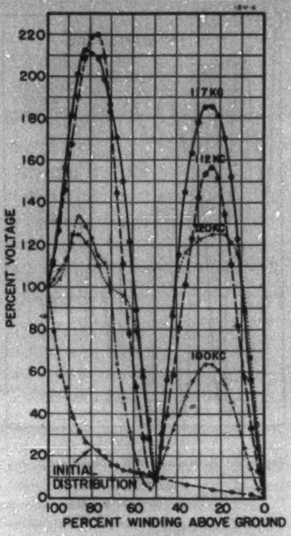

Figure 6. Envelope of sustained oscillations near second harmonic resonance

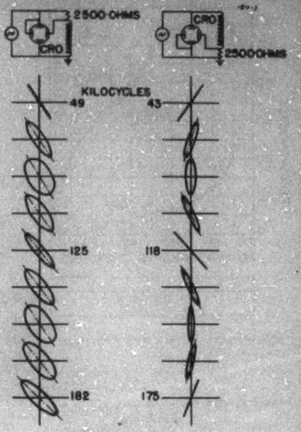

Figure 7. Voltage-current ellipses

steady state voltage and current at the line terminal are of the form:

$$e=E\sin bt,\qquad i=I\sin(bt+\alpha)$$

As shown in appendix II, these are the parametric equations of an ellipse with an inclined major axis. The inclination of the major axis shifts as the applied frequency is varied and the ellipse becomes a straight line for $\alpha=0$ when current and voltage are in phase.

For an applied frequency equal to the harmonic frequency $b=\omega_s$, the dominant terms of the current, according to equation 11 of appendix I are:

$$i\cong bCE\left[\frac{x^2}{2l}\cos bt-\frac{lA_s}{s\pi}\cos\frac{\pi sx}{l}\left(\frac{b}{2\gamma_s}\right)\sin bt\right]$$

The amplitude of the harmonic (A_s) is always less than unity and grows successively smaller with an increase in s (the order of the harmonic). Thus at the line end, $x=l$, the cosine term may be of the same order of importance as the sine term for the fundamental, and of even greater importance for the higher harmonics. However, at the neutral end, $x=0$; the cosine term

$$\frac{x^2}{2l}\cos bt$$

vanishes. This term principally represents the charging current entering the line end, which is dissipated along the winding directly to ground and does not flow through the neutral. The neutral current is

$$i\cong bCE\frac{lA_s}{s\pi}\left(\frac{b}{2\gamma_s}\right)\sin bt$$

Consequently, at resonance, the voltage-current ellipse is practically a straight line for the neutral current, but for the line current resonance occurs under the condition of an open ellipse, although this ellipse may be quite slender.

This conclusion is confirmed by the test results shown in figure 7. As the applied frequency was varied, the inclination of the ellipse shifted back and forth, tending towards a straight line at the points of current resonance and towards an open ellipse at the points of voltage resonance. The swing is between two straight lines on opposite sides of the vertical ellipse for neutral current, because the neutral current for the even harmonics is 180° out of phase with the corresponding part of the line current.

It is difficult to determine, by the slenderness of the ellipse, the exact points of resonance, particularly with line current, since the presence of the cosine terms materially opens up the ellipse. Now there is no assurance that an actual circuit under test will behave in accordance with an idealized circuit, and for an unknown circuit it would be highly unreliable to determine resonance by matching neutral current with line voltage. For these reasons the ellipse method is not recommended as a means for determining resonance, except in those cases where it is known definitely to give a fair indication.

IV—Impedance-Frequency Characteristics

A commonly-accepted method of testing for the natural frequencies of a multi-element circuit is to apply a sustained constant voltage varied over a sufficiently wide range in frequency and measure the current at each frequency. From these data the *impedance* is plotted against the frequency, as in figure 8, and the points of "series" and "parallel" resonance are then taken to correspond to the maximum and minimum points of the curve.

As in the case of the voltage-current ellipses discussed in the previous section, the impedance curve of figure 8 was tested for both line and neutral currents. For the idealized circuit here assumed the neutral current gives more definite indication of resonance than does the line current due to the absence of the x^2 term in equation 9. But for any actual circuit of unknown characteristics, there is no reason to expect any correlation between line voltage and neutral current as a condition of resonance. However, it is interesting to observe, in the case of the particular transformer coil on which these tests were made, that its behavior closely approximates that of the idealized circuit whose analysis is given in appendix I and consequently, for this case, that the neutral current is a more definite indication of resonance than the line current, as seen in figure 8.

If "resonance" is defined as a maximum or minimum terminal impedance, then a curve of this type certainly gives the resonance points. However, if resonance is defined as an oscillation at a natural frequency, then this method does not give an exact result for, referring to equation 9 of appendix I, it is evident that the condition $b=\omega_s$ is not synonymous with a maximum or minimum current except for the case of zero decrement factors. For small decrement factors the approximation may be very good but for normal decrement factors, such as occur in transformer windings, there may be an appreciable shift of the maxima or minima points away from the natural frequencies. To determine the direction of shift, put $b=\omega_s+\Delta$ in equation 9, where Δ is a small deviation from ω_s. Then upon expanding coefficients in series form it becomes apparent that the current is a maximum for positive values of Δ, that is, for applied frequencies somewhat greater than the resonant values; but maximum current is minimum impedance, and, therefore, the minima points of the impedance curve are further to the right than the true resonance points.

In figure 8 the minima points in the vicinity of the fundamental and second harmonics for grounded neutral are at frequencies of 44 and 120 kilocycles, respectively, whereas the true natural frequencies, as given in figure 1, are 41 and 105 kilocycles.

It is also shown in appendix I that the ratio of line terminal voltage to line terminal current under resonant conditions is *not* the surge impedance for the resonant frequency.

Conclusions

Results obtained on a transformer coil by the several methods and their variations are given in the following table.

	Harmonic Frequencies (Kilocycles)		
Method	1st	2nd	3rd
Free oscillations	41	105	Indefinite
Resonance with damped oscillations	40	105	Not tried
Resonance with sustained oscillations	42	112 117 (?)	Not tried
Voltage-current ellipses (neutral current)	43	118	175
Voltage-current ellipses (line current)	49	125	182
Impedance-frequency curve (neutral current)	44	120	180
Impedance-frequency curve (line current)	43	120	180

The agreement is not bad, with the exception of the line-current ellipse method. The ellipse and impedance methods indicate higher values than the oscillation tests and this is in accord with the theoretical reasoning; but the normal testing error by most of these methods is probably five or ten per cent and for the line-current ellipse method perhaps twice as much.

It is believed that the most satisfactory method of test is by free oscillations using an impulse generator and a cathode ray oscillograph, if the frequencies of the fundamental and the second harmonic will suffice. This method gives much more detailed information about the characteristics of the transient than the other methods; however, it fails to give definite information on harmonics higher than the second (unless they are pronounced), and, of course, selected points of the winding must be accessible for connecting to the oscillograph.

The second choice is resonance with sustained oscillations, using an oscillator and a CRO. Here again points of the winding must be accessible, but higher harmonics can be segregated.

If only the terminals of the circuit are accessible, the impedance method using line current gives the most reliable information, although there may be an appreciable deviation of the maxima and minima points from the natural frequencies.

Appendix I

The voltage distribution along the winding of a grounded neutral transformer subjected to an infinite rectangular applied wave ("unit function") is of the form:

$$e(t)=E\left[\frac{x}{l}+\sum_1^\infty A_s\epsilon^{-\gamma_s t}\cos\omega_s t\ \sin\frac{s\pi x}{l}\right] \quad (1)$$

in which

l = total length of winding
x = distance along the winding measured from the neutral
s = order of space harmonic ($s=1, 2, 3, \ldots$)
A_s = amplitude of the s space harmonic
γ_s = decrement factor of the s space harmonic
ω_s = angular velocity of the s space harmonic

According to this equation, the transient voltage distribution consists of an infinite series of space harmonics oscillating at different frequencies, and decaying exponentially, about a fixed linear distribution (x/l).

If, now, the applied surge is a damped sinusoidal wave

$$E(t)=E\epsilon^{-at}\sin bt \quad (2)$$

then the corresponding solution is given by Duhamel's theorem

$$f(t)=E(t)e(o)+\int_0^t E(t-u)\frac{\partial e(u)}{\partial u}\,du \quad (3)$$

Substituting (1) and (2) in (3) and simplifying, there results

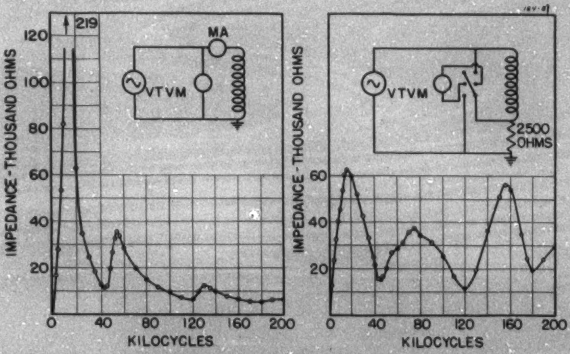
$$\frac{e}{E}=\frac{x}{l}\epsilon^{-at}\sin bt+\sum_1^\infty A_s\sin\frac{s\pi x}{l}\left\{\epsilon^{-at}\times\sin bt+\frac{1}{2}\sqrt{\frac{\gamma_s^2+\omega_s^2}{(a-\gamma_s)^2+(\omega_s+b)^2}}\times\left[\epsilon^{-at}\sin(bt+\psi_s)+\epsilon^{-\gamma_s t}\sin(\omega_s t-\psi_s)\right]+\frac{1}{2}\sqrt{\frac{\gamma_s^2+\omega_s^2}{(a-\gamma_s)^2+(\omega_s-b)^2}}\left[\epsilon^{-at}\sin(bt-\lambda_s)-\epsilon^{-\gamma_s t}\sin(\omega_s t-\lambda_s)\right]\right\} \quad (4)$$

where

$$\psi_s=\tan^{-1}\frac{a\omega_s+b\gamma_s}{\gamma_s(a-\gamma_s)-\omega_s(\omega_s+b)}$$

$$\lambda_s=\tan^{-1}\frac{a\omega_s-b\gamma_s}{\gamma_s(a-\gamma_s)-\omega_s(\omega_s-b)}$$

Figure 8. Impedance-frequency characteristics



It will be noticed from equation 1 that the *initial* voltage, at $t=0$, is

$$e(o)=E\left[\frac{x}{l}+\Sigma A_s \sin\frac{s\pi x}{l}\right] \tag{5}$$

so that the first two terms of (4) may be written

$$\frac{e}{E}=e(o)\epsilon^{-at}\sin bt+\ldots\ldots \tag{6}$$

The corresponding current is

$$i=C\int\frac{\partial e}{\partial t}\,dx=I(t)-CE\frac{x^2}{2l}\sqrt{b^2+a^2}\,\epsilon^{-at}\times$$
$$\sin\left(bt-\tan^{-1}\frac{b}{a}\right)+\sqrt{b^2+a^2}\,CE\sum_1^\infty\frac{lA_s}{s\pi}\times$$
$$\cos\frac{s\pi x}{l}\left\{\epsilon^{-at}\sin\left(bt-\tan^{-1}\frac{b}{a}\right)+\right.$$
$$\frac{1}{2}\sqrt{\frac{\gamma_s^2+\omega_s^2}{(a-\gamma_s)^2+(\omega_s+b)^2}}\left[\epsilon^{-at}\sin\left(bt+\psi_s-\right.\right.$$
$$\left.\tan^{-1}\frac{b}{a}\right)+\sqrt{\frac{\omega_s^2+\gamma_s^2}{b^2+a^2}}\,\epsilon^{-\gamma_s t}\sin\left(\omega_s t-\psi_s-\right.$$
$$\left.\left.\tan^{-1}\frac{\omega_s}{\gamma_s}\right)\right]+\frac{1}{2}\sqrt{\frac{\gamma_s^2+\omega_s^2}{(a-\gamma_s)^2+(\omega_s-b)^2}}\times$$
$$\left[\epsilon^{-at}\sin\left(bt+\lambda_s-\tan^{-1}\frac{b}{a}\right)+\right.$$
$$\left.\left.\sqrt{\frac{\omega_s^2+\gamma_s^2}{b^2+a^2}}\,\epsilon^{-\gamma_s t}\sin\left(\omega_s t-\lambda_s-\tan^{-1}\frac{\omega_s}{\gamma_s}\right)\right]\right\} \tag{7}$$

where $I(t)$ is an integration constant with respect to x (and therefore a possible function of t), whose evaluation depends upon the particular assumptions made regarding the inductance of the winding. It will not be necessary for the present purposes to evaluate $I(t)$.

For a sustained sinusoidal applied wave ($a=0$), and after the transient has died away ($\epsilon^{-\gamma t}\rightarrow 0$), equations 4 and 7 reduce to

$$e(o)\sin bt+\sum_1^\infty A_s\sin\frac{s\pi x}{l}\times$$
$$\left\{\frac{1}{2}\sqrt{\frac{\gamma_s^2+\omega_s^2}{\gamma_s^2+(\omega_s+b)^2}}\sin(bt+\psi_s)+\right.$$
$$\left.\frac{1}{2}\sqrt{\frac{\gamma_s^2+\omega_s^2}{\gamma_s^2+(\omega_s-b)^2}}\sin(bt-\lambda_s)\right\}\ldots\ldots \tag{8}$$

$$i=I(t)+bCE\frac{x^2}{2l}\cos bt-bCE\sum_1^\infty\frac{lA_s}{s\pi}\times$$
$$\cos\frac{sx\pi}{l}\left\{\cos bt+\frac{1}{2}\sqrt{\frac{\gamma_s^2+\omega_s^2}{\gamma_s^2+(\omega_s+b)^2}}\times\right.$$
$$\cos(bt+\psi_s)+\frac{1}{2}\sqrt{\frac{\gamma_s^2+\omega_s^2}{\gamma_s^2+(\omega_s-b)^2}}\times$$
$$\left.\cos(bt-\lambda_s)\right\}\ldots\ldots \tag{9}$$

If the applied frequency is in resonance with some particular harmonic ($b=\omega$), then (8) and (9) give, for γ_s small compared with ω_s,

$$e\cong e(o)\sin bt+EA_s\sin\frac{s\pi x}{l}\times$$
$$\left(-\frac{3}{4}\sin bt+\frac{b}{2\gamma_s}\cos bt\right)+$$
$$\Sigma[\text{remaining harmonic terms of (8)}] \tag{10}$$

$$i=I(t)+bCE\frac{x^2}{2l}\cos bt-bCE\frac{lA_s}{s\pi}\times$$
$$\cos\frac{s\pi x}{l}\left(\frac{1}{4}\cos bt-\frac{b}{2\gamma_s}\sin bt\right)+$$
$$\Sigma[\text{remaining harmonic terms of (9)}] \tag{11}$$

It is clear from these equations that the steady-state of the circuit to a sustained sinusoidal applied wave in resonance with one of the natural frequencies of the circuit is by no means restricted to the space harmonics corresponding to that particular frequency. It is only under the condition of zero losses ($\gamma_s=0$) that the resonant term predominates to such an extent as to create the illusion that it is the only harmonic present.

At the line end ($x=l$), (10) and (11) give

$$e=E\sin bt \tag{12}$$

$$i=I(t)+bCE\frac{l}{2}\cos bt-bCE\frac{lA_s}{s\pi}\times$$
$$\cos s\pi\left(\frac{1}{4}\cos bt-\frac{b}{2\gamma_s}\sin bt\right)+$$
$$\Sigma[\text{remaining harmonic terms of (9)}] \tag{13}$$

Thus at the line end, e and i are substantially in phase (for $b/2\gamma_s$ large) and not 90 degrees out of phase as might be suspected under resonant conditions. It will be observed that

$$\left.\frac{e}{i}\right|_{x=l}\neq\text{(surge impedance for the resonant harmonic)} \tag{14}$$

At the neutral end ($x=0$)

$$i=I(t)-bCE\frac{lA_s}{s\pi}\left(\frac{1}{4}\cos bt-\frac{b}{2\gamma_s}\sin bt\right)+$$
$$\Sigma\text{(harmonic terms)} \tag{15}$$

from which it is clear on comparing (13) and (15) that the current is not completely symmetrical at the two ends of the winding; although in the case of small losses the dominating terms might make it appear to be so.

For an applied frequency which is small compared to that of any of the natural frequencies ($\omega_s\gg b$), so that b may be neglected in comparison with ω_s, there is $\lambda_s\cong 180°$ and $\psi_s\cong 180°$ and (8) then reduces to

$$e=E\frac{x}{l}\sin bt \tag{16}$$

Thus at 60 cycles the distribution is substantially linear.

Appendix II

For a sinusoidal applied terminal voltage

$$e=E\sin\omega t \tag{1}$$

The steady-state terminal current, according to equation 9 of appendix I, is of the form

$$i=I\sin(\omega t-\alpha) \tag{2}$$

Eliminating ωt between (1) and (2)

$$\left(\frac{i}{I}\right)^2+\left(\frac{e}{E}\right)^2-2\cos\alpha\left(\frac{i}{I}\right)\left(\frac{e}{E}\right)=\sin^2\alpha \tag{3}$$

and for a given value of α this can be plotted as a curve having (i) and (e) as coordinates. If the equation is transformed to a new set of axes, i', e' by rotation of axes through an angle β such that

$$i=i'\cos\beta-e'\sin\beta \tag{4}$$

$$e=e'\cos\beta+i'\sin\beta \tag{5}$$

then equation 3 becomes

$$\left[\frac{\cos^2\beta}{I^2}+\frac{\sin^2\beta}{E^2}-\frac{\cos\alpha\sin 2\beta}{EI}\right]i'^2+$$
$$\left[\frac{\sin^2\beta}{I^2}+\frac{\cos^2\beta}{E^2}+\frac{\cos\alpha\sin 2\beta}{EI}\right]e'^2+$$
$$\left[\frac{\sin 2\beta}{E^2}-\frac{\sin 2\beta}{I^2}-\frac{2\cos\alpha\cos 2\beta}{EI}\right]e'i'=\sin^2\alpha \tag{6}$$

This is the equation of an ellipse if the coefficient of the $e'i'$ term can be made to vanish by a suitable choice of β. The condition is met by

$$\tan 2\beta=\frac{2EI}{I^2-E^2}\cos\alpha \tag{7}$$

Thus (1) and (2) define an ellipse, the inclination of whose axes are given by (7).

In particular, if $\alpha=90°$

$$\left(\frac{i}{I}\right)^2+\left(\frac{e}{E}\right)^2=1 \tag{8}$$

and this is an ellipse whose axes coincide with the coordinate axes. If $\alpha=0°$,

$$e=\frac{E}{I}i \tag{9}$$

which is the equation of a straight line with a slope of

$$\Theta=\tan^{-1}\left(\frac{E}{I}\right) \tag{10}$$

Now since the current will either lag or lead the voltage by 90°, the angle is restricted to the range ($-90°\leq\alpha\leq 90°$), for which $\cos\alpha$ is always positive; and therefore by (7) the angle β varies from a negative value (when $I<E$) to a positive value (when $I>E$), and at the two extremes ($\alpha=0$) the ellipse degenerates to a straight line. Thus, as the frequency is varied over a wide range, nodes and anti-nodes are encountered successively (that is, $I<E$ and $I>E$); and correspondingly the axis of the ellipse swings back and forth between the straight lines to which it degenerates. This is indicated by the test results in figure 7.

Protection of Low-Voltage Circuits by Air Circuit Breakers in Cascade Arrangement

A. E. ANDERSON
FELLOW AIEE

C. H. BLACK
ASSOCIATE AIEE

Synopsis: This paper deals with and outlines a new solution to the problem of providing adequate short circuit protection for low-voltage distribution systems and circuits operating at 600 volts or less.

Recent tests and field experience have dispelled the illusion that protective devices of very limited interrupting ability will satisfactorily protect *any* low-voltage circuit. A recently published calculating procedure makes possible the accurate determination of the short circuit currents obtainable in low voltage circuits or systems. Modern types of low-voltage air circuit breakers in a wide range of interrupting ratings are now available. While the best short circuit protection is obtained by selecting those of interrupting ratings at least equal to the calculated short circuit current, such a procedure is not always justifiable.

In many instances a relatively large number of main feeder circuits, emanating from a bus fed through one or more main breakers or incoming line breakers, supply an even larger number of branch feeders. The short circuit currents obtainable at the branch-feeder breaker locations may not be materially less than those obtainable at the main bus. Yet the selection of branch feeder breakers, or possibly even main feeder breakers, with interrupting ratings high enough to match these obtainable currents, may prove completely impractical when viewed with any reasonable regard for space requirements or cost.

Air circuit breakers of varying interrupting ratings, properly coordinated in design may be used in a "cascade" or series connection in such manner that in event of a severe fault, the main breakers "back-up" the smaller main feeder breakers, and these, in turn, "back-up" the branch feeder breakers. Only the main breakers need have interrupting ratings equal to the obtainable short-circuit current, yet the system is adequately protected, within the limits set forth in the paper.

Cascading also makes possible a simple means of selecting air circuit breakers to provide economical yet adequate protection for relatively small installations, where a complete short-circuit study might be difficult to justify and where a poor selection of protective devices would result in either an unnecessarily expensive installation or a serious hazard—generally the latter. An application table for such installations, based upon the principle of cascade operation is included.

Introduction

RECENT papers[1,2] on the subject of short circuits in low-voltage a-c systems (600 volts or less) have dispelled prevalent illusions with respect to faults in low-voltage systems and low-voltage gear. The first reference[1] states that faults in typical low-voltage bus structures are not self-clearing and that fault arcs do not show the drastic current-limiting effect which they were previously assumed to have exerted upon short circuits in low-voltage systems. The magnitude of fault currents obtained in this series of tests showed the fallacy of applying arbitrary and large discount factors to the calculated "bolted fault" short circuit current values in low-voltage systems. This justifies the present practice of determining the short circuit current on the basis of a "bolted fault."

The second reference[2] outlines a procedure for calculating the short circuit current for "bolted faults." The accuracy of the method has been verified by calculation and subsequent measurement of short circuit currents extending to values beyond 100,000 amperes. (Reference 1 and appendix *A* show typical examples.)

When using the calculating procedure of reference 2 for determining the interrupting duty imposed upon low-voltage air circuit breakers, the following specific steps are generally all that need be considered:

Determination of Short-Circuit Duty Placed on Air Circuit Breakers

A.—Low-Voltage Alternating-Current Systems

The maximum interrupting duty is assumed to occur 0.5 cycle from the inception of the fault. During this interval there is a decay of both the a-c and d-c components. For the various kinds of apparatus here used it has been possible to determine a factor *N* which represents the average decay of the sub-transient portion of the a-c component during this interval. Similarly, a factor *D* has been determined to express the average effect of the d-c component. This factor may be used to increase the calculated symmetrical current (a-c component) to obtain the average of the three unsymmetrical, available currents. Thus,

$$i_{0.5\ \text{cycle}} = Di_{ac} \qquad (1)$$

where i_{ac} is the a-c component.

However, the a-c component at any time, *t*, during the first few cycles, may be represented by:

$$i_{ac} = i'' - N(i'' - i') \qquad (2)$$

where,

i'' represents the maximum initial value of the a-c component, which is determined by the sub-transient reactance and other circuit impedance, and

i' represents the current determined by the transient reactance, and other circuit impedance. Hence,

---

Paper 41-128, recommended by the AIEE committee on protective devices, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 16, 1941; made available for preprinting May 16, 1941.

A. E. Anderson and C. H. Black are both with General Electric Company, Philadelphia, Pa.

[1] For all numbered references, see list at end of paper.

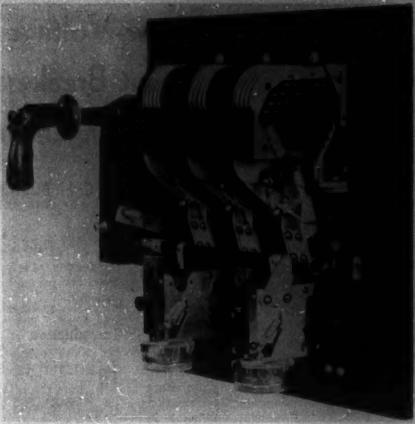

Figure 3. Manually operated air circuit breaker, 3-pole, 15,000-ampere interrupting rating, with arc-quencher side removed to show construction

$(i''-i')$ represents the sub-transient portion of the a-c component which diminishes exponentially.[2]

For most rotating apparatus, the average ratio of $i''/i'=1.5$ while the factor N is approximately 0.2, at 0.5 cycle.[2] The term $N(i''-i')$ at 0.5 cycle, then becomes approximately $0.07i''$.

Since, at 0.5 cycle the increase in short circuit current, obtainable under load conditions (due to increased excitation) is of the order of 5%, the second term in equation 2, indicating a decrease of the order of 7%, is largely offset and can be omitted for all practical purposes, resulting in,

$$i_{0.5\text{ cycle}}=Di'' \tag{3}$$

For air circuit breakers applied to single or three-phase circuits supplied by transformers or rotating apparatus, the factor D at 0.5 cycle, equals 1.25. Accordingly, for rotating apparatus, the total rms current at 0.5 cycle, becomes:

$$i_{0.5\text{ cycle}}=1.25i'' \tag{4}$$

For transformer banks connected to relatively large systems (see appendix *B*), practically the entire limiting impedance is found in the transformer, permitting equation 4 to be written as:

$$i_{0.5\text{ cycle}}=1.25i \tag{5}$$

where i is the a-c component, determined by the transformer impedance.

To the currents determined by equations 4, 5, must be added the short circuit current contributed by induction and synchronous motors. This current (including both a-c and d-c components but allowing for the effect of typical motor circuit impedance) at 0.5 cycle, is approximately 6 times rated current for synchronous motors and 4.5 times rated current for induction motors. (See appendix *B*, tables II and III.)

B.—LOW-VOLTAGE DIRECT-CURRENT SYSTEMS

As indicated in table I, appendix *B*, the fault current to be considered in d-c circuits is the maximum current obtainable and not some lower value during the initial rise in the transient. The resistance of the external circuit, frequently negligible in a-c systems, should be included in the calculations.

Air Circuit Breakers for Short-Circuit Protection

In the past, oil circuit breakers had commonly been used on low-voltage a-c systems. Because of smaller space requirements, lower cost, and faster interruption, the present practice is to apply air circuit breakers to such systems.

When there is a single circuit breaker between the source and load (figure 1) the interrupting rating of the circuit breaker must be at least equal to the fault current obtainable in the circuit. Air circuit breakers of adequate interrupting rating may be selected from table I, appendix *B*.

In low-voltage a-c systems of limited capacity, such as illustrated in figure 1, the circuit breakers are relatively few in number and the calculated short circuit current usually falls within the lower interrupting ratings given in table I. Hence the selection of air circuit breakers for adequate short circuit protection is a simple matter.

As the system capacity increases, the selection of air circuit breakers presents a more difficult problem. Figure 2 illustrates such a system, where, despite the influence of relatively long runs of connections to the transformers and the absence of appreciable short circuit contribution from the motor load, the calculated fault current on a feeder circuit, at 0.5 cycle reached almost 100,000 amperes. Application of air circuit breakers of 100,000 ampere interrupting rating throughout, would result in an equipment of high cost and occupying more space than available or justifiable in the average installation.

An alternative sometimes suggested is to use smaller air circuit breakers, but to render their tripping means inoperative whenever the short circuit current exceeds their interrupting ratings, thus supposedly "locking-in" the smaller breakers and transferring the severe interrupting duty to some larger or "group" circuit breaker. All modern air breakers are inherently and instantaneously trip-free and thus would be difficult to "lock-in," even though their mechanisms and contacts were made much larger, heavier, and more costly to permit them to close and hold their contacts closed against the strong opening forces produced by the excessive current. Many air circuit breakers could not withstand, for any appreciable interval, the heating losses of as much as 40,000 times normal that would result. For these and many other cogent reasons, this scheme may be dismissed as totally impractical.

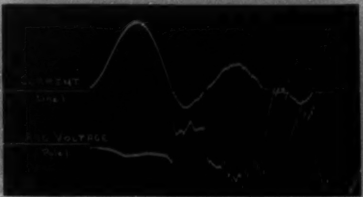

Figure 4. Low-voltage air circuit breaker (15,000-ampere interrupting rating) on verge of failing to interrupt short-circuit current considerably in excess of rating

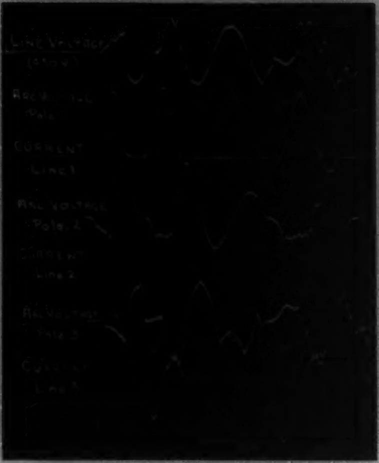

Figure 5. Low-voltage air circuit breaker (25,000-ampere interrupting rating) failing to interrupt satisfactorily short-circuit current exceeding 200 per cent of rating

Limitation of the short circuit current by sectionalizing or by the use of reactors provides a solution which is feasible under some conditions, but consideration must be given to the possible effect on cost, voltage regulation, and space requirements.

A generally more practical solution of the problem is the use of air circuit breakers in "cascade." "Cascading" consists in the use of air circuit breakers of interrupting ratings less than the calculated short circuit current but instead of being "locked-in," these breakers are allowed to trip and are assisted or "backed-up" by one or two larger breakers, the one nearest the source of power having a current interrupting rating at least equal to the calculated short circuit current. In figure 11 circuit breakers (*A*) (*B*) and (*C*) are in cascade. This scheme permits the use of air circuit breakers having lower over-all cost and occupying less space than a layout of breakers having full interrupting rating throughout.

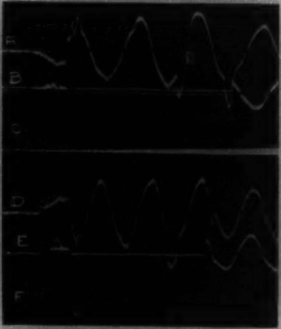

Figure 6. Low-voltage air circuit breakers of 25,000-ampere and 100,000-ampere interrupting ratings operating in series, in circuit calibrated for 89,000 amperes, short-circuit current

Curves C, *F*—Currents, lines 2 and 3

Actual rms values average 62,000 amperes

Performance Required of Breakers to Be Cascaded

It must not be assumed that *any* combination of air circuit breakers will operate effectively in cascade arrangement. They must be carefully and properly selected. For example, tests have revealed that—of the types of breakers with which the authors are familiar—the so-called "thermal" breakers, when subjected to currents considerably beyond their ratings, may clear the circuit and yet, if the current is too great, be destroyed during the first peak of 60-cycle current. Some users have been willing to accept this hazard, using larger breakers to protect the circuit only and recognizing the impracticability of preventing damage to the "thermal" breakers. This, however, is not considered as true "cascading," where one of the principles is that no breaker shall be damaged beyond repair, nor shall any breaker constitute a potential hazard to the safety of personnel or adjacent equipment.

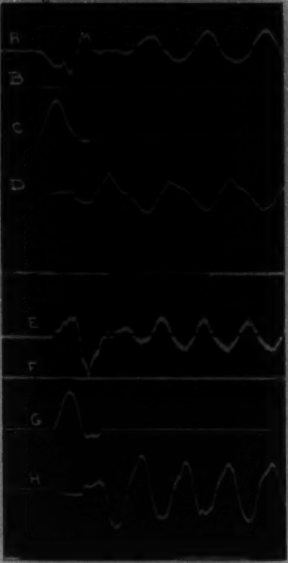

Figure 7. Low-voltage air circuit breakers of 25,000-, 50,000-, and 100,000-ampere interrupting ratings operating in cascade connection, in circuit calibrated for 89,000 amperes, short-circuit current

Curves *A*, *E*—Arc voltages, (*C*) breaker, 25,000-ampere rating

Curves *B*, *F*—Arc voltages, (*A*) breaker, 100,000-ampere rating

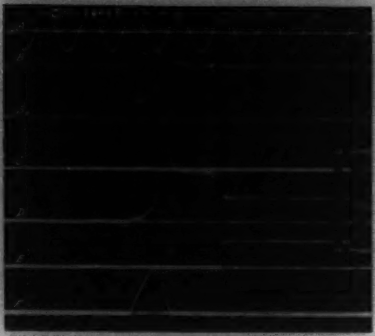
Curves C, G—Currents, lines 2 and 3

Actual rms values average 45,000 amperes

Curves *D*, *H*—Arc voltages, (*B*) breaker, 50,000-ampere rating

The authors, therefore, confine their recommendations for "cascading" to air circuit breakers of the conventional "magnetic" type (figure 3) somewhat larger and of greater thermal capacity than the corresponding "thermal" breakers. Although based upon breakers of the type with which the authors are most familiar[3] the following requirements may serve as a guide for the selection of any breakers having characteristics that permit their use in "cascade."

The smaller breakers (such as *C* in figure 11) must meet the following requirements throughout the range of short-cir-



Available short-circuit current 70,000 amperes

Figure 8. D-c interrupting test on low-voltage air circuit breaker number 9 (15,000-ampere) left pole and breaker number 15 (50,000-ampere) left pole

cuit currents for which they are to be recommended:

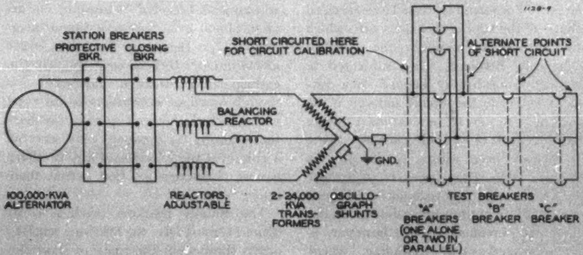
1. They must be capable of mechanically withstanding the "impact" resulting from the electro-magnetic forces set up by the excessive current. This is much more readily accomplished if these breakers have a quick-acting instantaneous tripping means [see reference (*a*) below table I, appendix *B*].

2. Having a quick-acting tripping mechanism, they should not otherwise be restrained from separating their contacts nor from transferring the current from contacts to interrupting unit. Undue delay may cause serious damage, but rapid current transfer, preferably accelerated by the electro-magnetic forces previously referred to, will transfer the burning from the contacts to the arc runners (see figure 3) where even a considerable amount of burning will not impair subsequent current-carrying ability.

3. Their interrupting units must be capable of withstanding arcing for such time as the "back-up" breakers (such as (*B*) in figure 11) may require to interrupt the current.

Representative tests depicted in figures 4 and 5, show that the foregoing requirements can be met. Arc voltage records show that the main contacts are out of the circuit in substantially less than one cycle and—even though the currents were such that these breakers, operating alone, were on the verge of failing to interrupt—the contacts were not seriously damaged. The decided current-limiting tendencies of the arc quenchers can be seen, as can also the temporary interruption of current. Circuit interrupting failures of air circuit breakers are not always—as has been commonly supposed—characterized by prolonged, continuous arcing without appreciable diminution of current.

Figure 9. Diagram of connections for cascade tests on low-voltage air circuit breakers (a-c tests)



Figures 4 and 5 give a picture of what might be called the "mechanism of failure" of the smaller sizes of modern breakers. It can be seen that, while "back-up" breakers (such as (*B*) in figure 11) interrupting during the first cycle of current might share the interrupting duty with the (*C*) breakers, such rapid operation would impose much greater duty on the "back-up" breakers than would operation during the subsequent cycle. In fact, figure 5 indicates a strong probability that the "back-up" breaker might merely serve to remove potential from the protected circuit, without interrupting any current whatever.

Since the "back-up" breakers must protect not only the circuit but also the smaller breakers, the following requirements are indicated for the (*A*) or (*B*)* breakers of figure 11:

1. They must trip whenever the current reaches a value equal to or slightly less than the interrupting rating of the smaller breakers next in line.

2. They must completely interrupt this current (or, in the case of the (*B*) breakers, must at least reduce its magnitude) just rapidly enough to avoid serious damage to the smaller breakers, yet not so rapidly as to participate unnecessarily in the actual interruption of current, thereby requiring unnecessarily increased maintenance. A reasonable and effective solution is that the "back-up" breaker need not actually separate its contacts in less than the normal interrupting time of the smaller breaker next in line, so long as the current does not greatly exceed the rating of the smaller breaker. However, the operating time should become proportionately shorter at higher currents in order to obtain better circuit protection.

Fortunately, a "back-up" breaker of the next larger or even the second larger size (see table I, appendix *B*) generally meets this requirement. A breaker more than two sizes larger would introduce an unnecessarily long time element, as shown in figure 6, where a 100,000 ampere breaker operates in series with the 25,000 ampere breaker of figure 5. Although this large "back-up" breaker did prevent "restriking," it was not rapid enough to assure satisfactory protection had the 25,000 ampere breaker not functioned quite so satisfactorily.

Much better protection is obtained (in the same circuit) when a 50,000 ampere breaker is inserted, as in figure 7. Here, although the "back-up" breaker still performs no appreciable interrupting duty, it now assures complete clearing of the circuit in one cycle instead of 3 cycles. Incidentally, it may be noted that the 100,000 ampere breaker did not receive an impulse of sufficient magnitude or duration to cause it to trip. This was due, at least in part, to some current limiting action resulting from the addition of the 50,000 ampere breaker to the circuit. Although the circuit was the same, the actual currents were reduced from approximately 62,000 amperes (figure 6) to approximately 45,000 amperes (figure 7).

Similar results in 250 volt direct-current circuits are typified by figure 8, where a 50,000 ampere breaker backs up a 15,000 ampere breaker in a 70,000 ampere circuit, limiting the actual current to 28,000 am-

---

*The (*B*) breakers, when operating at currents beyond their ratings must also meet the requirements previously outlined for the (*C*) breakers.

peres, maximum. The same 15,000 ampere breaker when used alone in the same circuit allowed a maximum current of more than 30,000 amperes and failed to clear the circuit satisfactorily.

Figure 10 shows a typical test data sheet, with some of the higher current tests summarized thereon to indicate the current magnitudes obtained, and the manner of recording the data, as applying to one of the representative combinations of breakers actually tested. Other varieties, not shown, were substituted from time to time during the tests. The a-c test circuit (shown in figure 9) was capable of delivering currents as high as 140,000 total r.m.s. amperes. These data supplemented by visual observation of these and many other tests establish the possibility of "cascading" air circuit breakers and pave the way toward determining reasonable limits for such applications.

Application of Air Circuit Breakers in Cascade Connection

Using the current available at the line terminals of breaker (*A*) (figure 11) (that is, neglecting impedances of all breakers and their connections), the maximum combination of three breakers in cascade may be applied up to the limits indicated in the table.

Breaker	Application Limit
(*A*)	Calculated short circuit duty placed on air circuit breaker nearest source must be within its published interrupting rating
(*B*)	Calculated short circuit duty placed on second air circuit breaker must be within 200% of its published interrupting rating
(*C*)	Calculated short circuit duty placed on third air circuit breaker must be within 300% of its published interrupting rating

The overcurrent tripping mechanism of breaker (*A*) must be adjusted to operate instantaneously when the total current through any (*B*) breaker reaches a value equal to or slightly less than the interrupting rating of (*B*). In this manner breaker (*B*) takes care of fault currents up to its interrupting rating, without assistance from breaker (*A*). The same consideration must be given to the combination of circuit breakers (*B*) and (*C*) in cascade.

Combinations of two and three air circuit breakers in cascade have been used, with successful operation. A maximum of three circuit breakers appears to meet present day requirements.

To assist in the selection of air circuit breakers in cascade, the following comments pertaining to specific types of low voltage installations are given:

1. Systems Supplied by Single Transformer Banks

For these frequently encountered, and relatively simple installations, a practical tabulation is given and its use fully described in appendix *B*, tables II and III.

2. Systems Supplied by Multiple Sources

The larger breakers in such systems must completely isolate the faulted circuit from *all* sources of short circuit current. It cannot be safely assumed that mere reduction of short circuit current (such as would result from opening only 1 or 2 of the transformer or bus tie breakers of figure 2) is sufficient.

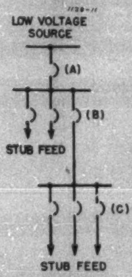

Figure 11. (above) Cascade connections

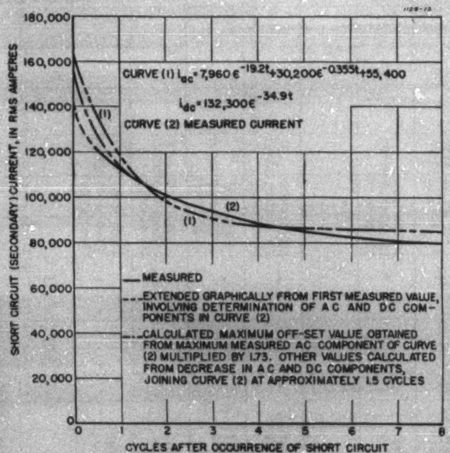

Figure 12. (right) Calculated and measured short-circuit currents obtained in a 440-volt circuit, producing maximum rms values in excess of 100,000 amperes

In applying the cascade principle to the installation illustrated in figure 2, where a calculated short circuit current of approximately 100,000 amperes was available, feeder breakers rated 50,000 amperes could be selected if properly "backed up." It is obvious that complete back-up protection cannot be obtained from the bus tie breakers alone, since these breakers cannot isolate the fault from all sources of current. Consequently the transformer breaker supplying the faulted bus section would have to trip instantaneously when the current through it exceeded $^1/_3$ of 50,000 or approximately 16,700 amperes. While each transformer breaker requires this automatic operation at 16,700 amperes, the bus tie breakers (normally closed) are not required to operate in cascade and may, therefore, have any desired setting.

The normal current requirements of the transformer circuits dictated the selection of air circuit breakers having interrupting ratings of 75,000 amperes (see table I appendix *B*). Since the maximum calculated short circuit current through any one of them did not exceed 70,000 amperes (two transformers feeding a short circuit at low-tension terminals of third transformer, assumed to be disconnected from high tension system) the breakers selected met the requirements for (*A*) breakers.

The application of the cascade principle to this installation, resulted in a decrease in cost of approximately 50% and a reduction in floor area to approximately 50% of that which would have been required if the cascade principle had not been used. Other factors include a substantial saving in weight and resulting building costs.

3. D-C Systems

Except that the calculated short circuit current is the maximum obtainable (see quoted standard following table I appendix *B*) the application of the cascade principle is the same as that discussed in connection with figure 11.

Servicing and Maintenance of Circuit Breakers in Cascade

While the cascade combination assures successful operation and adequate protection in the case of the heaviest short circuits, a majority of the faults occur some distance from the breakers, resulting in currents within the interrupting ratings of the smaller breakers. Thus the maintenance due to a large portion of the faults is not increased over that ordinarily expected.

The occurrence of a nearby short circuit may impose on breaker (*C*) in figure 11, interrupting duty considerably in excess of its rating. Consequently it is reasonable to require inspection and possible servicing on such occasions, before this circuit breaker can be reclosed with the expectation that it can successfully perform its usual duty.

When faults occur beyond the (*C*) breakers, the (*B*) breaker should preferably be inspected after each interruption, but little—if any—maintenance is expected and it should be capable of reclosing and carrying its rated current until inspection and minor maintenance can be provided. When subject to faults occurring on the source side of the (*C*) breakers, the (*B*) breaker then becomes the smallest breaker in the series and will require inspection and possible servicing as outlined in the preceding paragraph.

The main breakers (*A*) will probably operate only in event of very severe faults. Since these breakers are not applied beyond the limits of their interrupting ratings, their interrupting performance should be within the qualifications of the AIEE and NEMA Standards. Inspection and maintenance should be provided after completion of the standard interrupting duty-cycle, i.e., two operations at 100% of interrupting rating.

In the cascade connection, the greater the number of smaller circuit breakers protected by any "back-up" breaker, the greater will be the probability of severe faults requiring the "back-up" breaker to operate and the greater will be the maintenance it will require.

Conclusions

Cascading of suitably co-ordinated air circuit breakers is a practical and economical system of protection for extensive low voltage radial feeder systems. Proper performance of breakers in cascade has been verified by test, and several years' experience with the system has been satisfactory, both from the standpoint of operation and maintenance.

It is true that in the cascade arrangement severe faults will occasionally trip the "back-up" breakers and thus interrupt power supply to some circuits not in trouble. However, this might happen even though circuit breakers with interrupting ratings to take care of the full short circuit current were used in the same connection. But, such faults are not common and most of the troubles will be taken care of by the individual feeder breakers without tripping the "back-up" breakers and without the loss of service to the rest of the system.

Appendix A. Calculated Vs. Measured Short-Circuit Current in 100,000-Ampere Test Circuit

In the tests made to compare actual current obtainable with the calculated current available in the low tension circuit of figure 9, the reactors were set to limit the current to approximately 100,000 amperes, average of three phases, through about 10 ft. of bus between the transformer terminals and the point of connection to the short circuited air circuit breakers. All connections were securely made and the short circuit was applied and removed by closing and opening the station breakers.

Since the rating of the transformer was appreciable compared with that of the alternator, low tension short-circuits had a more pronounced effect on the alternator voltage, than would be found in the usual application, where the ratio of alternator to transformer rating is of the order of 10:1 or greater. Hence, it became necessary to convert the reactance and resistance of the low voltage circuit to equivalent primary circuit values and combine these with the remaining constants of the primary circuit, including those of the alternator. The method used in calculating the short circuit current, including both a-c and d-c components, was based on the per-unit system.[4] It was found that the resistance had an effect of less than 1% on the total impedance, but did reduce the d-c time-constant to approximately one-third that of the alternator.

The equations of a-c and d-c components, in terms of the secondary circuit, are shown in figure 12, and the total rms current, plotted as curve (1).

The actual measured value of the maximum current (of the three phases) is plotted as curve (2) in figure 12. This curve was extended graphically to 0 time, after determining the a-c and d-c components. By multiplying the a-c component by 1.73 and graphically determining the rate of decay of the a-c and d-c components, it was possible to obtain the extension located between curves (1) and (2). This extension indicates the current that might have been obtained if the fault had occurred so as to produce maximum off-set.

The close agreement between curves (1) and (2) of figure 12 is indicative of the soundness of the method. No attempt was made to obtain additional refinement since the purpose of the test was to check the results obtained from calculations based on a generally accepted method and confining the data to that which was readily available. Therefore, it can be said that for all practical purposes, the measured values agreed with those obtained from the calculations.

Appendix B. Air Circuit-Breakers —Ratings and Selection

Table I. Standard Ratings of Low-Voltage Air Circuit Breakers

Interrupting Rating*	Continuous Current Rating
15,000 amperes	(15–225 amps., incl.)
25,000 amperes	(15–600 amps., incl.)
50,000 amperes	(15–1,600 amps., incl.)
75,000 amperes	(2,000–3,000 amps., incl.)
100,000 amperes	(4,000 amps. and above)

* Air circuit breakers are rated in amperes interrupting capacity as follows, in accordance with NEMA Large Air Circuit Breaker Standards SG-7-25:

"A. *Interrupting Rating*

1. The published ampere interrupting rating shall be given in rms total amperes at the rated voltage of the breakers, and based upon the standard operating duty (duty cycle).

2. The rms total amperes shall be determined by measuring the current flow in the test circuit as follows:

(*a*). The circuit breaker shall be short circuited or omitted.

(*b*). In alternating-current circuits, the current measured shall be the total rms current including the d-c. component, if any; it shall be measured at an instant one-half cycle after the short circuit occurs and shall be calculated in accordance with Appendix to AIEE Oil Circuit Breaker Standard No. 19, dated April 19, 1938. (For three-phase test circuit, the rms total current shall be the average of all three phases. For a single-phase test circuit, three successive tests shall be made to determine the average current in that circuit.)

(*c*). In direct-current circuits the current measured shall be the maximum value."

Reference (*a*)—By instantaneous is meant that no delay is purposely introduced in the action of the device. In accordance with present standards, "all air circuit breakers shall be inherently instantaneous at current values in excess of the following:

(*a*) 2,000 amperes and below—15 times rated current of the breaker.

(*b*) Above 2,000 amperes—12 times rated current of the breaker, but not exceeding 75% of the interrupting rating."

Selection of Air Circuit Breakers for Low-Voltage Systems Supplied by Single Transformer Banks

When single transformer banks of various sizes are supplied from relatively complex high tension systems, selection of low-voltage air circuit breakers is based, in part, on the short circuit KVA available at the primary terminals of the transformer. When more definite information is lacking, this KVA value may be deduced from the KVA interrupting rating of the power circuit breaker, connected to the primary or high tension terminals of the transformer, on the assumption that the power circuit breaker has been economically and properly applied. Furthermore, it is assumed that the available primary KVA is a measure of the a-c component obtainable from the primary system, and hence is merely a means for determining the equivalent reactance of the primary circuit from the power transformer to the generated source of voltage.

Referring to the example given in figure 13, it will be seen that the equivalent reactance of the primary system can be combined readily with that of the power transformer, so that the three-phase symmetrical short circuit current can be quickly calculated. (In most cases only the transformer reactance is given, and the omission of the resistance has, as a rule, very little effect on the a-c component.) This method makes possible the plotting of a series of curves, from which the short circuit current, available from a given size of transformer, having a specified reactance, can be determined. Those plotted in figure 13 are on the basis of 5% reactance, although the example readily indicates the procedure to be followed if some other reactance value is used. In order to obtain the average rms values at 0.5 cycle, the calculated symmetrical values shown in figure 13 should be multiplied by 1.25.

The short circuit currents obtained from the transformers listed in tables II and III were determined in accordance with the method shown in figure 13. Thus for a given low tension voltage, and for the transformer

*All selections in tables II and III are based on:

(1) Multiplying factor, $D = 1.25$, giving average rms value of three phases, at 0.5 cycle.

(2) Negligible external resistance and reactance.

(3) Connected motor load as indicated, (†), not more than approximately 25 per cent of which is synchronous.

(4) Breaker selections are based on all breakers having modern arc quenchers, and properly co-ordinated in operation.

†For table II a total connected motor load of 50 per cent, and for table III, of 100 per cent, of the transformer rating is assumed.

‡Breaker (A') selections are in all cases governed by the necessary continuous current ratings of the transformer, and this accounts for the fact that in some cases the interrupting ratings are higher than the ratings given for the corresponding (A) breakers.

(ϕ) Requires special consideration.

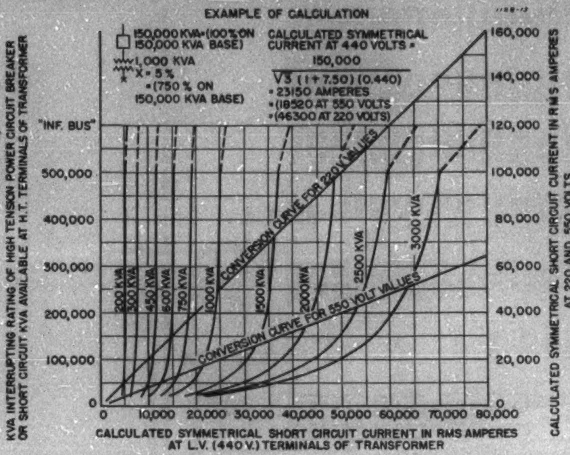

Figure 13. Calculated symmetrical three-phase short-circuit current obtained at low-voltage terminals of transformers (having assumed reactance of 5 per cent) in terms of kva-rating of high-voltage power circuit breaker or short-circuit kva available at high-voltage terminals of transformer

For average rms value, at 0.5 cycle, multiply calculated (symmetrical) value by 1.25

ratings listed in the first column, together with the primary system KVA listed in the second column, the short circuit currents obtainable from the transformer may be found in the fourth column. To these values are added the short circuit current contributed by connected motors as shown in column 5, giving the total short circuit current as shown in column 6.

The remaining four columns give the required interrupting ratings for the circuit breakers in cascade. The values listed are the standard steps of interrupting ratings of air circuit breakers (table I).

As an example of the use of these tables, assume an installation consisting of a single 1,500 KVA transformer supplying a 440 volt system, with a power circuit breaker on the high tension side, having an interrupting rating of 250,000 KVA, from which it may be deduced that the high tension system will deliver not more than 250,000 KVA in the case of a short circuit at the high tension terminals of the transformer. Data pertaining to this installation would be found under table III (440 volts). Since the power circuit breaker rating is 250,000 KVA, and this value does not appear in table III opposite the 1,500 KVA transformer rating, use the next higher value, namely, 500,000 KVA. Although the short circuit current values will increase as the primary system KVA increases between the limits of 100,000 and 500,000 KVA, the increase is not sufficient to affect the selection of low-voltage circuit breakers. Hence, the intermediate primary KVA values are not listed.

Reading across from the 500,000 KVA value in column 2, the transformer has a continuous rating of 1,970 amperes (column 3) and the required rating of a transformer breaker (A') would be 2,000 amperes (next standard size over 1,970 amperes). Such a breaker has an interrupting rating of 75,000 amperes (table I) which is adequate, since the transformer contributes only 46,500 amperes to the short circuit (column 4). The motor load contributes 9,600 amperes (column 5) giving a total of 56,100 amperes (column 6). If there is no transformer breaker (A') circuit breaker (A) would be required to have an interrupting rating of over 56,100 amperes, resulting in the choice of a 75,000 ampere circuit breaker (next higher standard rating). The requirement of breaker (B) is that its rating exceed 56,100/2 which results in a 50,000 ampere circuit breaker at this location, while that of (C) is 56,100/3, resulting in a 25,000 ampere circuit breaker. The continuous ampere ratings of (A), (B), or (C) depend on the rating of the feeder in which each is connected. The range in continuous current values for a given interrupting rating is indicated in table I.

Diode Rectifying Circuits With Capacitance Filters

D. L. WAIDELICH
ASSOCIATE AIEE

Synopsis: This paper presents the results of an investigation of the half wave and full wave rectifier circuits with a simple capacitance filter and using either high vacuum or mercury vapor tubes. In the fore part of the paper an equivalent circuit is set up such that when the tube is conducting, a mercury vapor tube is represented by a constant voltage drop or a high vacuum tube by a constant resistance. A detailed analysis of this circuit is carried through in the appendix, and it is found that the output characteristics depend upon three parameters.

The results of this analysis are presented in the form of curves giving the angles at which the tubes begin conducting and cease conducting and also the d-c output voltage. For the more special case of no tube drop, curves of ripple voltage, maximum tube current, and tube inverse peak voltage are presented. The comparisons made between the calculated results and test results show very satisfactory agreements. It is shown that the curves given in the paper may be used in the design of rectifier circuits with capacitance filters.

THE need for a high voltage, low current d-c power supply such as those used to supply the plate voltage requirements of the tubes in small radio receivers or of the cathode ray tubes in television receivers, is fulfilled by the half wave or full wave rectifier circuit with a single condenser as the smoothing filter and storage capacity. Up till now accurate knowledge as to the d-c voltage output and the ripple of the output voltage has been incomplete. Glaser and Müller-Lübeck[1] have solved the half wave case with no drop in the rectifier tube when conducting but gave no experimental results confirming their theoretical curves. Roberts[2] has discussed the half wave and full wave circuits using high vacuum rectifier tubes and also gives some excellent experimental curves of the d-c voltage output. Others[3-7] have also treated this subject at some length.

Equivalent Circuit and Wave Form

The half wave rectifier circuit shown in figure 1*a* has R_L as the load resistance and C as the smoothing capacitance. The corresponding full wave circuit is shown in figure 1*b*. While a mercury vapor rectifier tube is conducting, the voltage drop across the tube is almost constant and may be indicated in an equivalent circuit by a battery voltage V. Roberts[2] has shown that during the conduction period a thermionic vacuum tube rectifier may be considered as either a constant resistance R_R or a constant resistance R_R plus a constant voltage drop V. The resulting equivalent circuit is given in figure 1*c*, where $e = E_m \sin \theta$ is the alternating voltage applied. E_m is the maximum value of this voltage, and $\theta = \omega t$, where $\omega/2\pi$ is the frequency of the source and t is the time in seconds. Switch S is closed when the tube is conducting and is open when the tube is not conducting.

The waveform of the half wave circuit is given in figure 2 with 180 degrees of the impressed voltage wave also shown. The tube starts conducting at $\theta = \alpha$ because the potential of the anode becomes sufficiently positive with respect to the cathode. The tube current i_R shown in figure 2 flows until $\theta = \beta$, i.e., when the current becomes zero. It is zero thereafter until the tube begins to conduct again at $\theta = \alpha + 360°$. The condenser C is charged during part of the period that the tube is firing and is discharged during the rest of the cycle. The waveshape of the resulting load current i_L is shown in figure 2, and this is also the shape of the voltage across the load resistance. The waveform of the full wave circuit given in figure 3 is very similar to that of the half wave circuit except that the condenser C is charged twice every cycle instead of once. In the following n is taken as one for the half wave circuit and for the full wave circuit, $n = 2$.

Parameters of the Circuits

If the Fourier series coefficients of the load current i_L are determined, there will be a d-c component I and the a-c components, the most important of which are M_1 and N_1 with a frequency the same as the supply frequency in the half wave case or double the supply frequency in the full wave case.

$$i_L = I + M_1 \sin n\theta + N_1 \cos n\theta + M_2 \sin 2n\theta + N_2 \cos 2n\theta + \dots \quad (1)$$

where

$$I = \frac{n}{2\pi} \int_{\alpha}^{\alpha + \frac{2\pi}{n}} i_L \, d\theta \quad (2)$$

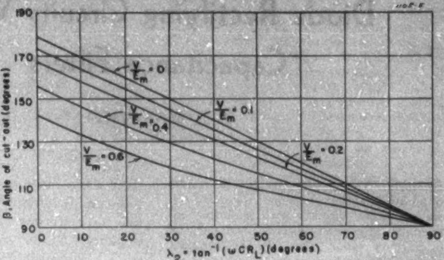
$$M_1=\frac{n}{\pi}\int_{\alpha}^{\alpha+\frac{2\pi}{n}} i_L \sin n\theta d\theta \tag{3}$$

$$N_1=\frac{n}{\pi}\int_{\alpha}^{\alpha+\frac{2\pi}{n}} i_L \cos n\theta d\theta \tag{4}$$

and with similar expressions for the rest of the *M*s and *N*s. In order to study the voltage output of these rectifier circuits it will be advantageous to define two ratios. The first is the ratio of the load d-c voltage IR_L to the maximum value of the a-c supply voltage E_m and will be denoted by IR_L/E_m. Since M_1 and N_1 will be large compared to the coefficients of the higher frequencies in the load ripple voltage, the ripple fraction r will be defined as the ratio of the effective value of the load ripple voltage involving M_1 and N_1 to the d-c voltage across the load.

Figure 5. Cut-out angle β for various values of V/E_m

Half-wave or full-wave circuit using mercury vapor tubes



$$r=\frac{\sqrt{\frac{M_1^2}{2}+\frac{N_1^2}{2}}R_L}{IR_L}=\frac{\sqrt{\left(\frac{M_1R_L}{E_m}\right)^2\left(+\frac{N_1R_L}{E_m}\right)^2}}{\sqrt{2}(IR_L/E_m)} \tag{5}$$

In appendix II it is shown that the quantities α, β, IR_L/E_m, and r depend on three parameters, and for a mercury vapor tube these parameters are (ωCR_L), V/E_m, and n. If the vacuum tube is considered as a resistance R_R alone, the parameters become (ωCR_L), R_L/R_R, and n. The purpose of this paper is to indicate how α, β, IR_L/E_m, and r vary with the above parameters, and to explain the use of the resulting curves in the design of the rectifier circuits. Several assumptions have been made to simplify the results derived in the appendix, and these assumptions are:

1. The secondary voltage of the transformer is sinusoidal;
2. The leakage reactance and resistance of the transformer is zero;
3. The tube resistance when non-conducting is infinite;
4. When conducting, the mercury vapor tube has a constant voltage drop V, while the vacuum tube has a constant resistance R_R; and
5. The filter capacitance C has zero power factor, and the load resistance has no inductance.

Angles of Cut-in and Cut-out

The angle of cut-in α at which the tube begins to conduct and the angle of cut-out β at which the tube ceases to conduct are shown in the first group of curves constructed from calculated results. All of the curves are plotted against the angle λ_2 where $\tan \lambda_2=(\omega CR_L)$. The angle α is always between zero degrees and 90 degrees, while angle β is between 90 and 180 degrees. For the half wave circuit using a mercury vapor tube, figures 4 and 5 show curves of angles α and β respectively for several values of V/E_m, the ratio of tube voltage drop to maximum value of a-c voltage. The corresponding curves for the full wave circuit are those of figures 6 and 5. In this particular case angle β is the same for both the half wave and full wave connections. When a high vacuum tube is used in the half wave circuit, figures 7 and 8 give curves of angles α and β respectively for various values of R_L/R_R which is the ratio of the load resistance to the tube resistance. In the same way figures 9 and 10 show the curves of α and β for the corresponding full wave circuit. With the same circuit parameters each tube conducts for a shorter period of

time in the full wave circuit than in the half wave circuit.

Output Voltage Characteristics

The ratio of the average d-c voltage across the load resistance to the maximum value of the a-c voltage impressed on the circuit, i.e., IR_L/E_m, is shown in the second group of curves which are also obtained from calculated results. The ratio IR_L/E_m varies between zero and one, but is never more than one since the maximum average output voltage cannot be more than the maximum value of the a-c voltage. Figures 11 and 12 show the curves of IR_L/E_m for the half wave and full wave circuits respectively using mercury vapor tubes. For the corresponding circuits using high vacuum tubes figures 13 and 14 give the curves of IR_L/E_m. The right side of each of these figures corresponds to light loads, while the heavier loads would be on the left side. In general, the output voltage is less for the half wave circuit than for the full wave circuit.

The ripple fraction r, which is the ratio of the rms value of the voltage of lowest frequency in the load to the load d-c voltage, is the third quantity shown in curve form. In most applications of these circuits using mercury vapor tubes V/E_m is very small and may be taken as zero with small loss in accuracy. Similarly for circuits with high vacuum tubes R_L/R_R is large and may be assumed infinite. Under these circumstances the ripple fraction curve for the half wave circuit is given in figure 15 as the solid line curve from calculated results. Figure 16 shows the corresponding curve for the full wave circuit. For the same parameters the full wave circuit will have a ripple fraction of approximately one half that for the half wave circuit. Also the frequency of the ripple voltage for the full wave circuit will be twice that of the half wave case.

Maximum Current and Inverse Peak Voltage of the Tube

When choosing the rectifier tube to be used in a given circuit, it is necessary to know the maximum current i_m that will flow when the tube is conducting and also the inverse peak voltage E_p that the tube must withstand when it is not conducting. Since I/n is the average tube current, the quantity ni_m/I will be the ratio of the maximum tube current to the average tube current. For the case when V/E_m is zero or R_L/R_R infinite, ni_m/I is given in figure 17. The half wave case is indicated by $n=1$ and the full wave by $n=2$. The ratio of the inverse peak voltage to the maximum value of the a-c voltage, i.e., E_p/E_m, is shown in figure 18. These two figures indicate that for the same circuit parameters, the tube in the half wave circuit has the lower maximum current to average current ratio and the lower inverse peak voltage than the tube in the full wave circuit.

Verification of Solution

The calculated results for the case where V/E_m is zero or R_L/R_R is infinite were checked experimentally by setting up the half wave and full wave circuits and measuring the d-c output voltage and current. The output ripple voltage was determined by means of a wave analyzer. To eliminate as many sources of error as possible the following precautions were observed:

1. The transformer used was much larger than necessary so that the leakage reactance and resistance would be small;
2. A mercury vapor tube with a small voltage drop while conducting was used, and also E_m was so large that V/E_m was practically zero; and
3. The condensers had a low power factor, and the voltmeter and wave analyzer a very high input resistance compared to the load resistance.

For the half wave circuit the circles in figure 19 show the experimentally ob-

tained values of IR_L/E_m as compared to the calculated curve which is the solid line curve. Figure 15 shows the results for the ripple fraction r. The same results for the full wave rectifier are shown in figures 19 and 16. The deviation of the observed values from the calculated ones may be explained in view of the sources of error mentioned above.

The calculated values of IR_L/E_m for the circuits using a high vacuum rectifier as given in figures 13 and 14 compare very well with the observed values as given by Roberts.[3] The values of the ripple fraction r as shown in figures 15 and 16 compare fairly well with the approximate expression derived by Reich[6] as long as r is less than one per cent. This approximate expression is

$$r=\frac{1}{n\omega R_L C} \qquad (6)$$

Method of Design

In many practical applications the ratio V/E_m is so small that it may safely be assumed zero. When this is true, figures 15, 16, 19 give the values of r and IR_L/E_m. Usually the d-c output voltage, output current, and maximum allowable output ripple voltage are known, and it is desired to obtain the circuit parameters. In the case of the half wave circuit ($n=1$), figure 15 will give the value of λ_2 corresponding to the maximum ripple voltage allowable. The d-c output voltage and current will give the load resistance R_L, and from the λ_2 obtained above the minimum value of C can be determined. Figure 19 will give the value of IR_L/E_m corresponding to the λ_2 obtained, and from this value of IR_L/E_m may be obtained the voltage that the secondary of the transformer must deliver to the circuit. Also for the above value of λ_2 and from figures 17 and 18, it is possible to predict the necessary maximum current and the required inverse peak voltage that the tubes must withstand. Thus from these data and the average current, a suitable rectifier tube may be selected. The procedure for the full wave case ($n=2$) is exactly similar except that figures 16 and 19 are used for r and IR_L/E_m.

If V/E_m is not small enough to be assumed zero, or R_L/R_R not large enough to be assumed infinite, a tentative value of λ_2 may be obtained as in the preceding paragraph, and this may be used with the value of V/E_m or R_L/R_R to determine α and β from figures 4 to 10. More exact values of r may then be obtained from the equations for r in the appendix and the value of IR_L/E_m from figures 11 to 14.

The choice between the full wave circuit and the half wave circuit depends upon a number of factors, among which are:

1. The half wave circuit needs only one tube and half the transformer secondary required by the full wave case; and
2. The d-c output voltage is higher and the ripple voltage lower for the full wave case. The ripple voltage is also of double frequency in the full wave connection.

Conclusion

The solution of the equivalent circuit equations gives results which agree well with the experimental results, and from these results it is possible to predict the average voltage output and the load ripple voltage for any values of the circuit parameters. In addition these circuits may be designed readily from the curves given in the paper, and both the proper circuit constants and the proper tubes may be chosen.

Appendix II—Calculation of Performance Characteristics From the Equivalent Circuit

(a) Cut-in and Cut-out Angles

Referring to the equivalent circuit of figure 1*c*, when i_R is flowing (S closed) the equations for the currents are:

$$i_R=i_L+i_C$$

$$E_m\sin\theta=V+R_Ri_R+R_Li_L$$

$$\frac{1}{\omega C}\int_\alpha^\theta i_c\,d\theta+\frac{q_\alpha}{C}=R_Li_L$$

These three equations are solved for the three currents i_R, i_C, and i_L, and then the condition, $i_L=i_\alpha$ at $\theta=\alpha$, is substituted to give the following results:

$$i_R=\frac{E_m}{Z_1}\frac{\sin(\theta-\lambda_1+\lambda_2)}{\cos\lambda_2}-\frac{V}{Z_1\cos\lambda_1}+\frac{\sin(\lambda_1-\lambda_2)}{\cos\lambda_2\sin\lambda_1}\left[i_\alpha-\frac{E_m}{Z_1}\sin(\alpha-\lambda_1)+\frac{V}{Z_1\cos\lambda_1}\right]\epsilon^{-(\theta-\alpha)\cot\lambda_1}\quad(7)$$

$$i_C=(\tan\lambda_2)\left\{\frac{E_m}{Z_1}\cos(\theta-\lambda_1)-(\cot\lambda_1)\left[i_\alpha-\frac{E_m}{Z_1}\sin(\alpha-\lambda_1)+\frac{V}{Z_1\cos\lambda_1}\right]\epsilon^{-(\theta-\alpha)\cot\lambda_1}\right\}\quad(8)$$

$$i_L=\frac{E_m}{Z_1}\sin(\theta-\lambda_1)-\frac{V}{Z_1\cos\lambda_1}+\left[i_\alpha-\frac{E_m}{Z_1}\sin(\alpha-\lambda_1)+\frac{V}{Z_1\cos\lambda_1}\right]\epsilon^{-(\theta-\alpha)\cot\lambda_1}\quad(9)$$

Again from figure 1*c* when i_R is not flowing (S open), the equations for the currents are:

$$i_L=-i_C$$

$$\frac{1}{\omega C}\int_\alpha^\theta i_C\,d\theta+\frac{q_\alpha}{C}=R_Li_L$$

These equations are solved for i_L and i_C, and then the condition, $i_L=i_\beta$ at $\theta=\beta$, is substituted to give

$$i_L=-i_C=i_\beta\epsilon^{-(\theta-\beta)\cot\lambda_2}\quad(10)$$

At $\theta=\beta$, (9) becomes:

$$i_\beta=\frac{E_m}{Z_1}\sin(\beta-\lambda_1)-\frac{V}{Z_1\cos\lambda_1}+\left[i_\alpha-\frac{E_m}{Z_1}\sin(\alpha-\lambda_1)+\frac{V}{Z_1\cos\lambda_1}\right]\epsilon^{-(\beta-\alpha)\cot\lambda_1}\quad(11)$$

At $\theta=\alpha+\frac{2\pi}{n}$, (10) becomes:

$$i_\alpha=i_\beta\epsilon^{-\left(\alpha-\beta+\frac{2\pi}{n}\right)\cot\lambda_2}\quad(12)$$

At $\theta=\alpha$:

$$i_\alpha=\frac{E_m\sin\alpha-V}{R_L}\quad(13)$$

At $\theta=\beta$:

$$i_\beta=\frac{E_m\sin\beta-V}{R_L}\quad(14)$$

Substitution of equations 13 and 14 into 11 and 12 gives:

$$\left(\sin\alpha-\frac{V}{E_m}\right)\epsilon^{\left(\alpha+\frac{2\pi}{n}\right)\cot\lambda_2}=\left(\sin\beta-\frac{V}{E_m}\right)\epsilon^{\beta\cot\lambda_2}\quad(15)$$

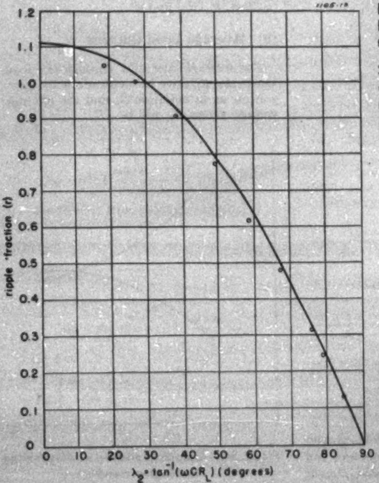

Figure 15 (left). Ripple fraction r for the half-wave circuit

Solid curve is calculated while the measured points are indicated by circles

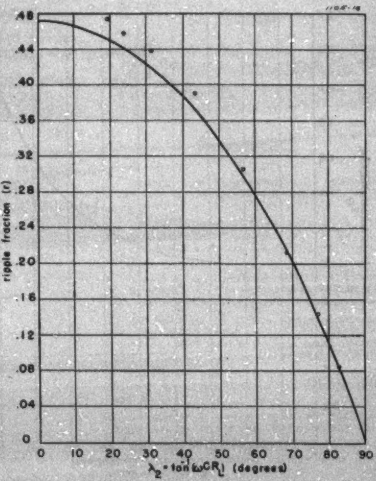

Figure 16 (right). Ripple fraction r for the full-wave circuit

Solid curve is calculated while the measured points are indicated by circles

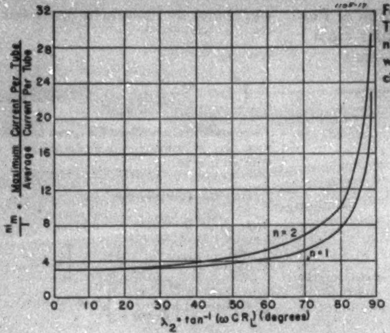

Figure 17 (left). Tube-current ratio ni_m/I for both full-wave and half-wave circuits

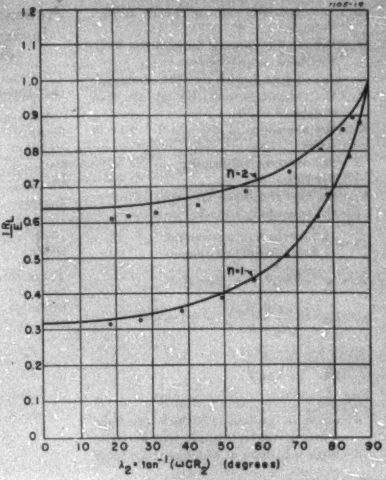

$$\left[\sin(\alpha-\lambda_1+\lambda_2)-\frac{V}{E_m}\frac{\cos\lambda_2}{\cos\lambda_1}\right]\epsilon^{\alpha\cot\lambda_1}=$$

$$\left[\sin(\beta-\lambda_1+\lambda_2)-\frac{V}{E_m}\frac{\cos\lambda_2}{\cos\lambda_1}\right]\epsilon^{\beta\cot\lambda_1} \quad (16)$$

These two equations 15 and 16, must be solved simultaneously to determine the angles α and β. To facilitate this let $\gamma=(\beta-\alpha)$. Equations 15 and 16 then become:

$$A_1\sin\alpha+B_1\cos\alpha=C_1 \quad (17)$$

$$A_2\sin\alpha+B_2\cos\alpha=C_2 \quad (18)$$

where:

$$A_1=1-(\cos\gamma)\epsilon^{\left(\gamma-\frac{2\pi}{n}\right)\cot\lambda_2}$$

$$B_1=-(\sin\gamma)\epsilon^{\left(\gamma-\frac{2\pi}{n}\right)\cot\lambda_2}$$

$$C_1=\frac{V}{E_m}\left[1-\epsilon^{\left(\gamma-\frac{2\pi}{n}\right)\cot\lambda_2}\right]$$

$$A_2=\cos(\lambda_1-\lambda_2)-[\cos(\gamma-\lambda_1+\lambda_2)]\epsilon^{\gamma\cot\lambda_1}$$

Figure 19 (right). Voltage ratio IR_L/E_m for both the half-wave and the full-wave circuits

Solid curve is calculated while the measured points are indicated by circles

$$B_2=-\sin(\lambda_1-\lambda_2)-[\sin(\gamma-\lambda_1+\lambda_2)]\epsilon^{\gamma\cot\lambda_1}$$

$$C_2=\frac{V}{E_m}\frac{\cos\lambda_2}{\cos\lambda_1}(1-\epsilon^{\gamma\cot\lambda_1})$$

If (17) and (18) are solved for α:

$$\alpha_1=\sin^{-1}\left(\frac{B_2C_1-B_1C_2}{A_1B_2-A_2B_1}\right) \quad (19)$$

$$\alpha_2=\cos^{-1}\left(\frac{A_1C_2-A_2C_1}{A_1B_2-A_2B_1}\right) \quad (20)$$

A value of γ must be found such that when substituted in equations 19 and 20, α_1 will equal α_2. This may be done graphically as in figure 20 by plotting α_1 and α_2 against γ. The point of intersection of the two curves has the required γ as its abscissa and α as its ordinate. The angle β may be found by adding α and γ. The angle α lies between 0° and 90°, while β lies between 90° and 180°. Angle γ ranges between 0° and 180°.

From equations 15 and 16 it is seen that α and β depend only on the four parameters, λ_1, λ_2, V/E_m, and n. Since λ_1 depends on (ωCR_L) and R_L/R_B, and λ_2 depends on (ωCR_L), the angles α and β depend on the four parameters (ωCR_L), R_L/R_B, V/E_m, and n. For mercury vapor tubes the parameters are (ωCR_L), V/E_m, and n, while for vacuum tubes the parameters are (ωCR_L), R_L/R_B, and n.

(b) Average Load Current

The average current I through the load resistance R_L may be determined by integration as in equation 2, and the average voltage across R_L will be IR_L.

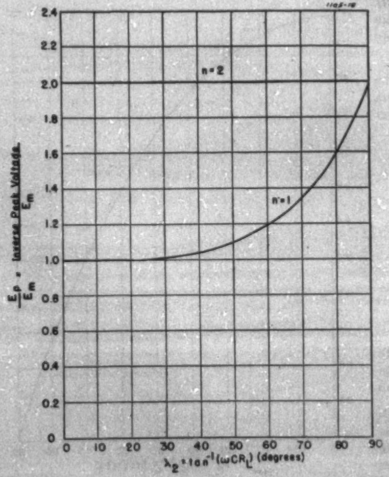

Figure 18. Tube-voltage ratio E_p/E_m for both full-wave and half-wave circuits

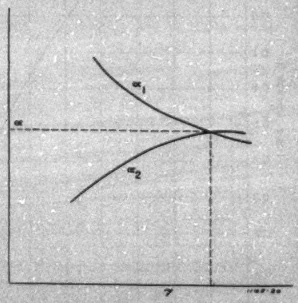

Figure 20. Graphical method of determining the angles α and γ

$$I=\frac{n}{2\pi}\int_{\alpha}^{\alpha+\frac{2\pi}{n}} i_L d\theta=\frac{n}{2\pi}\frac{E_m}{R_L}\left(1-\frac{\tan\lambda_1}{\tan\lambda_2}\right)\times$$
$$\left[\frac{\cos(\alpha+\lambda_2)-\cos(\beta+\lambda_2)}{\cos\lambda_2}-\frac{V}{E_m}(\beta-\alpha)\right]\quad(21)$$

The two expressions for i_L are given in equations 9 and 10, and after the integration is performed, the expression for I may be simplified by the use of equations 11, 12, 13, and 14. IR_L/E_m is found to depend only on (ωCR_L), R_L/R_R, V/E_m, and n.

(c) Ripple Fraction

The ripple fraction r is defined by equation 5 in which M_1 and N_1 are obtained from equations 3 and 4. By the use of equations 9 to 14 inclusive, M_1R_L/E_m and N_1R_L/E_m may be expressed as follows:

For $n=1$:

$$\frac{M_1R_L}{E_m}=\frac{\sin(\lambda_2-\lambda_1)}{2\pi\sin\lambda_2}\left\{(\beta-\alpha)\cos\lambda_1-\right.$$
$$\left.\frac{1}{2}\left[\sin(2\beta+\lambda_1)-\sin(2\alpha+\lambda_1)\right]\right\}+$$
$$\frac{\sin\lambda_2}{\pi}[\sin\beta\sin(\beta+\lambda_2)-\sin\alpha\sin(\alpha+\lambda_2)]-$$
$$\frac{\sin\lambda_1}{\pi}[\sin\beta\sin(\beta+\lambda_1)-\sin\alpha\sin(\alpha+\lambda_1)]+$$
$$\frac{V}{E_m}\frac{\cot\lambda_2}{\pi}\{(\sin\lambda_2)[\cos(\beta+\lambda_2)-$$
$$\cos(\alpha+\lambda_2)]-(\sin\lambda_1)[\cos(\beta+\lambda_1)-$$
$$\cos(\alpha+\lambda_1)]\}\quad(22)$$

$$\frac{N_1R_L}{E_m}=-\frac{\sin(\lambda_2-\lambda_1)}{2\pi\sin\lambda_2}\left\{(\beta-\alpha)\sin\lambda_1+\right.$$
$$\left.\frac{1}{2}[\cos(2\beta+\lambda_1)-\cos(2\alpha+\lambda_1)]\right\}+\frac{\sin\lambda_2}{\pi}$$
$$[\sin\beta\cos(\beta+\lambda_2)-\sin\alpha\cos(\alpha+\lambda_2)]-$$
$$\frac{\sin\lambda_1}{\pi}[\sin\beta\cos(\beta+\lambda_1)-\sin\alpha\cos(\alpha+\lambda_2)]-$$
$$\frac{V}{E_m}\frac{\cot\lambda_2}{\pi}\{(\sin\lambda_2)[\sin(\beta+\lambda_2)-$$
$$\sin(\alpha+\lambda_2)]-(\sin\lambda_1)[\sin(\beta+\lambda_1)-$$
$$\sin(\alpha+\lambda_1)]\}\quad(23)$$

For $n=2$:

$$\frac{M_1R_L}{E_m}=-\frac{\sin(\lambda_2-\lambda_1)}{3\pi\sin\lambda_2}[\sin(3\beta-\lambda_1)-$$
$$\sin(3\alpha-\lambda_1)]+\frac{\sin(\lambda_2-\lambda_1)}{\pi\sin\lambda_2}\left\{\sin(\beta+\lambda_1)-\right.$$
$$\sin(\alpha+\lambda_1)+(\sin\lambda_3)[\sin(2\beta+\lambda_3)\times$$
$$\left.\sin(\beta-\lambda_1)-\sin(2\alpha+\lambda_3)\sin(\alpha-\lambda_1)]\right\}-$$
$$\frac{\sin\lambda_3}{\pi}[\sin\beta\sin(2\beta+\lambda_3)-$$
$$\sin\alpha\sin(2\alpha+\lambda_3)]+\frac{\sin\lambda_4}{\pi}\times$$
$$[\sin\beta\sin(2\beta+\lambda_4)-\sin\alpha\sin(2\alpha+\lambda_4)]+$$
$$\frac{1}{\pi}\frac{V}{E_m}\left\{\frac{\sin(\lambda_2-\lambda_1)\cos\lambda_3}{\cos\lambda_1\sin\lambda_2}[\cos(2\beta+\lambda_3)-\right.$$
$$\left.\cos(2\alpha+\lambda_3)]\right\}+\frac{1}{\pi}\frac{V}{E_m}\{(\sin\lambda_3)\times$$
$$[\sin(2\beta+\lambda_3)-\sin(2\alpha+\lambda_3)]-(\sin\lambda_4)\times$$
$$[\sin(2\beta+\lambda_4)-\sin(2\alpha+\lambda_4)]\}\quad(24)$$

$$\frac{N_1R_L}{E_m}=-\frac{\sin(\lambda_2-\lambda_1)}{3\pi\sin\lambda_2}[\cos(3\beta-\lambda_1)-$$
$$\cos(3\alpha-\lambda_1)]+\frac{\sin(\lambda_2-\lambda_1)}{\pi\sin\lambda_2}\{-\cos(\beta+\lambda_1)+$$
$$\cos(\alpha+\lambda_1)+(\sin\lambda_3)[\cos(2\beta+\lambda_3)\times$$
$$\sin(\beta-\lambda_1)-\cos(2\alpha+\lambda_3)\sin(\alpha-\lambda_1)]\}-$$
$$\frac{\sin\lambda_3}{\pi}[\sin\beta\cos(2\beta+\lambda_3)-$$
$$\sin\alpha\cos(2\alpha+\lambda_3)]+\frac{\sin\lambda_4}{\pi}\times$$
$$[\sin\beta\cos(2\beta+\lambda_4)-\sin\alpha\cos(2\alpha+\lambda_4)]+$$
$$\frac{1}{\pi}\frac{V}{E_m}\left\{-\frac{\sin(\lambda_2-\lambda_1)\cos\lambda_3}{\cos\lambda_1\sin\lambda_2}[\sin(2\beta+\lambda_3)-\right.$$
$$\left.\sin(2\alpha+\lambda_3)]\right\}+\frac{1}{\pi}\frac{V}{E_m}\{(\sin\lambda_3)[\cos(2\beta+\lambda_3)-$$
$$\cos(2\alpha+\lambda_3)]-(\sin\lambda_4)[\cos(2\beta+\lambda_4)-$$
$$\cos(2\alpha+\lambda_4)]\}\quad(25)$$

For the case of no tube drop or tube resistance, equations 22 to 25 inclusive, become:

For $n=1$:

$$\frac{M_1R_L}{E_m}=\frac{1}{2\pi}\{\gamma-\sin\gamma\cos[\gamma+2(\alpha+\lambda_2)]\}\quad(26)$$

$$\frac{N_1R_L}{E_m}=\frac{1}{2\pi}\{\sin\gamma\sin[\gamma+2(\alpha+\lambda_2)]\}\quad(27)$$

For $n=2$:

$$\frac{M_1R_L}{E_m}=\frac{1}{\pi}\left\{\sin\beta-\sin\alpha-\frac{\sin3\beta-\sin3\alpha}{3}+\right.$$
$$(\sin\lambda_4)[\sin\beta\sin(2\beta+\lambda_4)-$$
$$\left.\sin\alpha\sin(2\alpha+\lambda_4)]\right\}\quad(28)$$

$$\frac{N_1R_L}{E_m}=\frac{1}{\pi}\left\{\cos\beta-\cos\alpha-\frac{\cos3\beta-\cos3\alpha}{3}+\right.$$
$$(\sin\lambda_4)[\sin\beta\cos(2\beta+\lambda_4)-$$
$$\left.\sin\alpha\cos(2\alpha+\lambda_4)]\right\}\quad(29)$$

The ripple fraction depends only on (ωCR_L), R_L/R_R, V/E_m, and n.

(d) Maximum Tube Current

To determine the maximum tube current i_m for the case of no tube drop:

From equation 7:

$$i_R=\frac{E_m}{R_L}\frac{\sin(\theta+\lambda_2)}{\cos\lambda_2}$$

Since maximum i_R is i_m:

$$\frac{di_r}{d\theta}=\frac{E_m}{R_L}\frac{\cos(\theta+\lambda_2)}{\cos\lambda_2}=0$$

or $\theta=90°-\lambda_2$

First case when

$90°-\lambda_2\geq\alpha$

or for

$n=1,\quad 0\leq\lambda_2\leq74.3°$

for

$n=2,\quad 0\leq\lambda_2\leq64.65°$

$$i_m=(E_m/R_L)\frac{1}{\cos\lambda_2}$$

$$\frac{i_m}{I/n}=\frac{\text{maximum current per tube}}{\text{average current per tube}}$$
$$=\frac{n}{(IR_L/E_m)\cos\lambda_2}$$

Second case when

$90°-\lambda_2<\alpha$

or for

$n=1,\quad 74.3°\leq\lambda_2\leq90°$

for

$n=2,\quad 64.65\leq\lambda_2\leq90°$

$$i_m=(E_m/R_L)\frac{\sin(\alpha+\lambda_2)}{\cos\lambda_2}$$

$$\frac{i_m}{I/n}=\frac{\text{maximum current per tube}}{\text{average current per tube}}$$
$$=\frac{n\sin(\alpha+\lambda_2)}{(IR_L/E_m)\cos\lambda_2}$$

(e) Inverse Peak Voltage

To determine E_p for the case of no tube drop:

For $n=1$, the inverse voltage on the rectifier tube between $\theta=\beta$ and $\theta=(\alpha+2\pi)$ is

$$-E_m\sin\theta+R_Li_L=-E_m\sin\theta-$$
$$E_m(\sin\beta)\epsilon^{-(\theta-\beta)\cot\lambda_2}\quad(30)$$

The angle at which the maximum inverse voltage occurs is found by putting the derivative of (30) with respect to θ equal to zero and solving the resulting equation for θ.

This is

$$-E_m\cos\theta+E_m\times$$
$$(\sin\beta\cot\lambda_2)\epsilon^{-(\theta-\beta)\cot\lambda_2}=0$$

and if the angle θ thus found, is substituted in (30), the inverse peak voltage E_p will result.

For $n=2$, $E_p=2E_m$.

D-C Machine Flashover and Bus Short-Circuit Protection

ASSOCIATE AIEE

Synopsis: The transient induced voltage across the interpole and compensating windings of d-c motors or generators on short circuit or flashover provide a quick and convenient means of actuating circuit breaker or other protective devices. Such means have made possible quicker tripping times than are obtained with the conventional series overload or reverse current protection.

LIKE an Indian Scout with his ear to the ground—quick to forewarn of approaching danger—the interpole transient may be used to instantly and infallibly guard the dynamo against costly outage.

It is generally appreciated that the concentration of power on a-c systems in the last twenty years resulting from growth of generating capacity and inter-connection of systems has been accompanied by a proportionate improvement and development in protective relay systems so that the large investment in apparatus could be protected from damage resulting from short circuit or ground faults. This protection is achieved by relays such as differential, impedance, carrier current, ground relays, and the like, as well as by better insulation, adequate bracing of windings, etc., in the machines themselves.

Such latter means prevent damage to a machine until the relaying equipment can act upon occurrence of a fault. The relaying means themselves are operated by characteristics of the system which become active only under the particular condition to be protected against.

In d-c systems it is generally recognized that the machine commutators are the weakest link in the system under short-circuit conditions. This is so because arc-over occurs above a limiting value of current due to the limiting value of volts per commutator bar and commutating ability consistent with economical design. The machine windings and pole pieces are not subject to like limitations as they may be adequately supported for the maximum stresses, as is also the case with bus bars.

In d-c systems in which individual generating units are relatively separated, such as traction systems, short circuit currents are not usually of such magnitude as to present a serious problem, due to the relatively large feeder resistance between stations. It is unusual for a large amount of power to be concentrated on one bus in a single station.

The application of large blocks of d-c power in the steel industry, however, presents a different condition; particularly illustrative is the continuous hot strip mill, and the recent cold reducing mills, which, with modern demands for high speeds and high tonnage, require large amounts of d-c power. Furthermore, accurate speed control and ease in mill manipulation require that the motors and generators be on a single bus of as low resistance as possible to give good speed regulation. The apparatus connected to a continuous hot mill bus may have as high as 500,000 amperes short circuit capacity.

Until recently, short circuit protection for d-c machines consisted simply of an overload trip coil on the air circuit breaker of either time delay or instantaneous type, and where required, reverse current trip coils. Such devices must be set high enough to prevent tripping on maximum load. In addition, even the instantaneous trip type has an inherent delay, which, on short circuit, necessarily allows the current to rise to a higher value than its setting before the circuit can be interrupted and stresses set up are proportionately high.

Attempts have been made, with partial success, on constant or relatively constant loads, to provide inductively actuated trip coils so that tripping would be accomplished by the rate of increase in current, thus distinguishing between load currents and short circuits.

On a hot strip mill particularly, load is applied suddenly to each motor as a strip enters the mill. Though current may and does increase at different rates on load application as compared to short circuits, yet, due to difficulty in predicting such factors as momentary load fluctuations and total inductance of the system, and due to the existence of system disturbances, the protective device has to be set with a wide margin, so that a large proportion of the quickness of response on short circuit is lost.

A great deal of study has been given to d-c breaker design in an effort to secure interruption in the shortest possible time both by quick breaker opening time and improved means of extinguishing the arc. Very commendable results have been accomplished and proved by thorough tests. The object sought is, of course, to stop and arc before the current has risen to a destructive value, or in as short a time as possible after current has risen above the maximum safe overload value.

To protect the machine commutator, however, it is desirable to *prevent*, if possible, any excessive current. Protection on a large steel mill system is more vital than on other d-c systems, since the loss of a single commutator will result in a costly shutdown, for each machine forms a link in the production process. Unlike a utility, the load cannot be shifted to other units on the system. The loss of a machine means loss of production until repairs can be made or a spare machine set in place. The total apparatus protected may cost from 500,000 dollars to a million dollars, and considering overhead, the outage cost may run 200 dollars per hour and more.

The system to be described has been in use for some time on busses up to 40,000 kw capacity. While no bus to bus short circuits have occurred since its installation, there have been some few commutator flashovers. These resulted in the clearing of the circuits by breaker opening with decidedly less current flow in the cases observed, as judged from arcing at the breaker contacts, under flashover condition than under openings due to motor overload. Effects on the commutator were negligible.

There have been two schools of thought on d-c bus layout and protection:

> Separate positive and negative busses sufficiently spaced so that forces between them can be neglected under any possible condition of current. Busses with extra heavy cross section to give best motor speed regulation, supported with heavy insulators. Breakers of sufficient capacity to open maximum short circuit current, with a breaker in each of the positive and negative leads of each machine giving double break. This construction entails heavy expense.

Or

> Only heavy enough bus to be consistent with good motor speed regulation with nominal bracing. Dependence on a protective scheme to prevent excessive current on commutator flashover and short circuit.

The second scheme is based on the experience that bus to bus short circuits

seldom ever occur. If one should occur and damage result, the outage would result in less cost than the fixed investment under the first scheme. Both arrangements demand that the machine windings and pole pieces be adequately secured against worst conditions.

The bus shown in figure 1 has the construction of the first scheme and, in addition, the protective relay scheme.

As shown, there is connected to the bus 26,750 horsepower in motors and 18,000 kw in generators, or a total of 38,000 kw connected short circuit capacity, within a space less than 200 feet in length.

Each main bus consists of nine $^1/_4 \times 8$ inch copper bars. Figure 2 shows main positive bus and motor bus for stand number 7 motor. Figure 3 shows an installation with each positive and negative main bus of 2–10 inch aluminum channels and 2–10 inch aluminum channel cross over busses. This view indicates the simpler system of bus supports due to the rigidity of the aluminum channels. With the latter system the bus has a somewhat lower inductance, which has a direct bearing on service requirements of the breakers. (See figure 6.)

Figure 2 (left). Main positive bus and cross-over bus for 4,500 - horsepower mill motor

Figure 3 (below). Main positive bus and crossover bus, channel aluminum construction

To determine how effectively such systems are protected by standard breakers, it is well to examine some standard breaker characteristics.

Figure 4 shows an oscillogram of the interrupting of 41,200 peak amperes d-c overload current in a total time of 0.082 second or 4.92 cycles. Under this test there was no inductance except that inherent in the test generator and connections. Tripping was done by an instantaneous series overload trip coil.

Figure 5 shows test interrupting times of a similar air circuit breaker under both a-c and d-c heavy short circuits. Figure 6 shows variation of system back voltage and arcing time with circuit inductance.

It is to be particularly noted that in each test, although current interruption is relatively fast, the arc energy expended is large. This gives rise to contact deterioration, and the currents involved produce heavy stresses in the connected apparatus.

The effect of these momentary overloads can best be determined by examin-

ing some characteristics of the d-c machines under such conditions.

Most of such large concentrations of d-c power are of 600 or 700 volts, have low bus resistance, and are composed of high capacity machines each with a full load *IR* drop in armature and interpole winding of 2 to 4 percent of rated voltage. Thus the short circuit current of a machine may be as high as 25 to 50 times the full load current, which would produce very severe mechanical stresses in the windings and mechanical parts.

If a short circuit occurs on the bus outside the machine, the time for the current to build up to maximum will depend on the resistance and inductance of the complete circuit. Since the bus run must necessarily be short in most large d-c power installations (see figure 1), the resistance and inductance of the lines is a comparatively small part of the whole and will be neglected in the following calculations. The factor of inductance is the only delaying force in the build up of current from the machine, and this has been reduced quite low in modern high capacity machines by the pole face or compensating windings. The compensating winding is spaced, and is of such strength in the face of the main poles as to completely neutralize the cross-magnetizing field of the armature. The purpose of the compensating winding is primarily to limit the maximum voltage between commutator bars to a safe value, and to reduce leakage from the interpoles in order to give high overload capacity to the machine. An incidental result is to reduce the inductance of the machine because much of the armature leakage and about $^1/_3$ of the interpole leakage flux is eliminated.

Figure 5. Air circuit-breaker interrupting time for heavy a-c and d-c short circuits

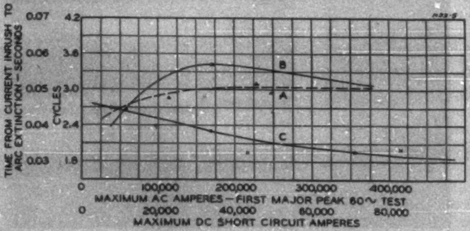

Figure 7 shows the relation of the armature, interpole, and compensating fields, in which *a* indicates a typical leakage flux path around a compensating bar; *b* is the leakage path of the interpole coil; *c* is a typical leakage path of an armature slot; and *d* is the useful, or mutual, commutating flux passing from the interpole into the armature. This flux is the resultant of the interpole plus compensating ampere turns minus the armature ampere turns. The compensating winding consists of turns taken off the interpole coil and disposed in the face of the main pole, resulting usually in the same number of turns in the pole face winding as there are on the interpole.

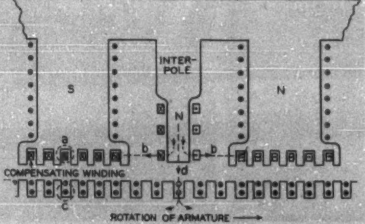
Figure 8 is a diagram showing the relation between the various magnetomotive forces, and the net resultant magnetomotive forces producing the mutual flux between the armatures and interpoles.

a is the shunt coil magnetomotive force
b is the armature magnetomotive force
c is the interpole and compensating magnetomotive force
d is the net resultant magnetomotive force which is usually from 20 to 40 per cent of the armature magnetomotive force at the center of the interpole

Figures 7 and 8 illustrate the fact that the interpole and armature fields are normally in opposition to each other on the same magnetic circuit, with each field having its own leakage flux. Using this as a basis for determining the action of a d-c machine under transient current loads, we find that the effective inductance is the standard equation of two coils with differential coupling, or $L = L_I + L_A - 2M_{IA}$.

Figure 7. Relationship between armature, interpole, and compensating fields in a d-c machine



L = effective inductance (1)

L_I = self inductance of interpole and compensating fields

L_A = self inductance of armature

M_{IA} = mutual inductance factor, where

$M < \sqrt{L_I L_A}$

The current change after a short circuit, as in figure 9*a*, is:

$$i = \frac{E}{r_1 + r_2}\left[1 - \epsilon^{-\frac{(r_1+r_2)t}{L_1 + L_A - 2M_{1,A}}}\right]. \tag{2}$$

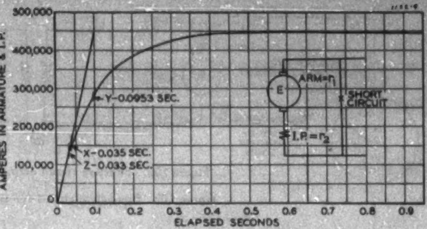


Figure 9a. Effective circuit during bus short circuit

Figure 9b. Current build-up at bus short circuit

Figure 9*b* shows the current build up on external short circuit in a 300 volt, 12,000 ampere generator. Calculations indicate that the effective inductance of a compensated machine is approximately 25 per cent of the unit resistance of the machine (rated volts divided by rated amperes) divided by the rated angular velocity, $\pi Pn/60$ (where P is the number of poles and n is the speed in revolutions per minute). For a non-compensated machine the inductance is about twice this amount. In equation 1 the value of M_{IA} is 60 to 70 per cent of $L_I L_A$ for a compensated machine, and the ratio of L_I to L_A is about 2 to 1.

The initial rate of current build up in figure 9*b* is about 4,500,000 amperes per second, which produces a transient voltage across the interpole and compensating fields of 200 volts, compared to a steady full load voltage across this winding of 3 volts. During normal operation the load builds up on this generator at a maximum rate of about 60,000 amperes per second, giving a normal transient voltage of about 4.8 volts plus *IR* drop. This shows that on external short circuit an interpole voltage of approximately 40 times the magnitude of normal load transient voltage is induced.

It is not uncommon to get a flashover on the commutator of a 600 volt machine because of some transient disturbance. It is worth investigating the difference between transient induced flashovers and short circuits external to the machine. Referring to figure 10*a*, suppose we have a motor with current flowing in at the positive line, through the armature, out the interpole to the negative line. When a flashover occurs, the current will flow in the armature in the direction of the counter electromotive force, while the line will feed in parallel through the arc and into the interpole winding in the normal direction of current. This produces the effect of the armature field and the interpole and compensating fields being additive instead of the normal subtractive condition, and the equivalent circuit is that for two coils in additive coupling connected simultaneously to two separate voltage sources, figure 10*b*. The solution for this case is:

$$i = A\epsilon^{-M_1 t} + B\epsilon^{-M_2 t} + C \tag{3}$$

derived from the fundamental expression,

$$E_1 = i_1 r_1 + L_1\frac{di_1}{dt} + M\frac{di_2}{dt}$$

which is equation 4 in the appendix.

Figure 11 shows the current flowing into the interpole winding from the line after a flashover on the commutator of a large motor. The maximum rate of current rise is 460,000 amperes per second, and the voltage drop across the interpoles is close to 600 volts as long as the voltage of the line is sustained, since the voltage drop in the arc across the commutator is small. The initial lag in current build up is caused by the mutual induction effect with the armature field, the induced voltage in the interpoles being nearly as high as the line voltage because the turns on the interpole and compensating field are about 30 per cent more than on the armature. This conclusively demonstrates that normal overload protection is subject not only to the handicap of delay due to inaction until the current from the line builds up to an excessive value, but also remains inoperative during the initial lag in line current build up, while the commutator is being subjected to excessive circulative currents.*

Flashover protection should also take care of the third possibility of machine operation—a commutator flashover when the machine is not connected to the line, such as a generator at full voltage on open circuit. The solution remains the same as equation 6 (derived in the appendix), but the result can be simplified because of the open circuit secondary which is the interpole circuit. In this case, $E_1 = L_1\frac{di_1}{dt}$ when $t=0$, which is the time of most rapid current build up in the armature caused by the flashover. Then the interpole voltage will be $E_2 = M\frac{di_1}{dt}$, so that normally the maximum voltage that appears across the interpoles $= E_1 \times \frac{M}{L_1}$. The factor $\frac{M}{L_1}$ is usually above $^3/_4$, so that the initial voltage appearing across the interpoles at the very start of the flashover is far above any normal operating voltage.

Referring to figure 9*b*, in case of a bus short circuit, assuming values of tripping time from figure 5, tripping will occur at point *x*, corresponding to 145,000 amperes, in 0.035 second, when using a standard overload trip coil (neglecting the effect of any external inductance).

If the average tripping time obtained from figures 4 and similar tests, is used, tripping will occur as indicated at point *y* at 275,000 amperes in 0.0953 second. Serious deterioration of the breakers will result and stresses will be very high. These values are conservative, because time constants under test are less than

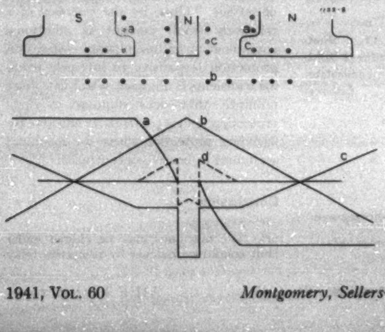

Figure 8. Magnetomotive forces in a d-c machine

---

* The circulative current referred to is a current flowing through the arc from brush to brush, while the current actuating the series overload trip must flow from the bus.

Figure 10b. Equivalent circuit during commutator flashover

those found under actual conditions of installation. Consequently, the tripping time would be more nearly that corresponding to figure 4. However, since latest design of breakers give a shorter tripping time, the average obtained as above is used.

Referring now to a case of commutator flashover, as illustrated in figure 11, and assuming the same values of tripping time, tripping occurs in 0.075 second at 25,000 amperes, as indicated at point *x*, or in 0.135 second at 52,000 amperes, as indicated at *y*. It is highly desirable that circuit interruption be effected before these high values of current are reached.

To accomplish this, advantage may be taken of the machine transient conditions described above, in order to obtain improved protection. Figure 12 shows an effective transient protective scheme when used for two mill motors supplied by two generators in parallel on one bus.

Consider motor number 2. This machine is protected by a circuit breaker *GM*2 in its positive lead. This breaker has two shunt trip coils. One is a standard trip coil (*GM*2—#2 trip) shown in the lower left hand corner of the diagram as operated by a control switch in conventional manner. A special low resistance shunt trip coil (*GM*2—#1 trip) is connected across the motor interpole winding. As previously explained, during normal operations transient voltages of not more than 4.8 volts occur across the interpole, whereas on a bus to bus short circuit the transient voltage produced is 200 volts. By means of resistance R_1 the value of voltage at which this trip coil will operate is set to a safe value above 4.8 volts. Thus it has a small current flowing through it normally. Upon a bus to bus short circuit, however, the induced voltage across the interpole and compensating winding rises and quickly trips the breaker. Since the voltage across the interpole instantly becomes at least 10 times its maximum load voltage, it immediately actuates the special breaker trip coil (*GM*2—#1 trip) before line current can build up to an excessive value.

On a flashover, the circuit becomes as shown by the dotted line around the armature (figure 12), and full bus voltage is instantly projected across the interpole and also the interpole trip coil.

Imposition of full bus voltage on the interpole trip coil, normally set to be actuated at, say 10 volts, causes very rapid actuation of this coil to trip the breaker. Thus it is seen that an interpole trip coil is effective for rapid circuit interruption upon occurrence of a fault, whether that fault be an external short circuit or a commutator flashover. If breaker construction is such that the special interpole shunt trip coil opens the breaker in two cycles, or 0.033 second, referring to figure 9*b*, the circuit will be interrupted at point *z* corresponding to 135,000 amperes on a bus to bus short circuit rather than at 150,000 amperes with conventional breaker overload protection. The advantage is even more pronounced on commutator flashover. Referring to figure 11, the circuit will be opened at point *z* corresponding to 7,000 amperes, if the machine is operating at no load, rather than the 25,000 amperes under conventional protection. With certain machine construction, the current from the bus will even reverse initially. Breaker construction can be made such that tripping from the special interpole trip coil is accomplished in less than the two cycles given above.

While the above discussion relates to motor protection, it is equally applicable to a d-c generator as illustrated in figure 12.

While the interpole trip coil is operative for both types of faults, its operation is even more rapid in the case of commutator flashover, because it is then subjected to full bus voltage.

In a mill installation, however, since a fault on one machine completely interrupts continuity of production, it is desirable to instantaneously trip all breakers, clearing the bus upon occurrence of such fault. Consequently, a blocking rectifier is inserted in the circuit and a common connection is made from the point between R_1 and the interpole trip coil, figure 12, in the special tripping circuit of motor number 2 to the corresponding point in the circuit to each of the other machines on the system. The presence of the rectifiers prevents the transient voltage, due to fault on one machine, from being fed into the interpole circuit of any other machine so as to interfere with its commutation. However, all trip coils are energized from the fault transient in any machine interpole. Also, relays *X*, *X*′, and *X*″ are connected to the common trip circuit. Contacts of these relays energize the standard shunt trip coils from the control voltage source and serve as back up protection. Each machine armature main circuit knife switch is provided with an extra contact blade to isolate the special trip circuit across its interpole when the machine is taken out of service. Thus, by the insertion of a relatively small amount of additional equipment at an insignificant cost circuit protection responsive to interpole winding transients is obtained, which acts more promptly than does standard overload protection, and is particularly effective for flashover protection where d-c machines are found in heavy concentration.

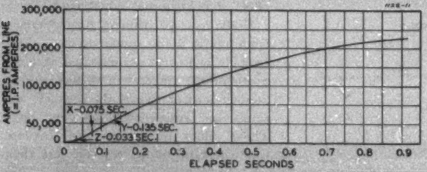

Figure 11. Short-circuit current build-up for commutator flashover

Build-up of current in interpoles from bus after flashover on commutator on a 3,500-horsepower 600-volt $\frac{165}{400}$-rpm d-c motor (Using constant inductance, line voltage, and motor counter emf)

Conclusion

(*a*). D-c machines may be cleared under fault conditions quicker by protective relay

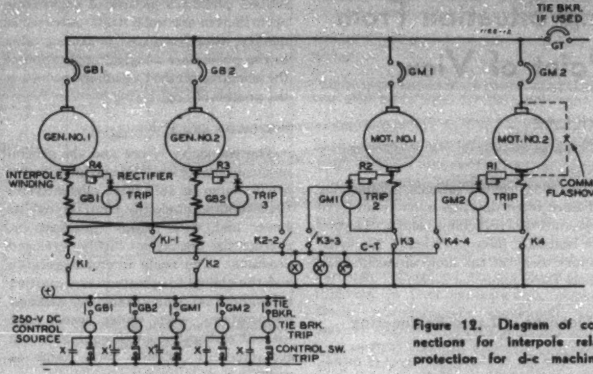

Figure 12. Diagram of connections for interpole relay protection for d-c machines

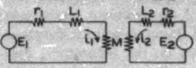
equipment responsive to transient machine characteristics than by conventional means responsive to load current.

(*b*). Such protection eliminates the necessity for bus tie breakers for sectionalizing faults.

(*c*). With adequate back up protection for breaker tripping, bus construction may be safely used with less margin against maximum ultimate short circuit stresses.

Appendix

Derivation of Transient Current for Accumulative Coupling of Two Coils When Connected Simultaneously to Two Different Voltage Sources (D-C)



$(M<\sqrt{L_1L_2})$

$$E_1=i_1r_1+L_1\frac{di_1}{dt}+M\frac{di_2}{dt} \quad (4)$$

$$E_2=i_2r_2+L_2\frac{di_2}{dt}+M\frac{di_1}{dt} \quad (5)$$

Differentiate (2):

$$0=r_2\frac{di_2}{dt}+L_2\frac{d^2i_2}{dt^2}+M\frac{d^2i_1}{dt^2} \quad (6)$$

From (1):

$$\frac{di_2}{dt}=\frac{1}{M}\left(E_1-i_1r_1-L_1\frac{di_1}{dt}\right) \quad (7)$$

Differentiating (7):

$$\frac{d^2i_2}{dt}=-\frac{r_1}{M}\frac{di_1}{dt}-\frac{L_1}{M}\frac{d^2i_1}{dt^2} \quad (8)$$

Substituting (7) and (8) in (6):

$$0=\frac{r_2}{M}\left(E_1-i_1r_1-L_1\frac{di_1}{dt}\right)-\frac{r_1L_2}{M}\frac{di_1}{dt}-\frac{L_1L_2}{M}\frac{d^2i_1}{dt^2}+\frac{M^2}{M}\frac{d^2i_1}{dt^2} \quad (9)$$

Simplifying (9):

$$\frac{d^2i_1}{dt^2}\left(\frac{L_1L_2-M^2}{M}\right)+\frac{di_1}{dt}\left(\frac{r_1L_2+r_2L_1}{M}\right)+i_1\left(\frac{r_1r_2}{M}\right)=\left(\frac{E_1r_2}{M}\right) \quad (10)$$

Simplifying (10):

$$\frac{d^2i_1}{dt^2}+\frac{di_1}{dt}\left(\frac{r_1L_2+r_2L_1}{L_1L_2-M^2}\right)+i_1\left(\frac{r_1r_2}{L_1L_2-M^2}\right)=\left(\frac{E_1r_2}{L_1L_2-M^2}\right) \quad (11)$$

Solution for (11) is:

$$i_1=\frac{E_1}{r_1}+A_1\epsilon^{m_1t}+A_2\epsilon^{m_2t} \quad (12)$$

Similarly:

$$i_2=\frac{E_2}{r_2}+B_1\epsilon^{m_1t}+B_2\epsilon^{m_2t} \quad (13)$$

Auxiliary equation is:

$$m^2+\left(\frac{r_1L_2+r_2L_1}{L_1L_2-M^2}\right)m+\left(\frac{r_1r_2}{L_1L_2-M^2}\right)=0 \quad (14)$$

By binomial equation:

$$m_1=\frac{-(r_1L_2+r_2L_1)-\sqrt{(r_1L_2+r_2L_1)^2-4r_1r_2(L_1L_2-M^2)}}{2(L_1L_2-M^2)} \quad (15)$$

By binomial equation:

$$m_2=\frac{-(r_1L_2+r_2L_1)+\sqrt{(r_1L_2+r_2L_1)^2-4r_1r_2(L_1L_2-M^2)}}{2(L_1L_2-M^2)} \quad (16)$$

When $t=0$, $i_1=0$

$\therefore 0=I_1+A_1+A_2$ from (12)
$$\therefore A_2=-(I_1+A_1) \quad (17)$$

and

$0=I_2+B_1+B_2$ from (13)
$$\therefore B_2=-(I_2+B_1) \quad (18)$$

From (12) and (17):

$$i_1=I_1+A_1\epsilon^{m_1t}-(I_1+A_1)\epsilon^{m_2t} \quad (19)$$

From (13) and (18):

$$i_2=I_2+B_2\epsilon^{m_1t}-(I_2+B_1)\epsilon^{m_2t} \quad (20)$$

Eliminate $\frac{di_2}{dt}$ between (4) and (5):

$$L_2\times(1) \text{ and } -M\times(2) \quad (21)$$

$$L_2E_1=i_1(r_1L_2)+\frac{di_1}{dt}(L_1L_2)+\frac{di_2}{dt}(L_2M) \quad (21a)$$

$$-ME_2=-i_2(r_2M)-\frac{di_2}{dt}(L_2M)-\frac{di_1}{dt}(M^2) \quad (21b)$$

$$L_2E_1-ME_2=i_1(r_1L_2)+\frac{di_1}{dt}(L_1L_2-M^2)-i_2(r_2M)$$

or

$$i_2=\frac{1}{r_2M}\left[i_1(r_1L_2)+\frac{di_1}{dt}(L_1L_2-M^2)-L_2E_1+ME_2\right] \quad (22)$$

When $t=0$, $i_2=0$,

So

$$0=(r_1L_2)(I_1+A_1-I_1-A_1)+(L_1L_2-M^2)\times[A_1M_1-(I_1+A_1)m_2]-L_2E_1+ME_2 \quad (23)$$

Simplifying (23),

$$0=A_1(m_1)(L_1L_2-M^2)-I_1m_2(L_1L_2-M^2)-A_1m_2(L_1L_2-M^2)-L_2E_1+ME_2 \quad (24)$$

Simplifying (24)

$$A_1=\frac{L_2E_1-ME_2+m_2I_1(L_1L_2-M^2)}{(m_1-m_2)(L_1L_2-M^2)} \quad (25)$$

Similarly

$$B_1=\frac{L_1E_2-ME_1+m_2I_2(L_1L_2-M^2)}{(m_1-m_2)(L_1L_2-M^2)} \quad (26)$$

The Incandescent Lamp Situation From the Engineering Point of View

PRESTON S. MILLAR
MEMBER AIEE

Introduction

AT this time, when the incandescent electric lamp is perhaps at the zenith of its career, there is a certain propriety in recording its status, in appraising it as an illuminant, and in reviewing the circumstances surrounding its production and use.

As an instrument in the advance of civilization, the lamp is highly important. In its technical and economic relationships it has been, and is, the subject of intensive engineering study. Thereby has come benefit to the art of illumination, which it serves well, and to the public welfare, to which it has made large contributions. Incidentally, the lamp illustrates the process of transformation of a luxury through intensive and widespread use into a necessity.

Somewhat of an assay of the incandescent lamp being proposed, it has seemed in order for the writer to undertake it because for several decades, though connected with neither a manufacturer of lamps nor an electric light and power company, he has had continuing contacts with both through independent lamp testing services. This circumstance accounts for an unusually comprehensive acquaintance with developments in lamp engineering. In this respect, this paper may be considered a sequel to an Institute paper presented in 1936 entitled, "The Qualities of Incandescent Lamps."[1]

While the approach in this paper is from the engineering point of view, it will be observed that considerable attention is given to the economic and commercial aspects of the lamp situation. Experience teaches that under American conditions engineering and commercial considerations cannot well be divorced. Economics, of course, is an essential element in engineering consideration. Engineering advance often depends upon commercial exploitation of its achievements. The two are mutually interdependent. No satisfactory assay of the lamp situation may ignore the commercial aspects.

Objectives of Lamp Engineering

Among the evident objectives of incandescent electric lamp engineering are:

High efficiency of light production
Low cost
Simplicity and universality of application
Consistency of performance

EFFICIENCY OF LIGHT PRODUCTION

Though low in ratio of transformation of electrical energy into visible light, the record of gain in light produced per watt expended (figure 1) reflects sustained improvement. It is necessary to turn to luminescence to secure higher efficiency in commercial illuminants.

COST OF LAMPS

As efficiencies of light production have advanced and use of lamps has been extended, costs of lamps have been reduced. The record of figure 2 reflects a continuing high degree of industrial progress.

COST OF LIGHT

The combination of increasing efficiency of light production and decreasing prices of lamps affords a record of increasing lumen output for each cent of lamp cost which is shown in figure 3.

This sustained advance through the years has been more or less paralleled by a continuing decrease in the cost of electrical energy supplied to lamps. The public has benefited by an ever diminishing unit cost of light. Merrill[3] has diagrammed this as in figure 4, in which, for lamps of specification qualities, the chart of his devising has been brought up to date. The outer rectangle represents the unit cost of light in 1921. The culmination of twenty years' effort is shown by the inner rectangle. Data are for the best grade of lamps which consistently have met the Federal Specifications.

The charts which have just been described present a picture of engineering operations in one small field. Advance in quality, reduction in cost, increasing value to the public, are a logical application of the scientific method to affairs—which is the process of engineering.

SIMPLICITY AND UNIVERSALITY

The simplicity of use and the general applicability which Edison demonstrated for his lamp in 1879 have characterized the incandescent electric lamp through its career and, with minor qualifications, characterize the present highly developed products. The ready interchangeability and the ability to operate in any position throughout a wide range of ambient temperatures, even under water, and without elaborate control equipment are characteristics offering large value to users.

Of note also is the close-to-unity power factor which assists in avoiding those extravagant expenditures in power generating, distribution and utilization equipment that a low power-factor lamp would involve.

CONSISTENCY OF PERFORMANCE

The degree to which performance of lamps can be made to approach uniformity is a test of manufacturing competency and is one of the measures of service satisfaction. It has been the history of each type of incandescent lamp of specification quality that progress has been made toward performance consistency so long as the demand for the lamp continued to grow. Figure 5 offers in illustration two comparisons of, respectively, early and fully matured lamp products showing, for performance in the laboratory, distribution of hours lives of individual lamps in terms of the average.

A like progress toward uniformity with each largely-used type of lamp has been

Paper 41-123, recommended by the AIEE committee on production and application of light, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted March 31, 1941; made available for preprinting May 14, 1941.

PRESTON S. MILLAR is president of the Electrical Testing Laboratories, New York, N. Y.

Appreciation is expressed to L. J. Lewinson for assistance in collecting material for inclusion in this paper.

[1] For all numbered references see list at end of paper.

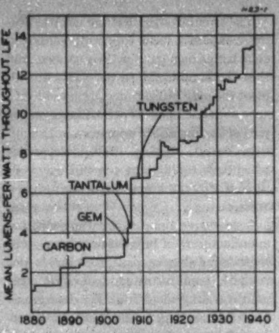

Figure 1. The record of advance in efficiency of light production

(Howell-Schroeder statistics up to 1915)

achieved in the matter of light output per watt for new lamps. Specification quality lamps have been brought within successively narrowed tolerances.

These statements as to attainment of lamp engineering objectives apply to the record of lamp products made by the larger and more competent manufacturers. Their products may be described as specification-quality lamps in that throughout the years they have been made to comply with the requirements of the Federal Specifications for Incandescent Lamps. There are other lamp products that do not attain to the quality required by these Federal Specifications and to which these statements are not applicable.[1] The data apply, however, to the majority of the lamps which have been made and sold in the United States.

The Basis of Lamp Engineering

In the United States it has been the endeavor to conform lamp engineering policies to the best interests of the public. Such an assertion rests upon no claim to especially high ethics or to unusually developed social consciousness on the part of anyone concerned. It rests upon the fact that enlightened selfishness dictates adoption of the best interests of the public as the objective to be sought in engineering procedures.

Of the individual in society Adam Smith in the "Wealth of Nations" wrote:

> "By directing . . . industry in such a manner as its produce may be of the greatest value he intends only his own gain and he is in this, as in many other cases, led by an invisible hand to promote an end which was no part of his intention. Nor is it always the worse for the society that it was no part of it. By pursuing his own interest he frequently promotes that of the society more effectually than when he really intends to promote it."

and on the other side of the picture Smith added:

> "I have never known much good done by those who affected to trade for the public good."

The writer has had the experience of having participated informally in discussions of lamp standardization, at times with responsible representatives of leading lamp manufacturers, at other times with responsible representatives of the largest public utilities, and at still other times with illuminating engineers who are variously connected. He has found these interests, in their capacities as, respectively, manufacturers, purchasers, and users of lamps, to be very generally actuated in their planning and their decisions by a desire to arrive at adjustments and procedures which will best serve the public interest in lamp matters.

Variables Confronting the Engineer

Underlying the standardization of lamps there must be decisions as to selection among available alternatives.

BULB SIZES

For example, it must be decided which of several possible bulb sizes will be used for lamps of a certain watts consumption. This decision is reached with realization that, other things being equal, smaller bulbs make possible more compact luminaires but involve greater blackening and higher temperatures than do larger bulbs. So far as the blackening is concerned, this is illustrated in the case of 25-watt vacuum-type round bulb lamps which are available in both $2^5/_{16}$-inch and $3^2/_{16}$-inch diameter bulbs. Data for the maintenance of light output and efficiency during life are as follows:

Table II. Bulb Size and Output Maintenance

	25-Watt Vacuum Tungsten Filament Lamps	
	G-$18^1/_2$ ($2^5/_{16}$ In.) Bulb (Per Cent)	G-25 ($3^2/_{16}$ In.) Bulb (Per Cent)
Mean throughout life in per cent of initial		
Lumens	85.0	87.7
Lumens per watt	80.2	92.4

TYPE OF TUNGSTEN FILAMENT

Sometimes decision must be reached whether a gain in efficiency of light production is worth more than a greater degree of filament ruggedness. For example, some twenty years ago the manufacturers were using two kinds of filaments offering such a choice.

Table III. Relative Performance of Lamps Having Different Types of Tungsten Wire (1920 Data)

	Type 1 (Per Cent)	Type 2 (Per Cent)
Filament breakage in new lamps after shipment	3.2	1.0
Filaments broken in careful handling during laboratory life tests		
At 300 hours	2.0	1.7
At 590 hours	10.8	3.7
At 880 hours	25.9	4.8
At 1,160 hours	31.5	7.6
Breakage index on a certain shock test*		
New lamps	64	30
After 500 hours	30	16
After 1,000 hours	21	15
Average laboratory life, at common initial efficiency, hours	1,090	2,270
Mean values throughout life, in per cent of initial		
Lumens	93.2	81.6
Watts	97.4	102.7
Lumens per watt	95.7	79.5

* Arbitrary scale.

A selection between these two types of filaments involved the kind of engineering decision which is here referred to. Actually, in the cited case, it was decided to select the first type of filament with its somewhat greater fragility but its better light-producing performance in the hope that gradually the manufacturers would be able to overcome the fragility difficulty. This subsequently proved to be the case.

CONVENIENCE VERSUS COST

Frequently, decisions involve the balancing of convenience against cost and the more or less arbitrary evaluation of each. A recent illustration of this is afforded by the two-filament lamp, used principally in

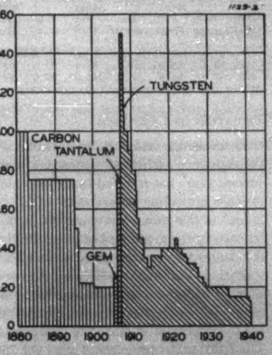

Figure 2. The record of decreasing list prices for the most largely used size of lamps

(Howell-Schroeder statistics up to 1915)

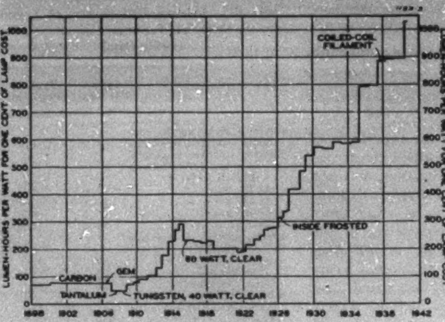

Figure 3. The record of lumen output per watt, per cent of lamp cost

(Howell-Schroeder statistics up to 1915)

Standard central station lamps

portable lighting equipment. To serve convenience, additional switching is provided and more costly lamps are made available in relatively small bulbs, that result in relatively poor light output maintenance through life. It might be difficult to justify such a development on any ground except provision of an appreciated convenience and facility to the public. Certainly it results in an increase in the unit cost of light over that which would be involved in the use of a single filament lamp.

Table IV. Mean Values Throughout Life of Three-Light (Two-Filament) and Single-Filament Lamps in Per Cent of Initial

	Two-Filament Lamps (Bulb Area, 48 Sq. In.)				Single Filament Lamp (Bulb Area, 100 W Lamp 27 Sq. In. 200-Watt Lamp, 56 Sq. In.)	
	Simultaneous Operation		Alternate Operation			
Filament (Watt)	Lumens	Lumens Per Watt	Lumens	Lumens Per Watt	Lumens	Lumens Per Watt
100	80.1	82.0	81.7	83.6	91.5	93.1
200	83.0	84.8	83.3	85.0	89.9	91.9

DURATION OF LAMP LIFE

A decision reached and reaffirmed through considerations extending over several years has resulted in the adoption of the prevailing convention of 1,000 hours' or 750 hours' average life in the laboratory for most sizes of general lighting lamps.[1,3] Setting aside unusual installations that might justify a longer or a shorter lamp life, and dealing with the generality of use, experience appears to have confirmed engineering judgment. The 1,000 hours (or in some cases the 750 hours) represents a balance between two considerations. In the case of 60-watt lamps, selling at 13 cents, and supplied with 4-cent current, the lowest cost of light would be obtained through use of a lamp designed for a life of the order of 330 hours. Thus, considering only the cost of lamps and energy, a shorter than prevailing life for lamps would be indicated. On the other hand, the advantages of convenience and freedom from replacement annoyance dictate a longer life. Here an important consideration is that relief from replacement increases largely with increased lamp life, while the cost of light increases but slightly with increased lamp life, throughout the range of commercial applications.

In all such matters the guiding principle has been the greatest satisfaction to the public upon which the maximum acceptance of lamps depends.

Favorable Aspects and Good Results

Numerous favorable dispositions, some perhaps peculiar to the United States, have affected the development of the lamp and its use with varying results.

EMPHASIS UPON GOOD QUALITY

It is difficult to say whether it was the spirit of the times or a chance disposition of fortune that gave rise to early emphasis upon good quality in incandescent lamps. We do know that Edison stressed this point from the start of commercial production of his lamps (figure 6). Following his example, there arose toward the latter part of the last century a group of men who perceived the essential importance of achieving in lamps the highest quality which it was commercially feasible to accomplish. These men introduced a regard for high quality, demonstrated its desirability, and so entrenched it in practice that to an unusual degree it has influenced the entire history of the incandescent lamp in this country.

The circumstance that the electric utility companies were supplying incandescent lamps as a part of their service, and that the lamp in the earlier years was almost the only utilization equipment led to specialization upon its performance on the part of leading utility operators, with salutary results. Those utility companies which now supply lamps in this way continue to exercise a large influence for good quality.

A predisposition among the principal manufacturers of lamps toward research, engineering development, and highly developed manufacturing technique met with encouragement from the determination of these largest purchasers of incandescent lamps to secure the best lamp performance that was commercially attainable. Manufacturers' expenditure for research and improvement in quality brought reward because principal purchasers were measuring quality and purchased the products of highest attainment. It is a fact that purchasing interest will stimulate producers to provide good quality while purchasing indifference will fail to bring such results. Lord Lyttleton, decades ago, illustrated this principle by

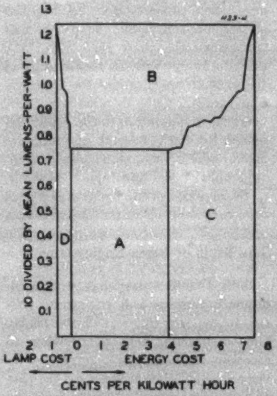

Figure 4. Lamp and energy cost of light (dollars per million lumen-hours) through the last 20 years

A—Cost of light—1941.........($3.04)

B—Reduction in cost since 1921 through increase in lamp efficiency...........($3.38)

C—Reduction in cost of light since 1921 through lowered rates for energy.....($3.25)

D—Reduction in cost of light since 1921 through lowered lamp prices.......($0.54)

A+*B*+*C*+*D*—Cost of light in 1921....... ($10.21) making his beautiful city girl in the country say—

> "Where none admire
> 'Tis useless to excel,
> Where none are beaux,
> 'Tis vain to be a belle."

Today, standards of quality in the incandescent lamp field are high. The Federal Specifications for Incandescent Lamps, revised periodically, call for good performance. The more competent manufacturers of lamps through research, engineering development, and advanced manufacturing technique quite generally equal or exceed these requirements. Their methods for accomplishing this include continual independent checks of performance to insure that it is accomplished, which same checks, if need be, may demonstrate its accomplishment.

A natural effect of critical purchasing methods in the United States has been that the lamp producing business has gravitated toward manufacturers who have been willing and able to produce the best lamps. The insistence by large purchasers that lamp products shall attain to high quality has tended to encourage manufacturing enterprises which were capable of meeting requirements that best serve the public.

The same influences which made for high quality of incandescent lamps tended to bring about mass production. This brought lowered costs and reduced prices for lamps.

Some evidence as to relative prices in several countries has been afforded by comparisons made by Swope[4] on the basis of the length of time an average workman in certain comparable industries in the several countries would have to toil to earn enough to purchase an incandescent lamp. The comparison was as follows:

Table V. Number of Hours' Work Required to Purchase an Incandescent Lamp (1937)

	Hours		Hours
Austria	1.8	Germany	1.4
Belgium	2.5	Holland	2.4
England	1.3	Hungary	3.4
France	1.2	Italy	2.0
United States of America	0.2		

Out of the laboratories and factories of the principal manufacturers of incandescent lamps in the United States have flowed a series of advancements and refinements which little by little have improved the qualities of incandescent lamps. From the same sources have come production economies which little by little have lowered the unit cost of the lamps.[5] In consequence, the American public has enjoyed the highest expression of the incandescent lamp making art at remarkably low prices.

Search for Markets Caters to the Public

It is a characteristic of the free enterprise, profit system that business, to prosper, must seek ever widening circles of purchasing power. Accordingly, manufacturers of lamps and electric light and power companies independently and by such means as seemed appropriate to their circumstances, have sought to further the use of lamps. On the principle that every satisfactory experience encourages other like experiences, and as a matter of enlightened self-interest, they have engaged in the development and promotion of good practice in lamp use. This has aided the public while serving their own commercial interests. The principal manufacturers of lamps through publications, service in technical societies, conduct of lighting schools, assistance with regard to new installations, etc., and the electric utility companies through like measures, including services in assisting with lighting layouts and advice regarding lighting, have participated in the advance of illuminating engineering applications. Thus has been formed a beneficent circle, featured by mass production of lamps, improved quality and lowered prices of lamps, greater use of lamps by the public, and more sale of less costly electrical energy for supply of lamps. Commercial interests and the public have benefited accordingly.

Importance of Long-Term Concern

Generally speaking, production, distribution, and use of the lamp may profit by the guidance of those who have long-term, comprehensive concern in the success of electric lighting. It is believed to have been an advantage that the principal manufacturers of incandescent lamps have also manufactured a wide range of electrical apparatus and equipment. Among their products there is a measure of mutual dependence and mutual stimulation. Deficiencies in any one hamper growth in another. Success of one stimulates others. Such manufacturers therefore unquestionably take an industry-wide view and feel a concern in the continuing success of lamps.

Manufacturers who have a long-term concern in the success of electric lighting and of a wide variety of equipment involved therein have no incentive to produce and sell novelties which offer little of real value but which temporarily might effect a profitable sale. To insure long-term business success, such manufacturers must be careful of their reputations and must seek to avoid advertising misrepresentations or guidance of the public that ultimately may prove misleading. Through years of testing of lamps privately for clients, during which test results obtained for them have been available to them for commercial purposes, a very general desire to represent findings accurately and honestly has been evident to the writer on the part of the more competent manufacturers of incandescent lamps.

Research in the Lamp Industry

The achievements of organized research which have been responsible for the advance in light production during the last 40 years are too well known to need recitation. American conditions in the lamp industry have resulted in the application to the lamp of the highest type of skillful scientific research, which has been facilitated by adequate equipment and resources. But for these, it is doubtful that electric lighting would have advanced and that the public would have benefited thereby to the existing degree.

This comment regarding research achievements applies as well to the niceties of manufacture. New methods, that make for more consistent and better products, are the result of engineering proficiency. Under the conditions that have existed in the United States, they have been developed to an advanced stage.

Black-Body Radiation an Advantage

Environmental influence, great though it be, is subject to the influence of heredity. The sense of sight in human beings has been evolved under the influence of sunlight. When this came to be supplemented at night by firelight glow, the abundance of daylight was replaced by the sparsity of firelight, and the white light of the sun was replaced by the red glow of the fire. The common characteristic of sunlight and firelight was a continuous spectrum throughout the visible range differing in color principally in that firelight was relatively much stronger in the red or longer wave lengths at one end of the visible spectrum and was much weaker in the blue or shorter wave lengths. It may be noted in passing that the redder glow of firelight became associated with warmth, relaxation, and pleasurable sensations in contrast with the white light of the sun which was associated with the intense activities of the day. There is thus evolutionary basis for speaking of the redder tints as warm and for associat-

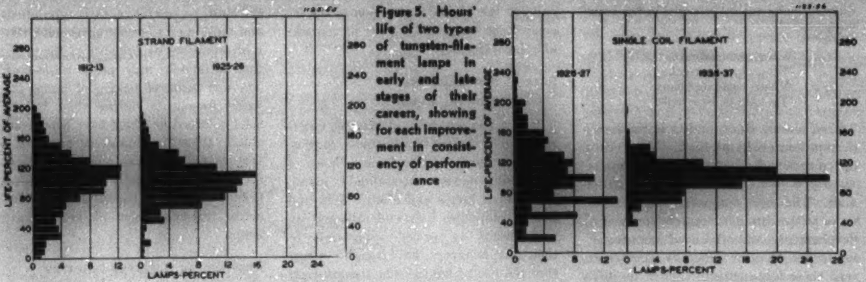

Figure 5. Hours' life of two types of tungsten-filament lamps in early and late stages of their careers, showing for each improvement in consistency of performance

ing them with social functions, while associating closer attainment to white light with the industries.

As artificial illuminants were developed, the incandescence of the flame, whether of fats or oils and whether burned crudely or with controlled drafts, found place along the black-body locus somewhere between the red glow of the fire and the white light of the sun. Not until the incandescent mantle gas lamp made its appearance did there enter into common use an illuminant which departed materially from the characteristic of black-body radiation. When electric lamps made their appearance, the carbon arc with its approach to the light color of the sun and the incandescent lamp with its lower color temperature were also found to lie on the locus of black-body radiation. Only the flame arc lamp with its selectively radiating impregnated electrodes, and, in modern times, mercury, sodium, neon, and the fluorescent lamps with their selective radiation, have departed materially from the black-body radiation characteristics. The incandescent electric lamps have a history of progress along the black-body radiation curve leading gradually away from the fire-glow in the direction of the white light of the sun (figure 7).

Light which does not depart materially in color characteristic from black-body radiation seems to satisfy human visual wants and to be pleasing. It meets with ready acceptance, apparently as a result of association and of developments of the evolutionary process. It is a valuable asset of the incandescent electric lamp that it produces light[6] which is eminently satisfactory in this particular.

Standardization

Lighting practice in the United States has benefited to an unusual degree by the fruits of lamp standardization. The prescience of Edison in selecting operating voltages for multiple circuits and in devising bases and sockets influenced later practice in these matters. The unfortunate inability early in the carbon lamp era to control carbon filaments led to dispersion of operating voltages throughout the 100- to 125-volt range in an endeavor to conform them with the voltages at which lamps as produced would yield stipulated candlepower. With the coming of the controllable tungsten filament, this trend as to operating voltages was reversed, with the result that during the last three decades operating voltages have tended toward standardization with 120 volts as the apparent goal.

Frequencies in the United States, with few exceptions, were standardized at 60 cycles per second—a frequency high enough to avoid flicker difficulties in the case of incandescent lighting.[7]

Lamp bases have long been standardized.[8] Their dimensions are controlled with care to keep them within close tolerances.

Sizes of lamps (identified for multiple lamps by watts consumed) have been well standardized, though sometimes special requirements have resulted in a larger number of sizes than engineering considerations would sanction.

Bulb dimensions have been arrived at as a compromise, but are well standardized, with consequent advantage to the trade and to the public.

The standardization of lamp efficiencies and lives for specification-quality lamps has resulted in more efficient and somewhat shorter lived lamps in the United States than in some other countries.

Modern lamp standardization has proceeded on the theory that for general lighting purposes the lamp should produce light as efficiently as practicable and should be of standardized construction with a minimum of variants. This theory for general purposes leaves to auxiliaries the task of redirecting, diffusing and, if desired, tinting the light. Through such auxiliaries general purposes may be served and specialized requirements may be met.

There are plenty of exceptions, however, to prove this rule. For specialized

Edison

Figure 6. Illustration of Edison's concern for good quality

(Note by courtesy of Mrs. E. P. Lovejoy, nee Jane Howell) applications bulbs are partly silvered, internal reflecting surfaces are provided for certain bulbs to produce the so-called reflector and projector lamps and sealed beam headlamps for motor vehicles. These do not detract, however, from the merit of the principle of standardized light sources for general purposes.

In proportion as standardization succeeds, opportunities are afforded for making something different and for selling it because it is different. The uninformed public may be approached with the argument that something which is different is better. To the degree that such approaches succeed, the purposes of standardization are somewhat frustrated. So in the case of incandescent lamps, bulb shapes and finishes which deviate from the conventional are sometimes adopted as manufacturing variants and attain to a certain sale, irrespective of value to the purchaser. These are perhaps exceptions which prove the rule of the value of standardization.

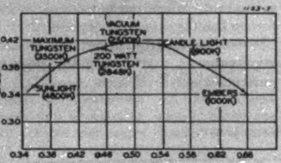

Figure 7. Color temperature of incandescent amps with reference to the locus of black-body radiation

Promotion and Use of More and Larger Lamps

Early incandescent electric lamps were but feeble light sources. So little light was produced that it was necessary to use the light without refinement in its crude state. As light came to be produced more efficiently, as lamps became cheaper, and as the costs of electrical energy were reduced, it became possible to utilize the light more effectively. Instead of employing it in its raw form that produced unsatisfactory illumination, it became possible to some extent to benefit through adherence to the principles which illuminating engineers had come to recognize. Lamps could be shaded. Light could be diffused and redirected with improvement in conditions for vision. The process of furthering conformity with illuminating engineering tenets involved the use of larger sizes of lamps (figure 8) which cost less per unit of light and which produced more light per watt. They were therefore more economical to use, and were better adapted to produce the improved illumination which was sought by all who were concerned in the success of electric lighting.

Table VI. Relative Cost of Light Produced by Lamps of Various Sizes

Lamps (Watts)	Cost Per Hundred Thousand Lumen-Hours*
25	$0.47
60	0.31
100	0.27
200	0.25
300	0.23

* Lamps at list prices, current at 4 cents per kilowatt-hour.

It is interesting to compare the crude lighting of, say, 1911 with that now provided. A 1911 living room with a candelabra fixture and wall brackets equipped with small, bare lamps may be compared with a similar modern room lighted by lamps which conform with IES Recommended Practices. Here are some of the comparative data:

	1911	1941
Total watts of lamps in room	260	400
Lumens produced	1,820	6,400
Maximum brightness to which eyes are exposed, candles per sq. in.	20	3
Average horizontal footcandles	2	8
Cost of light for 75 hours	$1.70	$1.26

It would be a reproach to engineering if, over a period of 30 years, there had been no marked advance in lighting effectiveness and economy. The actual progress is very creditable. The rough comparison indicates that a great deal more illumination is provided with better conditions for visibility and with a reduction in cost as compared with the accomplishments of 30 years ago. It now costs about one-fifth as much to obtain a given amount of lighting as it did in 1911. Actually, more light is now used, refined to greater serviceability, at a cost which is materially less than that incurred for less light more crudely used in 1911.

In proportion as improved results of engineered illumination were achieved, they were so satisfactory and acceptable to the public that they created demands for further applications. There resulted increased sales of lamps, increased sales of electrical energy for supply to lamps, and increased satisfaction to the public from improved illumination. And, due to engineering advance, such improved illumination costs but little more than the crude light formerly provided by less efficient, smaller lamps, supplied with electricity at higher rates. Both business interests and the public profited.

While there has been considerable advance along these lines, much further progress in application of illuminating engineering principles is required to satisfy aspirations for the welfare of the public as affected by artificial lighting. (Though it is not germane to this paper, it is hoped that fluorescent lamps, with their greater production of light per watt, will assist ultimately in achievement of the desired goal of well-engineered illumination.)

Electric Wiring

The advance of electric lighting through use of incandescent lamps has been somewhat hampered by absence from wiring procedure of some of the influences which have been beneficial in the case of the lamp. Following early developments of electric lighting, wiring practice came under the guidance of interests which had neither responsibility nor concern for the ultimate success of electric lighting. It seems to be generally agreed that as a result much electric wiring is inadequate for modern requirements.[9]

Clearly, the lamp cannot render optimum service if its preformance is subject to undue potential drop or to other inadequacies of wiring. As clearly, the achievements of large-scale production in decreasing the cost of light cannot be of maximum advantage to the public if electric wiring is needlessly costly.

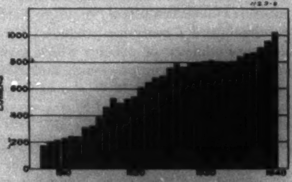

Figure 8. Average initial lumens of large incandescent lamps sold in the United States

Latest Attainments in Incandescent Lamps

The lamp manufacturers advise that the tiniest incandescent electric lamp regularly produced for commercial use is the "grain-of-wheat" lamp for surgical use, consuming about $1^{1}/_{2}$ watts. On the other extreme, the largest incandescent lamp regularly made and sold is intended for flood lighting applications and is rated at 50 kw. Within this range there are thousands of sizes, styles, and types of incandescent electric lamps. There are about 200 which are regularly listed by the manufacturers. The 60-watt, 120-volt lamp is the most generally used size.

It is estimated that during 1940 approximately 575,000,000 "large" incandescent electric lamps, or 4.4 lamps per capita, were sold in the United States. It has been estimated that about one-third of the domestic use of electric energy is for lighting.

So well is the lamp industry being handled that a laboratory procedure, which concerns itself with difficulties encountered in lighting service, finds about as many difficulties arising from the relatively simple auxiliary equipment with which lamps are used as it does from the delicate and complicated lamps themselves. This, in the writer's judgment, is attributable to the fact that, in the case of lamps, manufacturers' quality control methods are highly developed, with results that are constantly being checked by critical purchasers. In the case of sockets, switches, etc., the undoubted competency of many of the manufacturers receives no equivalent stimulus from purchasing interests.

The provisions for determining the performance of the principal makes of incandescent electric lamps and for securing correction where deficiencies are encountered have been described previously[10] and are an outstanding example of measures taken by industry to insure good serviceability of consumer products. Under the influence of policies which give rise to this advanced procedure, and as a result of the procedure itself, standards of lamp quality in the United States are of the highest. It appears that this relatively satisfactory lamp situation is attributable to the fact that, with the public interest as a touchstone, leadership is exercised by manufacturing and purchasing interests that have a long-term concern in the success of electric lighting.

New Current Transformer for Bus Differential Protection

L. F. KENNEDY
MEMBER AIEE

A. T. SINKS
ASSOCIATE AIEE

Synopsis: Perfect current transformers would make all differential relaying simple, but such transformers would be of excessive size and cost. A new idea in current transformer design makes it possible to maintain a linear relation between primary and secondary currents in a transformer of reasonable size, even where high current values, completely offset, are encountered. Such a current transformer is particularly valuable for applications where high speed bus differential protection is required. The basic principles of design and test results are reviewed showing that the air gap core current transformer retains a fixed ratio over the full range of current for which it is designed. There is thus made available a current transformer of reasonable size, which may be easily applied and may be used with simple relays.

1. Introduction

SINCE practically all protective relays are energized from the secondaries of current transformers, the overall performance of the relay system is considerably influenced by current transformer action. This is particularly true with the differential forms of protection, where, if the current transformers reproduce accurately the current flowing in each primary circuit, the relay to be used can be of the most simple type. The various features of relays used for differential protection, such as percentage restraint, harmonic restraint, or even time delay, are used, or were developed, to overcome the effects of known or suspected current transformer errors.

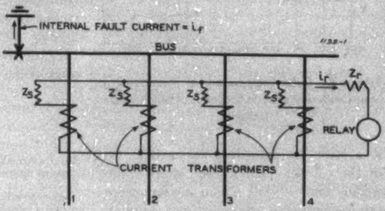

Figure 1. Schematic diagram of current transformers differentially connected to relay

In simple series differential connections, such as are commonly used for generator protection, where each current transformer has the same primary current, it is not essential that the current transformers be capable of reproducing the primary current exactly. If such current transformers are matched (i.e. have identical characteristics) a very simple type of relay is adequate. In practice, matched current transformers are not generally used, preference being given to the percentage restrained relay as a means of overcoming slight differences in current transformer characteristics.

When differential protection is applied to a station bus section, even matched current transformers are not necessarily suitable, because each of the current trans-

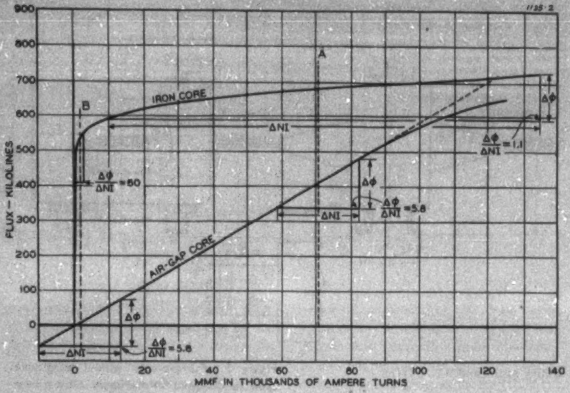

Figure 2. Comparison of magnetization curves for air-gap-core current transformer and conventional current transformer of same dimensions without gaps

formers may carry a different value of current and therefore have a different ratio error (refer to figure 1). In such applications, the vector sum of all the primary currents for an external fault is of course zero, but the vector sum of all the secondary currents will be zero only if each secondary current bears the same relation to its primary current as each other secondary does to its primary. In the application of current transformers to bus protection problems, it has been found that conventional transformers deviate very materially from their nominal ratio at the high current values frequently encountered. The amount of deviation is a function of transformer design, current magnitude, secondary burden, and d.c. time constant. To obtain even reasonably good current transformer performance where high speed bus differential protection is required, as for example, on a 13.8 kv bus section with a short circuit capacity of 1,000,000 kva, requires a transformer of excessive physical size. To overcome the errors introduced by transformer saturation by the use of special relay characteristics, requires a very careful and laborious study of both transformer performance and relay characteristics over a wide range of conditions to insure that the protective equipment will always operate to trip all internal faults and never cause tripping for any external faults.

No amount of relay development seems capable of overcoming these difficulties, but the development of a special type of current transformer in which the secondary current bears a linear relation to the primary current up to values of 25,000, 50,000, or 100,000 amperes would be an ideal solution. This paper describes such a transformer which at all times reproduces the a.c. component of the primary current with the same degree of accuracy. At the same time, in effect, it rejects the d.c. component present in a displaced wave, so that the secondary current is always proportional to only the a.c. primary component. Such transformers when applied to bus problems (or other problems) will produce no relay current for external faults except that due to permissible, and easily predictable manufacturing tolerances.

2. New Principle

As mentioned before, the difficulty with conventional current transformers is not so much that they have errors but that the errors are different with different currents. This variation of error with current is caused by the change of permeability of the iron with flux density. A current transformer having a core material of constant permeability, such as air, would be free from such variations and therefore, it is reasonable to consider the performance of an air-core transformer.

The following mathematical analysis will show that a group of such identical transformers operating together will produce no false differential currents with either symmetrical or assymmetrical current waves.

It is well known that the relation between the primary and secondary currents in a current transformer having constant inductances and resistances can be calculated as follows:

Let

M = Mutual inductance—henrys

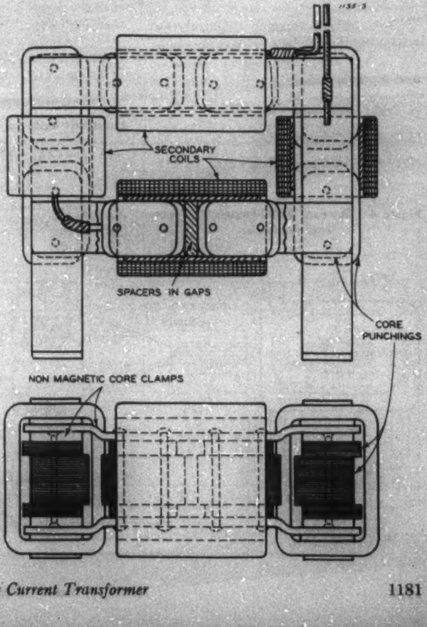

Figure 3. Core and coil construction of air-gap-core current transformer

L_c = Self inductance of the secondary with the primary open—henrys
L_b = Inductance of burden—henrys on individual transformers
$L_s = L_c + L_b$—henrys
R_s = Resistance of individual secondary circuit including secondary coil—ohms
$Z_s = R_s + L_s d/dt$
i_p = Primary current—amperes
i_s = Secondary current—amperes
t = Time in seconds
L_r = Inductance of relay
R_r = Resistance of relay
$Z_r = R_r + L_r d/dt$

The voltage generated in the secondary is, therefore, given by:

$$E_s = -Mdi_p/dt$$

and in the case of one transformer operating a relay E_s also must equal

$$i_sR_s + L_sdi_s/dt + i_sR_r + L_rdi_s/dt$$

Therefore, for one transformer the equation relating the currents is:

$$i_s(R_s+R_r)+(L_s+L_r)di_s/dt = -Mdi_p/dt \quad (1)$$

If now several transformers, say 4, are differentially connected to a relay as in figure 1, and i_f = fault current in the protected area and i_r = the relay current, the equations for the individual current transformers of identical design and identical burdens become for

$$\text{(CT \#1)}\quad -Mdi_{p1}/dt = i_{s1}R_s + L_sdi_{s1}/dt + i_rR_r + L_rdi_r/dt$$

or

$$-Mdi_{p1}/dt = Z_si_{s1} + Z_ri_r \quad (2)$$

and similarly

$$\text{(CT \#2)}\quad -Mdi_{p2}/dt = Z_si_{s2} + Z_ri_r \quad (3)$$

$$\text{(CT \#3)}\quad -Mdi_{p3}/dt = Z_si_{s3} + Z_ri_r \quad (4)$$

$$\text{(CT \#4)}\quad -Mdi_{p4}/dt = Z_si_{s4} + Z_ri_r \quad (5)$$

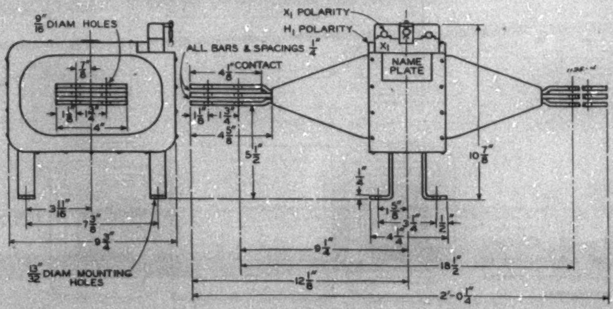

Figure 4. Standard 3,000-ampere JK-9 current transformer

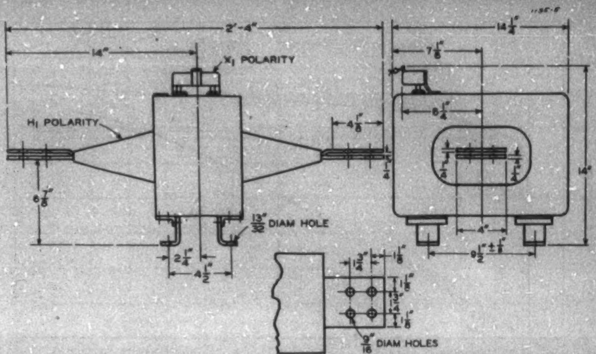

Figure 5. Air-gap-core current transformer type JD designed for maximum rms a-c component of short-circuit current of 50,000 amperes with 100 per cent d-c transient of any time constant, ratio 2,500/1

adding equations 2 to 5 gives:

$$-Mdi_{p1}/dt - Mdi_{p2}/dt - Mdi_{p3}/dt - Mdi_{p4}/dt = Z_si_{s1} + Z_si_{s2} + Z_si_{s3} + Z_si_{s4} + 4Z_ri_r$$

or

$$-Md/dt(i_{p1}+i_{p2}+i_{p3}+i_{p4}) = Z_s(i_{s1}+i_{s2}+i_{s3}+i_{s4}) + 4Z_ri_r$$

but

$$i_{p1}+i_{p2}+i_{p3}+i_{p4} = i_f$$

and

$$i_{s1}+i_{s2}+i_{s3}+i_{s4} = i_r$$

therefore

$$-Mdi_f/dt = Z_si_r + 4Z_ri_r$$

or

$$-Mdi_f/dt = i_r(R_s+4R_r) + (L_s+4L_r)di_r/dt \quad (6)$$

On steady state a.c. this equation becomes

$$-jX_mI_f = I_r(Z_s'+4Z_r') \quad (7)$$

where

$X_m = 2\pi fM$
f = frequency
I_f = effective value of fault current
I_r = effective value of relay current
Z_s' and Z_r' = conventional a.c. impedances corresponding to Z_s and Z_r

It should be noted that equation 6 relating to the fault current in the protected area to the relay current is the same in character as equation 1 relating to the primary current of an individual current transformer to the secondary current. Hence for identical transformers the relay current i_r bears a fixed relation to the total internal fault current i_f regardless of the distribution of this current through the several current transformers, and there can be no relay current unless there is an internal fault. Moreover, this statement holds irrespective of wave form, d.c. transients, or frequency. The principle of the air cored current transformer is thus demonstrated to be sound.

However, for the idea to be practical, the value of i_r corresponding to the minimum internal fault current must be sufficient to operate the relay. It will be noted in equation 7 that the impedance Z_r is multiplied by 4, the number of current transformers. If there were N current transformers, this impedance would be multiplied by N. The relay burden, therefore, acts as if it were N times its actual value. Consequently, assuming a one to one ratio for simplicity, and realizing X_m will always be somewhat smaller than Z_s', the value of X_m must be at least as large as NZ_r' in order that I_r will be a reasonable proportion of I_f. Moreover, any attempt to increase I_r by decreasing secondary turns is ineffective because a decrease in secondary turns decreases X_m.

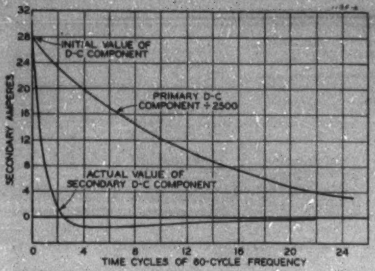

Figure 6. Transient performance of air-gap-core current transformer for 100 per cent offset of primary current wave

Reproduction of d-c transient in current transformer with air-gapped core

Rated 2,500:1 ampere

Therefore, with a core of a given permeability and length there is a minimum value of core cross section which will provide the requisite value of X_m and the longer the core length the greater this cross section. With such low permeability as air, this core cross section has to be quite large even with a normal length of magnetic circuit with the result that the copper of the secondary has to be large to keep down the value of secondary resistance. This in turn requires a larger than normal length of magnetic circuit requiring a still larger cross section so that by the time everything is made large enough to get any desired amount of power out of the secondary of an air core transformer such a device becomes substantially as large as a closed iron core transformer designed for the same service.

3. Practical Use of the Principle

Obviously, therefore, it is desirable to replace the air with a material of higher constant permeability, if satisfactory performance is to be obtained with a transformer of reasonable size. Unfortunately, such a material is not yet available. A reasonable approach to the ideal can be obtained by providing an iron core with gaps in it to maintain a linear characteristic providing the total length of gaps required is not as great as the length of the complete magnetic circuit. It so happens that in the range of short circuit currents usually encountered the total length of gaps required is only about 17% of the necessary length of magnetic circuit. Thus, by using an iron core with gaps, a core which will not saturate but which has about 6 times the effective permeability of air can be constructed. This 6-fold improvement is sufficient to reduce the size of the air core transformer to a reasonable value with the result that a transformer only moderately larger than standard transformers can be built to operate properly at the highest short circuit currents encountered, for which the standard transformer would not be suitable.

A question that is likely to arise at this point is "If a transformer of conventional design requires so much cross-section of iron to reproduce the d.c. transient in the secondary circuit,[2,3] how are air gaps in the magnetic circuit going to make possible a reduction in this iron." The answer is that in the air gap core transformer the d.c. transient can hardly be said to be reproduced at all. A d.c. transient current does occur in the secondary, but its rate of fall is so high and its duration so short that the flux required to generate the voltage corresponding to it is small.

4. Principles of Design

If the equation for the actual primary current (including the transient) be substituted for i_p in equation 1, it can be shown[1] that for a transformer having a constant permeability core the reproduction of the a.c. component of current in the secondary is unaffected by the presence of the d.c. component. This fact, together with the fact that the d.c. in the air gap core current transformer is not reproduced to any extent provides the criterion for the size of the gaps because these two conditions mean that the maximum value of magnetizing ampere turns acting on the core of the transformer will be something slightly less than the sum of the maximum primary d.c. transient ampere turns and the maximum crest value of the a.c. exciting ampere turns that will be required. The latter quantity will ordinarily be a rather small part of the total magnetizing ampere turns and will be determined by the maximum primary current and the maximum percent a.c. error that will be considered permissible. (The limitations of this error will be discussed later.) If the transformer is a bar or window type de-

sign as will usually be the case for bus differential protection, the maximum ampere turns acting on the core are then established. If now the maximum flux density that can be permitted without requiring appreciable ampere turns for the iron part of the circuit is found from the magnetization curve the total length of air gaps necessary to keep the flux density down below this permissible maximum is established.

Having established the total length of air gaps and the a.c. exciting ampere turns, the a.c. flux density corresponding to these ampere turns is determined. The total a.c. core flux necessary is then determined in the usual manner from the induced voltage necessary to supply the secondary coil *IR* drop plus the burden voltage. The necessary core cross-section is thus established by dividing the total core flux required for the induced voltage by the flux density which the permissible a.c. exciting ampere turns will produce.

Figure 2 shows a comparison between the operation of the magnetic circuit of the air gap core transformer and that of a conventional current transformer of the same core and coil dimensions without the gaps. Without any d.c. in the magnetizing current, the increment of exciting current required for the a.c. flux is very much smaller in the conventional transformer than in the air gap core transformer, but with much d.c. present in the magnetizing current, the exciting ampere turns in the conventional transformer for the same increment of a.c. flux density is increased enormously, even way above that required for the air gap core transformer whose a.c. exciting current remains the same. It is this constancy of ratio between flux and exciting ampere turns in the air gap transformers which make them balance properly when operating differentially even though their errors are large.

5. Construction

Figure 3 shows the mechanical construction of the air gap core current transformers. The punchings of the core are rounded and stepped back at the gaps to prevent concentration of flux at the edges thereby avoiding local saturation of the iron. Several gaps are employed rather than one and symmetrically disposed in the core in order to reduce interference effects to a minimum as well as to reduce the fringing of flux that would occur with one large gap. Non-metallic spacers of textolite are used in the gaps to insure the mechanical stability of the punchings against the large magnetic forces exerted at high currents. The core and coil assembly is held together with non-magnetic clamps. Four secondary coils are used so as to provide nearly uniform turns per inch of core around the magnetic circuit thereby minimizing leakage flux and interference.

The coils and core of the transformer are surrounded by a copper case soldered or brazed at the joints thereby forming a very effective electromagnetic shield against stray flux interference from nearby current carrying conductors. Figures 4 and 5 show comparative dimensions between a standard 3,000 ampere bar type current transformer and a sample 2,500 ampere air gap core transformer made for test.

This sample was designed for a maximum short circuit current of 50,000 am-

peres r.m.s. a-c component of current with 100% d-c transient of any time constant. The following tabulation shows a comparison between this sample and a conventional current transformer designed for the same service assuming a 0.25 second time constant for the d-c transient.

Table I

	Air-Gap-Core Transformer	Iron-Core Transformer
Weight	120 lb	500 lb
Size	28"x14"x14¼"	30"x18"x18"

6. Characteristics of the Air-Gap-Core Transformer

Figure 6 shows the transient performance of the 2,500 ampere transformer referred to above with primary current wave 100% offset and a d-c time constant of 0.2 second. Figures 7 and 8 show ratio and phase angle errors of this same transformer plotted against burden. It is not necessary to plot curves of accuracy against current, since the per cent error for a given burden is fixed (within 1% or less) for any current up to the limit of the design.

Figure 9 shows the equivalent circuit of the transformer from which operation under any conditions can be calculated. It is interesting to note that since the d-c in the secondary is almost negligible and since the impedances are constant, any calculation of the performance of the air gap current transformers, either individually or in a group, becomes simply a conventional a-c network problem.

It will be noted from the figures given on the drawings that a one-ampere secondary was used on the transformer referred to. The reason for this as well as the reason for the selection of the impedance values given will be discussed under application.

While theoretically air gap core current transformers of identical design with identical burdens should be perfectly balanced and give no false differential current when operated differentially, in practice some unbalance must be expected not so much on account of any difficulty of matching the transformers and burdens accurately but mostly because of the variation of the secondary resistance with temperature. An analysis of the equivalent circuit, figure 9, will show that the transformer error is affected considerably by variation in the secondary resistance, a 15% variation in the value of 21 ohms producing approximately a 2% vectorial shift of secondary current. A 15% change in resistance will result from about 37°C temperature change, a difference which may readily exist between two transformers on different branches of the same bus, if possible differences in ambient temperature and load current in the two locations are considered. To reduce this effect means an increase in the size of core to increase the magnetizing impedance, or in other words, reduction in the permissible per cent exciting current. This temperature variation factor is, therefore, one of the factors limiting the permissible errors of the transformer.

7. Tests

In order to check the calculations and theory on the air gap core transformer, many tests were made, the more important of which will be described here.

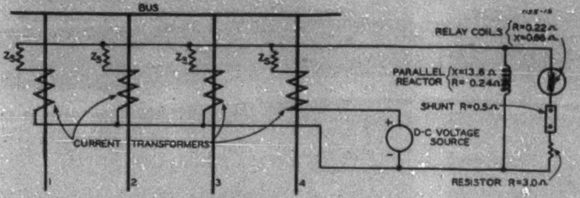

Figure 12. Schematic diagram of test set up for high currents and superimposed d-c in the secondary of number 4 current transformer

First, to be sure that no unforeseen saturation effects existed, an exciting current test on a sample transformer was made in which the crest value of flux was measured by a rectifier voltmeter across the secondary winding and the crest value of current was also measured by a rectifier voltmeter across the secondary of a mutual inductance whose primary was in series with the secondary coils of the transformer. The results of this test are:

Table II

RMS Amperes	Crest Amperes	Crest Amp Turns	RMS Secondary Volts	Average* Secondary Volts ×1.11	Ratio of Average Volts ×1.111 to Crest Amps
12	17.0	42,500	1,832	1,814	106.8
18	25.5	63,700	2,740	2,740	107.2
20.2	28.6	71,500	3,050	3,020	105.5
23.8	33.6	84,000	3,600	3,600	107.2

* Average voltage is measure of crest flux.

It is apparent from the figures that the ratio of flux to exciting ampere turns was linear within the accuracy of the measurements, and that the maximum ampere turns were in excess of 70,000 amperes, the d-c component corresponding to a 50,000 ampere rms a-c component.

Tests were also made for interference effects which were found to be approximately 1% without the copper casing and practically imperceptible with the case.

To find the effect of variation in gaps and iron stacking, impedance measurements were made on four sample transformers and three of the four were then balanced against the remaining transformer one at a time to find the actual differences in ratio and phase angle errors. It was found that although the mutual inductances M and the self inductance L_c of the transformer secondaries varied between one transformer and another by as much as 4% the difference in the errors was less than 1%. The reason for this, is of course, that variations in L_c are always almost exactly the same in percent as the variations in M because practically the same magnetic circuit controls both inductances. Therefore, the accuracy is not greatly affected by small variations of inductances between individual transformers of the same design.

A survey of testing facilities suitable for testing the air gap core current transformers under actual operating conditions showed that about the only way large short circuit currents with large d-c time constants could be obtained was to use a large generating station. As such stations are not readily available for current transformer tests, two sets of tests were devised to duplicate actual conditions as nearly as possible with available equipment.

In the first set of tests, 4 sample 2,500:1 air gap core current transformers of design previously described were connected together essentially as shown in figure 1. Current was fed in through lines 1, 2, and 3 and out through line 4. For the condition of a through fault outside the protected area, the secondaries were connected as in figure 1 and to get the effect of a fault inside the protected area the secondary leads of transformer #4 were reversed. The current was supplied through large reactors in order to get long d-c time constants. Because of saturation, the usefulness of these reactors was limited to a few thousand amperes.

Although the currents were too low to prove the capacity of the current transformer, these tests did demonstrate the correctness of the principles as indicated by the oscillograms, figures 10 and 11. It will be noticed that the primary d-c transient was of long duration whereas the d-c in the secondaries disappeared very quickly. The current in the relay for the through fault test in figure 10 was about 0.6% of the total fault current referred to secondary and the relay did not operate, whereas for the "internal fault" conditions of figure 11 the relay current was twice the fault current referred to the secondary and the relay did operate.

Since long d-c time constants could not be obtained at high currents, in order to produce d-c magnetizing ampere turns on the core equivalent to actual operating conditions a d-c voltage was inserted in the secondary circuit of current transformer #4 and the relay by-passed by a low resistance reactor as shown in figure 12. The d-c voltage produced a d-c circulating current in the secondary of #4 transformer producing magnetizing ampere turns on the core similar to what would be produced by a long d-c transient. The purpose of the reactor in parallel with the relay was to by-pass the d-c around the shunt of the differential circuit without by-passing an appreciable amount of a-c so that the oscillograph sensitivity could be made high enough to measure the unbalance in the transformers without the elements being forced off scale by the d-c, most of which returned through the differential circuit.

The maximum sustained d-c current in the secondary of #4 transformer that could be obtained with the voltage available was 20 amperes making 50,000 ampere turns. The primary a-c which had a short d-c time constant was raised to slightly over a 100,000 amperes rms symmetrical with 50,000 d-c ampere turns superimposed on #4 transformer.

The results of these tests were essentially the same as the tests made at low currents with the large reactors. The maximum unbalance observed was about 2%, some of which was undoubtedly due to the extra burden of the generator armature in #4 transformer secondary. That it was not due to saturation effects was evidenced by the fact that the per cent unbalance was the same for all currents. When the secondary leads of #4 transformer were reversed, the relay current was again approximately equal to twice the total fault current referred to the secondary.

With these tests completed it was concluded that the engineering calculations had been adequately confirmed by test.

8. Choice of Ratings

The selection of transformer sizes and ratings to be available was based primarily upon the maximum rms value of the symmetrical current which might be encountered. Transformer cores suitable for use with primary currents of 25,000, 50,000, and 100,000 amperes, have been designed. These correspond approximately to short circuit capacities of 500,000 kva, 1,000,000 kva, or 2,000,000 kva at 13.8 kv and are intended in fact to be applied on this basis.

Nominal primary ratings which are really continuous current ratings have been established corresponding to the above as 1,000 amperes, 2,500 amperes, and 4,000 amperes. It is possible, however, to wind on these cores suitable coils to permit other nominal ratings if a need for them should arise. It was felt that the ratings selected above were, in general, high enough to carry continuously the maximum single circuit current which might be encountered on busses having the designated short circuit capacity. Since these transformers are intended for differential protection only, there is no need to rate the current transformer down to the circuit rating.

Since these transformers are not suitable for metering service it was felt that the ratio did not have to be such as to give 5 amperes secondary at nominal rating, particularly if there was some good reason for using some other value. As far as the performance of the relay system is concerned, once a selection of relay types and a transformer core size has been made it does not matter what the ratio of transformation may be. Any changes in ratio require a corresponding change in relay setting and hence in relay burden. If we decrease the ratio, using fewer turns, we can increase the relay setting and reduce its burden. But as long as the only load on the transformer is the relay, the overall performance remains unchanged. The reduction in burden is compensated for by the lowered burden capacity of the transformer with fewer turns. Thus, considering only the relays and the transformers it would make no difference what ratio was chosen.

There is, however, the lead burden in addition to the relay burden imposed on the current transformers. Frequently the lead burden may be larger on one transformer than on another. If the accuracy curves figures 7 and 8 were based on 5 ampere secondaries instead of 1 ampere secondary the impedances given would all be divided by 25 and a variation of $^{1}/_{2}$ ohm in lead resistance would be equivalent to a variation of 12.5 ohms on the curves as plotted. The difference in accuracy resulting from such a burden difference is apparent from the curves. A $^{1}/_{2}$ ohm difference in burden on the 1 ampere secondary transformer on the other hand makes practically no difference in accuracy. Since in many applications the secondary lead lengths will vary considerably the selection of a 1 ampere secondary should greatly simplify the application problem by eliminating any necessity of balancing lead resistances.

9. Application

The application problem is made very simple through the use of this air gap core current transformer. Up to the present time the application of high speed bus differential protection has been very largely a matter of judgment. While it is possible to calculate with fair accuracy the performance of any particular installation of conventional design transformers, these calculations are quite laborious and require data on the transformers which have not always been available. With the data from such calculations it has been possible, however, to determine the type of relay necessary to obtain correct performance of the relay system, provided of course that the errors as determined by the calculation are not too great. The amount of time required for such exact determination is so great, however, that most applications have been made based on the individual's judgment of the expected performance and the required relay characteristics to offset the expected error. Despite the generally satisfactory results obtained in service most engineers have felt a considerable degree of dissatisfaction because of the inability to prove the soundness of application made in this way.

The amount of application effort where high speed differential protection is to be applied has proved to be very great. Furthermore, many cases studied showed that standard current transformers were not capable of giving the desired characteristics. When special designs of conventional construction were considered these were found to be either physically too large or too costly to permit installation. Thus, many busses do not have adequate protection.

With the air gap core current transformer, there are no uncertainties regarding performance. The difficulty formerly experienced in finding the required space has been minimized or entirely eliminated since the transformer shown in figure 5 can be made as a bushing type suitable for mounting over either a bushing in station type cubicles or the insulated conductor in metal clad gear. Knowing the maximum symmetrical short circuit current which can be supplied, the current transformers are selected which give a linear performance up to this current value. There is no need to attempt to determine the time constant of the d-c component since the transformer performance is not affected by this factor.

Since for any value of short circuit current within the limit for which the current transformer is designed, a linear relation is maintained between primary and secondary currents, there will be essentially no difference in current for any external fault, and it is thus possible to use a simple overcurrent relay of the instantaneous type. The setting of this relay would be such that it would have a safe operating margin, say 2:1, to insure operation on the minimum internal faults.

With the air gap core current transformer, application difficulty is encountered only where the current to a single phase to ground fault is limited by neutral impedance to a small percentage of the maximum phase fault. While the design and manufacture of the transformers is such that agreement within 3% is expected and that the maximum differential current for any through fault would be generally less than this amount, it is felt that good practice for the moment dictates a minimum relay setting corresponding to not less than 10% of the maximum fault current. More sensitive settings are of course theoretically possible and can be used where necessary but with more careful consideration of all factors.

10. Conclusion

Through the development of the air gap core current transformer there is made available for high speed differential protection a transformer having the following advantages.

It has been designed to operate at currents as high as 100,000 amperes and has a *constant ratio* up to its designed value.

It is of reasonable size and weight.

It is easily applied because it requires only the determination of the maximum symmetrical current to which it may be subjected.

It is not affected by the d-c component of the short circuit current.

It can be used with the simplest type of relay, i.e., instantaneous overcurrent or any other type desired.

It does not produce any appreciable d-c component in its secondary.

Simple and brief calculations establish its performance with certainty for all possible conditions of operation up to the current limit for which it is designed.

Measurement and Control of Conductor Vibration

GORDON B. TEBO
ASSOCIATE AIEE

Synopsis: A method is outlined for determining the effectiveness of devices used for prevention of vibration fatigue in transmission conductors. Measuring equipment is described which provides records of conductor vibration in the quantitative form essential for such determinations. Vibration records obtained on typical constructions are analyzed and correlated with fatigue tests and operating experience to determine the probable life of the conductor. Data are given on the performance of test spans of a special loose-core A.C.S.R., as well as A.C.S.R. of standard stranding, for various span lengths, tensions, and equipped with various devices, including a double-suspension clamp, armor rods, Stockbridge dampers and a newly-developed torsional damper. Of the devices tested, dampers are shown to be most effective in reducing vibration stresses.

The Problem

THE occurrence of fatigue failures in conductors, and the more rapid deterioration observed with increase of span length and tension, disclosed a serious hazard in existing transmission lines. Pioneer investigations of Relf and Ower,[1] Varney,[2] and others showed that the fatigue failures were due to vibration of conductors in steady winds of relatively low velocity, and that the vibration was excited by wind eddies which exert alternating vertical forces on the conductor.

Many subsequent studies have been directed toward prevention of vibration fatigue in conductors and in these numerous investigations there naturally were developed many devices for vibration control. Unfortunately no method for comparing their effectiveness has been generally accepted and as a result, such widely different devices as armor rods, festoons, dampers, or special clamps have been extensively applied. Although reports of operating experience indicated satisfactory performance for some of the devices, no definite opinion could be formed of their comparative effectiveness.

Preliminary Studies

The Hydro-Electric Power Commission of Ontario, faced with this difficulty in adopting measures for protection of existing and proposed lines, commenced a program of vibration research. Some phases of this program have been described previously,[3,4,5] in which analyses have been made of the effect of conductor shapes, stress distribution, and energy loss in conductors due to travelling waves, and fatigue characteristics of steel wires.

Preliminary studies indicated the desirability of testing vibration-suppressing devices on full-size wind-excited spans, because no other method took full account of the complex relations between the wind eddies and conductor. In field tests of this nature it was recognized that the vibration records should reliably indicate the effectiveness of the various devices tested, in reducing or eliminating vibration fatigue. A survey was made to determine the limitations of available recording apparatus for this purpose.

Recording Apparatus Available

Clock-driven live-line recorders of the Zenith and Servis types[6] indicate amplitude approximately, but give no indication of frequency. These may be supplemented by cycle counters of the Jaquet type,[7] which register the total number of vibration cycles above a fixed amplitude. From the combined records, it is possible to estimate the approximate amplitude, number of hours vibration per day, and average frequency.

More complex recording mechanisms, using motor driven wax charts[6] or oscillographs[8] have been described. These measure the amplitude, frequency, and wave shape at a point on the conductor two feet or more from the suspension clamp, and thus indicate the effectiveness of dampers in suppressing vibration. They do not, however, provide a measure of the stress-relieving properties of special clamps or conductor reinforcements.

Two methods of recording the actual bending in a conductor adjacent to a suspension clamp, have been described. One[8] uses a mechanical linkage, connected by waxed strings to the conductor on opposite sides of the suspension clamp. Another[9] employs an optical arrangement to record on photographic film, the motion of the vibrating conductor relative to the suspension clamp.

A carbon-pack type of curvature recorder[4] has been found useful for oscillographic recording of travelling waves in conductors, and for recording curvatures due to aeolian vibration. However, its tendency to change calibration when left unattended, made it unsuitable for continuous vibration recording.

Development of Recording Equipment

None of the devices available appeared entirely satisfactory for the purpose of this investigation. In the development of new equipment for recording conductor vibration, the following requirements were recognized:

1. Because all fatigue breaks occur within an inch of suspension or strain clamps, knowledge of stress conditions in that region was considered essential.

2. No strain gauge was available to measure stresses in the individual strands under field conditions. A satisfactory alternative appeared to be the measurement of conductor curvature adjacent to the clamp. This could be accomplished by measuring the deflection of the conductor, relative to the clamp.

3. Deflections of the conductor occurring within an inch of the clamp, even under severe vibration, amount to only a few

thousandths of an inch. One essential of the recording device was therefore a sensitivity of 0.0001 inch.

4. Ability to record vibration on live lines was not considered essential because adequate test spans were available to simulate any existing or proposed construction. Tests could be made on new lines during construction, and system conditions were such that many existing lines could be interrupted for suitable test periods.

5. Other desirable characteristics of the measuring device were the ability to record deflections at all frequencies up to 60 cycles per second, stable calibration, lightness, and ruggedness.

A magnetic method for measurement of small mechanical movements, described by Mershon[10,11] and others, appeared applicable to this problem. This type of measuring device uses an iron magnetic circuit, excited at a relatively high frequency, usually between 500 and 2,000 cycles per second. The length of a small gap in the magnetic circuit is altered by the motion to be recorded. The resulting change in impedance of the exciting coil may be made to produce an electrical output proportional to the motion.

Figure 1 shows some details of the device developed for recording conductor vibration. Use of the double magnetic circuit shown, resulted in linear calibration over practically the whole travel of the armature. Effect of the non-linear relation of resistance to current in the selenium rectifier at low current was avoided by using a suitable bias current, obtained by initially unbalancing the rheostat (*G*). Sensitivity of the recording elements could be varied to provide ratios of oscillograph deflection to conductor deflection of any value between 10 and 1,000.

lifting or depressing the conductor. Correlation of micrometer readings with oscillograph deflections provided a calibration which was found to be reliable, and accurate to plus or minus five per cent on an one-inch oscillograph deflection. The static calibration values were found to apply, without correction, for the range of frequencies encountered in power conductor vibration. Although measurements could be made of conductor deflections to within 0.1 inch of a clamp, it was customary in field tests to record conductor motion about three inches from suspension clamps.

Five such units, in conjunction with a multiple filter and a six-element oscillograph, provided continuous records of conductor vibration on 5 spans, the sixth oscillograph element being used for a timing wave. Figure 3 shows the recording equipment in portable form as used on high voltage lines during construction.

Provision was first made to run the oscillograph film at a speed of two inches per hour, obtaining a continuous record of amplitude, and once every half hour, to increase film speed momentarily to record amplitude, frequency, and wave shape. The high speed records were found to provide the more useful information, and in later tests, the low speed records were discontinued. Figure 4 shows a record obtained on the two skywires and three power conductors of a 220 Kv. line before dampers had been erected. Figure 5 shows a record after the installation of dampers on the power conductors and festoons on the steel skywires.

Anemometer Records

The linear relation of vibration frequency to wind velocity, determined by Relf and Ower,[1] has been generally accepted. Nevertheless, it was thought desirable to obtain field records of instantaneous wind velocity, since most of the values reported were obtained by rotating-cup anemometers which are unable to record rapid fluctuations in velocity or direction. Following, in some respects, the designs of Sherlock and Stout,[13] an anemometer was developed for recording instantaneous values of wind velocity and direction on the same film as the vibration records. Figure 6 shows the anemometer, which was capable of following rapid fluctuations of wind velocity and direction and had a linear calibration over a range of 3 to 15 miles per hour.

Correlation of the anemometer records with those of conductor vibration have confirmed the generally accepted ideas that most vigorous vibration occurs in steady winds at velocities of two to ten miles per hour directly across the line; that conductors vibrate in variable winds, but at lower amplitudes; and that wind gusts produce no appreciable vertical motion of the conductor. Vibration frequency was occasionally found to deviate rather widely from the accepted relation to wind velocity. However, it was concluded that wind velocity records, even of the instantaneous type, added little to the information available from the vibration records.

Test Spans

A number of towers, providing a choice of span lengths from 300 to 1,400 feet were available in a level district where aeolian vibration occurs on undamped spans about 60 per cent of the time. By erecting suitable conductors and accessories in these spans, full scale models of existing or proposed line construction could be provided.

Comparison of vibration records obtained on the test spans with those obtained on similar spans of new lines being constructed, showed close agreement in maximum amplitude, range of frequencies, and number of cycles per day. Predictions of the performance of vibration suppression devices based on records in the test spans were confirmed by subsequent tests on actual lines.

Test spans were also provided for

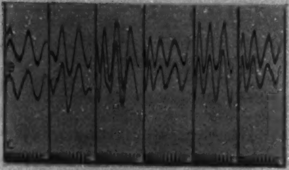

Figure 10. Conductor deflections recorded on opposite sides of rocking-type suspension clamp

C—Timing wave, 25 cycles per second

making endurance tests on 150-foot lengths of cable, strung at normal tension between concrete piers. At one end the cable was supported in a rigid clamp; at the other end, a motor drive was connected to produce vibration in the span at the desired frequency and amplitude.

Test Procedure

Under normal wind conditions at the test spans, it was found that vibration records covering a period of two weeks were sufficient to establish the performance of any span. During this period, the full range of effective wind velocities, vibration frequencies, and amplitudes were encountered, and additional records did not affect the average results appreciably. In testing damped spans, simultaneous records on undamped spans were usually obtained for comparison. It was found desirable that such undamped conductors be supported on separate towers to prevent excitation of the damped spans by tower vibration.

In analyzing the field data, certain assumptions were made to simplify the calculations and to permit presentation of the results in graphical form. For any one test, at least 500 momentary records of amplitude and frequency, taken one-half hour apart, were analyzed. Each half-hourly record, although it covered a time of less than one second, usually showed cycles of varying amplitude. Only the maximum amplitude was measured, and this was assumed to persist for the entire half-hour period. The frequency indicated was also assumed to persist for the half-hour period. Use of the maximum amplitude shown in each record introduces a conservative factor in the analysis, but this same factor would occur in analyzing any low-speed vibration record, which can register only the maximum values of quickly changing amplitudes.

Analyses of the records may be plotted to show the relations of amplitude, frequency, number of cycles per day, or number of hours vibration per day. The most useful types of graphs were found to be those shown in figure 7. The frequency range determined for any particular construction is essential information for the design of suitable dampers. The number of cycles per day at various deflections may be correlated directly with fatigue tests to determine the probable life of the conductor. It is not possible in fatigue tests to duplicate the varying amplitudes and frequencies which occur on field spans, but by choosing the frequency at which maximum stresses occur in the field, and by measurement of conductor deflection relative to the supporting clamp with the same instrument used to record field vibration, a satisfactory correlation may be obtained.

Effect of Span Length and Tension

In order to determine quantitatively the effect of variations in span length and tension, vibration records were obtained on three spans of 477,000 circular mil A.C.S.R. "Hawk" stranding. These spans were chosen to show the effects of fifty per cent reductions in either span length, tension, or both. Figure 8 shows the results obtained.

Reduction of span length only is shown to considerably reduce both the number of cycles per day and the maximum deflections. Reduction of both span length and tension further reduces the severity of vibration. The most significant fact, however, is that the installation of effective dampers on the longer span at the higher tension, provides much better suppression of vibration than is obtained by decreasing span length and tension.

Comparison of Loose-Core Cable and ACSR of Standard Stranding

Figure 11. Whiffletree suspension clamp on 477,000-circular-mil ACSR with deflection recorder mounted on ring-type suspension clamp

A form of cable described by Preiswerk,[13] is claimed to be vibrationless because of interference between the wind-excited outer aluminum envelope and the loose steel core. A 1,000-foot length of this cable (477,000 circular mil) was erected in suspension clamps on two towers, providing a test span of 650 feet, at a tension of 2,975 pounds. The ends of the cable were fitted with special strain clamps which provided the specified division of tension between the aluminum envelope and the steel core. On the same towers was erected a 477,000 circular mil A.C.S.R. "Hawk" stranding at a tension of 3,600 pounds. Records of vibration were obtained on both cables, with results as shown in figure 9. The loose-core cable shows considerably smaller deflections, due to vibration, than the undamped standard cable and entirely eliminates vibration at frequencies above 18 cycles per second. The suppression obtained on the loose-core conductor is, however, less complete than that provided by effective dampers on the standard cable.

Comparison of Suspension Clamps

Because vibrations in adjacent spans are seldom of the same frequency, conductor motions on the two sides of a suspension clamp continually shift in phase relation. When this relation is such that conductor motion is upward (or downward) on both sides of the clamp simultaneously, it is evident that the clamp,

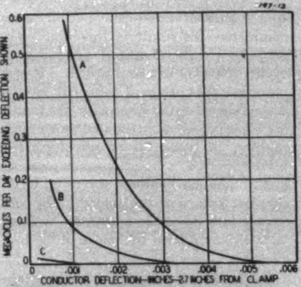

Figure 12. Comparison of single and double suspension clamp on 477,000-circular-mil ACSR Hawk in 650-foot spans at 3,600 pounds tension

A—Single ring-type suspension clamp

B—Two ring-type suspension clamps on 30-inch whiffletree

C—Single clamp on span equipped with dampers no matter how light or well pivoted, will remain stationary, and will react on the conductor as a rigid clamp. Thus an ideal clamp with zero pivot friction and zero inertia could be expected to reduce the number of stress cycles, but not to reduce the maximum stresses. Field measurements show that available types of pivoted suspension clamps fulfil this condition. Figure 10 is a record of deflections on opposite sides of the suspension clamp shown in figure 2, which shows the instantaneous conductor stresses to be equal on opposite sides of the clamp.

An attempt to overcome this limitation of the single pivoted suspension clamp resulted in development of a whiffletree clamp which consists of a bar about three feet long, supported at its centre, and carrying a suspension clamp at each end as shown in figure 11. A comparison of this form of clamp with the single suspension clamp is shown in figure 12. The benefit of the double suspension indicated in these tests has been confirmed by field experience, in which a decided reduction in the rate of fatigue breaks has been obtained over a 10-year period of observation, in comparison with single suspensions.

New Damper Developed

In the course of these investigations, a new principle was employed in the suppression of aeolian vibrations, which resulted in development of an effective and economical damper. It is well known that when a vertical motion is imparted to a 1,000-foot undamped span of power conductor, the resulting travelling wave may be clearly identified after several cycles of travel between towers. It was observed that when a torsional motion was imparted to the same span, the resulting torsional wave attenuated much more rapidly. A converter to transform the wind-imparted vertical oscillations to highly damped torsional waves is, in its simplest form, a mass clamped to the conductor with its centre of gravity horizontally displaced from the centre of the conductor.

On certain conductors, having exceptionally high torsional damping, the rigid eccentric weight is reported[14] to give satisfactory suppression of aeolian vibration. However, on long spans of A.C.S.R. at high mechanical tension, the simple torsional damper did not give the desired degree of suppression. A modification of this damper, employing a resilient joint of rubber at the centre of gravity of the weight, permitted more effective and economical design, and showed the following advantages in operation:

1. **The resilient connection between the weight and conductor lessened the possibility of stress concentration in the conductor at the point of attachment.**

2. **By properly proportioning the damper weight, moment of inertia, arm length, and resilience of the joint, effective suppression of aeolian vibration could be obtained over the entire range of frequencies encountered on any particular conductor.**

The determination of optimum values for these factors was guided by mathematical analysis[15] but in all cases, designs arrived at by theoretical considerations were checked for performance on wind-excited spans. Figure 13 shows a design of torsional damper found effective on 1,150-ft. spans of 795,000 c.m. ACSR "Drake" at 5,500 pounds tension using two dampers per span, one mounted 6 feet from each suspension clamp.

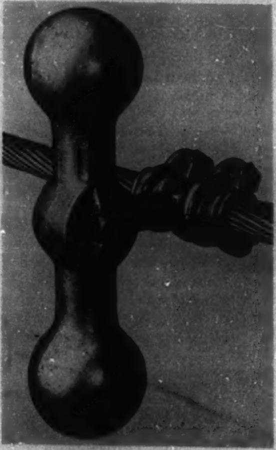

Figure 13. Torsional damper for 795,000-circular-mil ACSR

Comparison of Dampers and Reinforcing Devices

Devices designed to suppress the amplitude of vibration throughout the span to a value which will not produce fatigue failures in the conductor, are properly called "dampers" and in this investigation two forms were tested, the well-known Stockbridge damper, and a newly-developed torsional damper.

Devices which act primarily as reinforcements may effect only a small reduction in vibration amplitude throughout the span, but by stiffening the conductor in the region where failures usually occur, seek to prevent stress concentration. Of this type, two devices were tested: the well-known tapered aluminum armor rods which form a spiral wrapping around the conductor, and a cable absorber consisting of a six-foot length of the power conductor, carried above the main conductor in a double-barreled clamp, its ends fastened to the main conductor with light aluminum clamps.

A comparison of these four devices, installed as shown in figure 14, was made on spans representing a proposed 220 Kv. line. The essential information for comparing their effectiveness is also plotted in figure 14. Examination of the oscillographic records discloses other differences in operation. Spans equipped with reinforcing devices vibrate throughout the same range of frequencies as the undamped span, whereas dampers suppress all but the lowest frequencies. The Stockbridge damped span permitted vibrations at frequencies up to 3 cycles per second and deflections of 0.003 inch, of which a typical record is shown in figure 5. On the torsional damped span, no deflections exceeding 0.001 inch were recorded, and no single frequency could be identified to indicate resonant vibration.

The possibility of extending the effective frequency range of torsional dampers still lower, to suppress galloping of conductors has been considered. Present conceptions of a damper to be effective at 0.5 cycle per second appear unreasonably large for general use.

Estimated Safe Deflection

For any conductor, under normal tension and supported in a specified clamp, there is some value of alternating deflection which the conductor will withstand indefinitely without fatigue failure. One method of determining this value would be to vibrate specimens of the cable at normal tension and at various deflections until a strand failure occurs. By plotting a curve of deflection on number of cycles to failure, the deflection which the cable can withstand indefinitely may be determined. This procedure, especially for large aluminum conductors which vibrate normally at low frequencies, and which may require up to 500 million cycles to produce failure, is not considered justifiable until further investigation has determined the effects of such variables as corrosion, infrequent

overstresses such as those produced by galloping conductors, surface defects, or abrasions. These uncertainties must now be allowed for by an arbitrary safety factor.

The fatigue characteristics of an aluminum strand subjected to bending stress reversals, but without tension load, may be determined readily on a high speed fatigue test machine such as the Haigh-Robertson.[5] As shown in figure 15, the stress-life relation is such that if a stress which causes failure in one million cycles be reduced by 50 per cent, infinite life can be expected. Similarly, a stress reduction of 30 per cent will increase a ten million cycle life to infinity.

Little information is available concerning the fatigue characteristics of aluminum under the combined stresses of tension and reversed bending. It has been shown[16] that for steel, the superposition of tension on reversed bending stresses reduces the allowable stress range, but that the shape of the *S-N* curve is not greatly altered. Assuming that a similar relation exists for aluminum, it should be possible, from endurance tests on a stranded conductor at one measured deflection, to estimate the safe deflection below which fatigue failures would not occur. For example, an endurance test was carried out on a 477,000 circular mil A.C.S.R. at 3,600 pounds tension, set up to approximate the field test conditions of curves *A* or *B*, figure 8. The cable was vibrated to produce a deflection of 0.006 inch at a distance 2.7 inches from the clamp, and the first strand failure occurred at 26 million cycles. From figure 15, it appears that a stress reduction of 20 per cent would have prolonged conductor life to infinity. Referring again to figure 8, the estimated safe deflection for the conditions of curves *A* and *B* would be $0.006 \times 0.80 = 0.0048$ inch.

A third method, which was used in estimating the safe deflection shown in figure 14 is based upon operating experience with the actual conductor. Several hundred miles of 795,000 circular mil A.C.S.R. equipped with cable absorbers as shown in figure 14 have been in operation for 10 years. Periodic inspections have shown no fatigue failures at suspension clamps. Curve *A* of figure 14 shows that this construction has withstood deflections exceeding 0.006 inch totalling 0.030 megacycle per day, or about 100 million cycles in the 10-year period. Figure 15 shows that a stress reduction of 15 per cent would increase conductor life from 100 million cycles to infinity, hence the estimated safe deflection is $0.006 \times 0.85 = 0.0051$ inch.

Conclusions

1. Vibration of large diameter A.C.S.R. conductors in spans exceeding 1,000 feet and at tensions exceeding one-sixth the ultimate strength may be expected to produce fatigue failure unless protective devices are applied.

2. Reduction of such span lengths and tensions by fifty per cent provides less reduction in vibration stresses than is accomplished by the application of suitable dampers.

3. A special stranding "loose core" A.C.S.R. effectively suppresses vibration in the upper range of frequencies. The overall suppression is, however, much less effective than that provided by dampers on A.C.S.R. of standard stranding.

4. Reinforcing devices such as armour rods, are much less effective than dampers in reducing vibration stresses on large A.C.S.R. conductors.

5. Available dampers reduce conductor deflections well below the limit indicated as safe both by operating experience and by fatigue tests on conductors. The factor of safety thus provided is considered adequate to cover all uncertainties in field observations or in estimating fatigue limits for the conductors.

Analytical Methods of Solving Discrete Nonlinear Problems in Electrical Engineering

E. G. KELLER
MEMBER AIEE

Synopsis: More often than not, the non-linear problems of electrical engineering arise from discrete physical systems and are usually reducible mathematically to the solution of systems of non-linear total differential equations or to systems of non-linear integral equations. Six independent methods of solving discrete non-linear problems are given in this paper. Each method is illustrated by means of an electrical engineering problem. The illustrative examples employed pertain to a-c and d-c non-linear circuits, reluctance-induction motors, hunting of and dynamic braking of synchronous machines. References to additional methods are given in the bibliography. The 88 given references listed represent approximately ten per cent of the field, but many of the entries contain a bibliography on their respective fields.

The accelerated growth of research in the field of non-linearity is due to different causes. The general advancement of science requires increasingly more precise expressions for the laws of science. Accurate non-linear equations frequently depart from the linearized or postulated linear equations which have been previously used for approximate results. The quest for perfection and generalization and the love of difficult investigations by professional mathematicians play a large part in this growth. A recent incentive is the increasingly exacting requirements of modern manufacturing. These requirements are born of the competitive necessity of producing ever improved machines and equipment in the most economical manner.

Definition; Characteristics of Two General Fields

A NON-LINEAR problem (discrete or continuous) may be defined as one which, when formulated mathematically, reduces to (one or) a system of differential integral, or integro-differential equations such that at least one of the three quantities; a derivative, an integral, or a dependent variable is involved transcendentally or algebraically to a power other than the first in at least one equation of the system or in at least one mathematical boundary condition of the system.

Non-linear problems resolve themselves into two general types; continuous and discrete. The first type deals with the behavior of quantities in a field or in at least one continuous region of space and more often than not reduces mathematically to systems of non-linear partial differential equations. Problems relating primarily to this field have been treated by Dr. Theodore von Kármán in a paper[1] which is both a mile stone and a beacon of progress in that it is an admirable exposition and inventory of the non-linear problems of continuous fields and at the same time an inspiration and invitation both to the engineer and mathematician for further advancement in this difficult field. Discrete non-linear systems are characterized by a finite number of degrees of freedom. They are at least frequently reducible mathematically to systems of non-linear and ordinary (total) differential equations.

Scope and Plan of Paper

The material of the present paper is restricted to the field of discrete non-linearity. Six powerful methods of solving discrete non-linear problems are given but references to as many more are found in the bibliography. The method of presentation is to (*a*) display the fundamental systems of equations and forms of each method, (*b*) illustrate the application of each method by the solution of a non-linear problem in electrical engineering. The methods range over a time span from Euler to Galerkin, but the solutions of the engineering problems are new.

It should perhaps be stated that the elementary methods of variables separable, homogeneous forms, etc., of a first course in differential equations are excluded from this paper. They comprise a field with which everyone is familiar or can become so with little effort. Likewise, the solution of non-linear equations as power series in the independent variables is also excluded; partially for the same reason and for the additional reason that such solutions are, in general, largely devoid of physical interpretation.

Before displaying the first method it is recalled that any system of ordinary differential equations is reducible to the so-called normal form by the simple introduction of new variables. The reduction to normal form is made clear by the reduction of an equation of hunting of a synchronous machine. An equation of hunting,[2] in a certain reduced form, is

$$\frac{d^2\theta}{dt^2}+k(1-b\cos 2\theta)\frac{d\theta}{dt}+c\sin 2\theta+(1-\epsilon^{-at})\sin\theta=T \quad (1)$$

The substitution of $\theta=\theta_1$, $\dfrac{d\theta}{dt}=\theta_2$ in equation 1 yields

$$\frac{d\theta_1}{dt}=\theta_2$$

$$\frac{d\theta_2}{dt}=T-k(1-b\cos 2\theta_1)\theta_2-c\sin 2\theta_1-(1-\epsilon^{-at})\sin\theta_1 \quad (2)$$

Equations 2 are equation 1 reduced to normal form. The general normal form for an *n*th order system of differential equations is

$$\begin{aligned}&\frac{dx_1}{dt}=f_1(x_1, x_2, \dots, x_n;\ t)\\ &\dots\dots\dots\dots\dots\dots \qquad (3)\\ &\frac{dx_n}{dt}=f_n(x_1, x_2, \dots, x_n;\ t)\end{aligned}$$

or

$$x_i'=f_i(x_j;\ t) \qquad (i, j=1, 2, \dots, n) \qquad (4)$$

In equation 1 the terms represent respectively the inertial, amortisseur, reluctance, synchronous, and load torques.

Six Methods of Solution

1. Solution in Power Series in Parameters; Type I

The first method considered, and the second oldest, is due to Euler. If a system of differential equations is, or can be reduced by changes of variables, or by any method whatsoever to the form

$$x_i'=rf_i(x_j, r;\ t) \qquad (i, j=1, 2, \dots, n) \qquad (5)$$
$$x_j(t_0)=a_j$$

where the $f_i(x_j,r;\ t)$ are analytic in x_j and r and continuous in t for

$$|x_j-a_j|<r_j,\ t_0\leqq t\leqq T, \text{ and } |r|<r_0$$

then there exists a solution in the form of the infinite series

$$x_j=x_j^{(0)}(t)+x_j^{(1)}(t)r+x_j^{(2)}(t)r^2+\dots \qquad (j=1, 2, \dots, n) \qquad (6)$$

Paper 41-107, recommended by the AIEE committee on basic sciences, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 14, 1941; made available for preprinting May 2, 1941.

E. G. Keller is mathematician and research engineer, Lockheed Aircraft Corporation, Burbank, Calif.

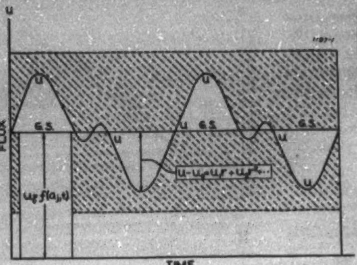

Figure 1 (left). Type I. Solution of a nonlinear problem whose generating solution is a constant

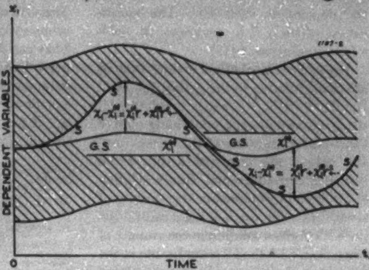

Figure 2 (right). Type II. Solution in the vicinity of a function

which is convergent for some value of $r>0$. The proof, which is by means of dominant functions, of the above statement is found in the literature.[3] The primary objective of this paper lies in the methods of construction of solutions.

To obtain the infinitude of functions $x_j^{(k)}$ in equations 6 expand the $f_i(x_j,r;t)$ in power series in x_j-a_j and r, substitute in these expansions the values of x_j-a_j from equations 6, equate to zero the coefficients of each power of r in the resulting equations thus obtaining the sequence of equations

$$x_i'^{(1)}=f_i(a_j,0;\ t)\quad (i=1,2,\ldots,n) \tag{7}$$

$$x_i'^{(2)}=\sum_{j=1}^{n}\frac{\partial f_i}{\partial x_j}x_j^{(1)}+\frac{\partial f_i}{\partial r} \tag{8}$$

……………………

$$x_i'^{(k)}=\text{polynominals in }(x_j^{(1)},\ldots,x_j^{(k-1)};\ t)\quad (k=3,4,\ldots) \tag{9}$$

Equations 7, 8, 9 are linear equations since the partial derivatives are constants, the x_j having been replaced by a_j. Equations 7 are integrable at once. The values of $x_j^{(1)}$ obtained from (7) are substituted in (8). The values obtained from (8) are substituted in (9). Equations 7, 8, 9 are thus said to be integrated sequentially. The solution of a system of differential equations defining the effect of resistance in non-linear control circuits[4] is an application of the first method. The equations are

$$\begin{aligned}u'&=-r(1+3b_3y_1^2+5b_5y_1^4)u\cos^2(t+v)\\ v'&=+r(1+3b_3y_1^2+5b_5y_1^4)\sin(t+v)\times\cos(t+v)\end{aligned} \tag{10}$$

where the b_n are constants and

$$y_1=u\sin(t+v),\quad y_2=u\cos(t+v)$$

By the theory there exists the solution

$$\begin{aligned}u&=u_0+u_1r+u_2r^2+\ldots\\ v&=v_1r+v_2r^2+\ldots\end{aligned} \tag{11}$$

where the functions $u_0,u_1,\ldots$ and $v_1,v_2,\ldots$ are defined by the equations

$$u_0'=0$$

$$u_1'=f_2\sin 2t+f_4\sin 4t+f_6\sin 6t,$$

……………………

$$\begin{aligned}v_1'&=-(e_0+e_2\cos 2t+e_4\cos 4t+e_6\cos 6t),\\ v_2'&=(g_2\sin 2t+g_4\sin 4t+g_6\sin 6t)u+2v_1(f_2\cos 2t+2f_4\cos 4t+4f_6\cos 6t)\end{aligned}$$

…………………… (12)

Since the right members of equations 12 are functions of the time only, the problem is reduced to quadratures.

The geometrical significance of the solution of equations 5 or 10 is important in view of the methods which follow. In figure 1 it is observed that the solution u is in the vicinity of a constant value labelled u_0. The parameter r measures the departure of u from u_0. Scale values are not shown on the figure because time t is not in seconds and u and v are functional values largely devoid of physical significance. (Reference 4 may be consulted.)

2. Solution in Power Series in Parameters; Type II

This method also had its beginning with Euler, but the analytical perfection of the method (questions of convergence, etc.) is due to Cauchy[5] and Poincaré.[6] The fundamental system of differential equations in the normal form is

$$x_i'=f_i(x_j;\ t)+rg_i(x_j,r;\ t)\quad (i,j=1,2,\ldots,n) \tag{13}$$
$$x_j(t_0)=a_j$$

where the $f_i(x_j;\ t)$ satisfy the same conditions as in method 1. The $g_i(x_j,r;t)$ are analytic in $x_j-x_j^0$ and r uniformly with respect to t and are continuous in t for all x_j, r, and t for which

$$|x_j-x_j^{(0)}|\leqq r_j,\quad |r|\leqq\sigma,\quad t_0\leqq t\leqq T\leqq T^{(0)}$$

The first step in the solution of (13) is to find the solution of the system

$$x_i'=f_i(x_j,t),\ x_i(t_0)=a_i,\ (i,j=1,2,\ldots,n) \tag{14}$$

The solution of this system may possibly be accomplished by the elementary methods of a first course in differential equations. If the solution of equations 14 is difficult, recourse may be had to the methods of this paper. Let us suppose then that the solution of (14) has been accomplished and denote this solution by

$$x_j=x_j^{(0)}(t)\quad (j=1,2,\ldots,n) \tag{15}$$

Solution 15 is called the generating solution of (13). It is provable[7] that there exists a solution of (13) of the form

$$x_j-x_j^{(0)}=x_j^{(1)}(t)r+x_j^{(2)}(t)r^2+\ldots\quad (j=1,2,\ldots,n) \tag{16}$$

which is convergent for r sufficiently small.

To construct the formal[7] solution of (13) expand $f_i(x_j,t)$ and $g_i(x_j,r;t)$ as a power series in $x_j-x_j^{(0)}$ and r, substitute in these expansions and in equation 13 the value of $x_j-x_j^{(0)}$ as given by equations 16, and finally equate to zero the coefficients of each power of r. The resulting differential equations are

$$x_i'^{(0)}=f_i(x_j^{(0)};\ t),\quad x_j^{(0)}(t_0)=a_j$$

$$x_i'^{(1)}-\sum_{j=1}^{n}\frac{\partial f_i}{\partial x_j}x_j^{(1)}=g_i(x_j^{(0)},0;\ t)$$

$$x_i'^{(2)}=\sum_{j=1}^{n}\frac{\partial f_i}{\partial x_j}x_j^{(2)}$$

$$=\tfrac{1}{2}\sum_{j=1}^{n}\sum_{k=1}^{n}\frac{\partial^2 f_i}{\partial x_j\partial x_k}x_j^{(1)}x_k^{(1)}+\sum_{j=1}^{n}\frac{\partial g_i}{\partial x_j}x_j^{(1)}+\frac{\partial g_i}{\partial r} \tag{17}$$

……………………

There are the following observations relative to equations 17. The solution of the first system of (17) is (15). (If this solution can not be obtained, then the present method is not applicable.) When the values $x_i^{(0)}(t)$ for the $x_j^{(0)}(t)$, determined by the solution of the first of (17) are substituted in the next system of (17) these differential equations are linear in $x_j^{(1)}$. The second system is now solved for $x_i^{(1)}$ and the values obtained are substituted in the third system whose dependent variables are $x_j^{(2)}$. Thus equations 17 are solved sequentially. All of equations 17, the first excepted, are linear in the dependent variables. The substitution of the $x_j^{(k)}$ in equations 16 yields a formal solution of (13).

The gist of this method is that if the rg_i are small relative to the f_i (say $1/_{10}$ of f_i) and if equations 14 are easy to solve and if the g_i are complicated, containing most of the troublesome terms of the system (usually only a few terms of a differential system are troublesome) then a solution of (13) can be obtained in the vicinity of $x_i = x_i^{(0)}(t)$. The method is a powerful one since it affords a solution in the vicinity of a function. Method 2 is applicable in the case of transients in synchronous machines when resistances are taken into account. Again it is applicable in perturbation theory in celestial mechanics,[8] where the method originated. If the perturbative forces of a third or of n bodies are slight, then the generating solution is the elliptical orbit in the problem of two bodies. The engineering problem illustrating this method is combined with that of method 4. See figure 2.

3. METHOD OF VARIATION OF PARAMETERS

Of the methods here presented the method of variation of parameters[9] is the oldest. Its first beginnings, in geometric form, are due to Newton. Let the fundamental differential equations be

$$x_i' = F_i(x_j;\ t) \equiv f_i(x_j;\ t) + g_i(x_j;\ t)$$
$$x_j(t_0) = a_j, \qquad (i, j = 1, 2, \ldots, n) \qquad (18)$$

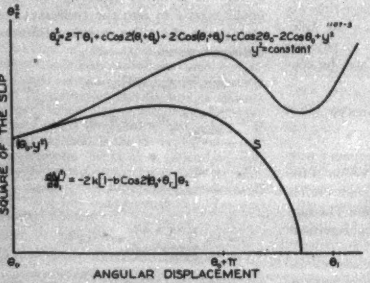

Figure 3. Hyperelliptic method

Synchronous motor operating as an induction-reluctance motor employed as an illustrative example

Generally, the n functions F_i can be resolved into $2n$ functions f_i and g_i in more than one way. This resolution is usually accomplished such that the f_i and g_i possess physical significance.

Let the solution of

$$x_i' = f_i(x_j;\ t) \qquad (i, j = 1, 2, \ldots, n) \qquad (19)$$

be

$$x_i = \phi_i(y_1, y_2, \ldots, y_n;\ t)\ (i = 1, 2, \ldots, n) \qquad (20)$$

The y_k in equations 20 can be viewed as n arbitrary constants of the solution of (19). They can also be viewed as a set of n new dependent variables and (20) are then not only the solution of (19) but are also equations of change of variables from x_i to y_i. If the second point of view is taken, the substitution of (20) in (19) yields

$$\frac{\partial x_1}{\partial y_1}\frac{dy_1}{dt} + \frac{\partial x_1}{\partial y_2}\frac{dy_2}{dt} + \ldots + \frac{\partial x_1}{\partial y_n}\frac{dy_n}{dt} + \underline{\frac{\partial \phi_1}{\partial t}} =$$
$$f_1\underline{[\phi_j(y_1, y_2, \ldots, y_n;\ t);\ t]} + g_1[\phi_i(y_k;\ t);\ t]$$
$$\frac{\partial x_2}{\partial y_1}\frac{dy_1}{dt} + \frac{\partial x_2}{\partial y_2}\frac{\partial y_2}{dt} + \ldots + \frac{\partial x_2}{\partial y_n}\frac{dy_n}{dt} + \underline{\frac{\partial \phi_2}{\partial t}} =$$
$$f_2\underline{[\phi_j(y_1, y_2, \ldots, y_n;\ t);\ t]} + g_2[\phi_j(y_k;\ t);\ t]$$
$$\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots \qquad (21)$$
$$\frac{\partial x_n}{\partial y_1}\frac{dy_1}{dt} + \frac{\partial x_n}{\partial y_2}\frac{dy_2}{dt} + \ldots + \frac{\partial x_n}{\partial y_n}\frac{dy_n}{dt} + \underline{\frac{\partial \phi_n}{\partial t}} =$$
$$f_n\underline{[\phi_j(y, y, \ldots, y_n;\ t);\ t]} + g_n[\phi_j(y_k;\ t);\ t]$$

Those terms in (21) which are underlined vanish because equations 20 satisfy (19).

The new system of differential equations to be solved then is (21) with the underlined terms deleted. This new system is solvable by determinants for dy_1/dt, $dy_2/dt, \ldots, dy_m/dt$. When this has been done the resulting system in $y_1, y_2, \ldots, y_n$ is in the normal form This system, in general, is non-linear but it may be more easily solvable than (18). Moreover, the system is of a form to which many devices[10] are applicable. For example, if it is known from physical considerations that the y_k are slowly changing functions of the time, then the y_k in $g_i(y_k;\ t)$ are replaceable by constant values. The accuracy is not seriously impaired. Under this condition the system (21) is linear.

The equation of hunting is used to illustrate method 3. The system is

$$\theta_1' = \theta_2$$
$$\theta_2' = T - k(1 - b\cos 2\theta_1)\theta_2 - c\sin 2\theta_1 - \sin\theta_1 \qquad (22)$$

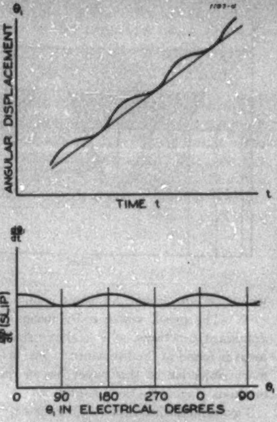

Figure 4. Variation of parameters

Hunting equations of a synchronous machine

$$\theta_1(t_0) = \theta_0,\ \theta_2(t_0) = y$$

Division of the second by the first of (22) yields

$$\frac{d\theta_2}{d\theta_1} = T - c\sin 2\theta_1 - \sin\theta_1 - k(1 - b\cos 2\theta_1) =$$
$$f(\theta_1, \theta_2) + g(\theta_1) \qquad (23)$$

The solution which satisfies the boundary conditions of (22), of

$$\frac{d\theta_2}{d\theta_1} = \frac{T - c\sin 2\theta_1 - \sin\theta_1}{\theta_2} \qquad (24)$$

is

$$\theta_2^2 = 2T\theta_1 + c\cos 2(\theta_1 + \theta_0) + 2\cos(\theta_1 + \theta_0) -$$
$$c\cos 2\theta_0 - 2\cos\theta_0 + y^2 \qquad (25)$$

where y^2 is an arbitrary constant or a new variable. The equation corresponding to (21) is

$$\frac{\partial\theta_2}{\partial(y^2)}\frac{d(y^2)}{d\theta_1} + \frac{\partial\theta_2}{\partial\theta_1} = \frac{T - c\sin 2\theta_1 - \sin\theta_1}{\theta_2} -$$
$$k(1 - k\cos 2\theta_1) \qquad (26)$$

or

$$\frac{d(y^2)}{d\theta_1} = -2k[1 - b\cos 2(\theta_0 + \theta_1)]\theta_2 \qquad (27)$$

Equation 27 is solvable by method 1. It should perhaps be stated that although (22) are not the latest[11] equations of hunting of a synchronous machine they serve the purpose of this paper.

4. HYPERELLIPTIC METHOD

This method is one of great power in the solution of problems involving non-linear springs, non-linear circuits, and in problems where the periods of the motions (currents) are dependent upon some nonlinear function of the displacements (charges). The fundamental system of differential equations and the general procedure are both evident from the solution of an illustrative example.

Let it be required to solve the nonlinear differential equation of motion of the rotor of an induction-reluctance motor. If the last term in the second of (22) is deleted then the resulting equations are the equations of performance of an induction-reluctance motor. If $2\theta_1 = x_1$ the equations become

$$\frac{dx_1}{dt} = x_2$$

$$\frac{dx_2}{dt} = 2T - kx_2 - 2r\sin x_1 + k\mu r x_2 \cos x_1 \qquad (28)$$

where $\mu r = kb$ and where typical numerical constants for machines of present manufacture are

$0 < b < 0.5$, $0.028 < k < 0.11$ (k for electrical degrees)
$0.3 < T < 0.8$, $0.250 < r < 0.50$

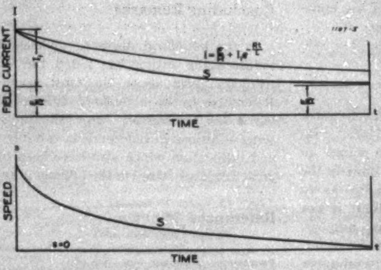

Figure 5. Method of nonlinear integral equations

Dynamic braking of a synchronous motor

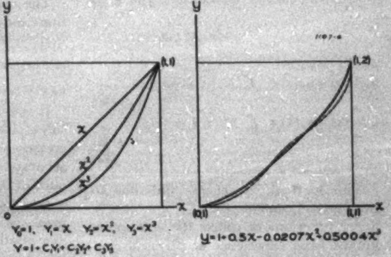

Figure 6. Exact and approximate solution by Galerkin's method

In the construction of a solution of (28) several characteristics of the desired solution must be kept in mind. It is known from experience and physical considerations that the steady-state solution of (28) consists of an oscillatory component superimposed on a constant component of slip. (See figure 4.) The oscillating component of slip is induced by the reluctance and damping torques represented by the last two terms in the second of (28). The oscillating component of the steady-state solution is periodic of unknown period. The period of the oscillating component and the magnitude of the constant component of slip are, from physical considerations, mutually dependent. The purpose of this solution is to determine the position of the rotor at the time of switching on of the field voltage for at this time the motor becomes a synchronous motor. In other words the present solution determines the initial conditions for the solution of (22). If in equation 1 the term representing the synchronizing torque is omitted and the changes of variables $2\theta = x_1$ and $t = (1+\delta)\tau$, where $\delta = \delta_1 r + \delta_2 r^2 + \ldots$, are performed then the resulting differential equation is

$$\frac{d^2x_1}{d\tau^2} = 2T(1+\delta)^2 - k(1+\delta)(1 - b\cos x_1)\frac{dx_1}{d\tau} - 2r(1+\delta)^2 \sin x$$

or, in the normal form

$$x_1' = x_2$$
$$x_2' = 2T(1+\delta)^2 - k(1+\delta)(1 - b\cos x_1)x_2 - 2r(1+\delta)^2 \sin x_1 \qquad (29)$$

where $x' = dx_i/d\tau$. Expand $\cos x_j$ and $\sin x_j$ in powers of $x_j - x_j^{(0)}$, substitute

$$x_j - x_j^{(0)} = x_j^{(1)} r + x_j^{(2)} r^2 + \ldots \quad (j = 1, 2) \qquad (30)$$

in (29) and equate to zero the coefficients of like powers of r. The resulting sequence of equations is

$$x_1^{(0)\prime} = x_2^{(0)} \qquad (31)$$

$$x_2^{(0)\prime} = -kx_2^{(0)} + 2T \qquad (32)$$

$$x_1^{(1)\prime} = x_2^{(1)} \qquad (33)$$

$$x_2^{(1)\prime} = -k(\delta_1 x_2^{(0)} + x_2^{(1)} - \mu x_2^{(0)} \cos x_1^{(0)}) - 2\sin x_1^{(0)} + 4T\delta_1 \qquad (34)$$

$$x_1^{(2)\prime} = x_2^{(2)} \qquad (35)$$

$$x_2^{(2)\prime} = -k\{\delta_2 x_2^{(0)} + \delta_1(x_2^{(1)} - x_2^{(0)}\mu \cos x_1^{(0)}) + x_2^{(2)} + x_1^{(1)} x_2^{(0)} \mu \sin x_1^{(0)} - x_2^{(1)} \mu \cos x_1^{(0)}] - 2x_1^{(1)} \cos x_1^{(0)} - 4\delta_1 \times \sin x_1^{(0)} + 2T(\delta_1^2 + 2\delta_2) \qquad (36)$$

……

The general solution of (31-32) is

$$x_1^{(0)} = -\frac{A_0}{k}\epsilon^{-k\tau} + \frac{2T}{k}\tau + C_0 \equiv -\frac{A_0}{k}\epsilon^{-k\tau} + e\tau + C$$

$$x_2^{(0)} = A_0\epsilon^{-k\tau} + \frac{2T}{k} \equiv A_0\epsilon^{-k\tau} + e$$

Since only a steady-state periodic solution is desired $A_0 = C_0 = 0$ and thus

$$x_1^{(0)}(0) = 0, \qquad x_2^{(0)}(0) = \frac{2T}{k} \qquad (37)$$

$$x_1^{(0)}(\tau) = e\tau, \qquad x_2^{(0)}(\tau) = e \qquad (38)$$

The general solution of (33-34) is

$$x_1^{(1)} = e\delta_1\tau + \left[\frac{e(k^2\mu+2)\sin e\tau - k(\mu e^2 - 2)\cos e\tau}{e(e^2+k^2)}\right] - \frac{A_1}{k}\epsilon^{-k\tau} + C_1 \qquad (39)$$

$$x_2^{(1)} = e\delta_1 + \left[\frac{k(\mu e^2 - 2)\sin e\tau + e(k^2\mu+2)\cos e\tau}{(e^2+k^2)}\right] + A_1\epsilon^{-k\tau} \qquad (40)$$

Evidently, $A_1 = C_1 = 0$. If a term linear in τ remains in (39-40) then the solution of (35-36) will contain terms of the form $\tau \sin e\tau$ and $\tau \cos e\tau$. Periodicity renders this impossible. Consequently $\delta_1 = 0$.

Next (38) and (39-40) are substituted in (35-36). The periodicity condition determines δ_2 which does not vanish. The process of sequential integration can be carried as far as desired.

The final solution in θ_i as far as the terms in r^2 is

$$\theta_1 = \frac{e\tau}{2} + \frac{r}{2} \times \left[\frac{e(k^2\mu+2)\sin e\tau - k(e^2\mu - 2)\cos e\tau}{e(e^2+k_2)}\right] + \frac{r^2}{2}\left[\frac{(k\beta - 2e\alpha)\sin 2e\tau - (k\alpha + 2\beta e)\times \cos 2e\tau}{2e(k^2+4e^2)}\right] + \ldots$$

$$\theta_2 = \frac{e}{2} + \frac{r}{2}\left[\frac{k(\mu e^2 - 2)\sin e\tau + e(k^2\mu+2)\cos e\tau}{(e^2+k^2)}\right] + \frac{r^2}{2}\left[\frac{(k\beta - 2e\alpha)\cos 2e\tau + (k\alpha + 2\beta e)\times \sin 2e\tau}{(k^2+4e^2)}\right] + \ldots$$

where

$$\delta_2 = \frac{2 - \mu e^2}{e^2(e^2+k^2)}, \quad \alpha = \frac{k^2\mu(\mu e^2 - 2) - (k^2\mu + 2)}{(e^2+k^2)},$$

$$\beta = \frac{ke^2\mu(k^2\mu+2) + k(\mu e^2 - 2)}{e(e^2+k^2)}$$

The solution is periodic of period 2π in τ, and of period $2\pi(1+\delta)$ in t.

5. Method of Nonlinear Integral Equations

If a problem is reducible to Lalesco's non-linear integral-equation system

$$u_1(x)=\phi_1(x)+\int_0^x K_1[x,\xi,u_1(\xi),\ldots,u_n(\xi)]d\xi$$
$$u_2(x)=\phi_2(x)+\int_0^x K_2[x,\xi,u_1(\xi),\ldots,u_n(\xi)]d\xi$$
$$\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots$$
$$u_n(x)=\phi_n(x)+\int_0^x K_n[x,\xi,u_1(\xi),\ldots,u_n(\xi)]d\xi \qquad (41)$$

then there exists a solution which is the limit of the infinite sequences

$$u_1(x)=\phi_1(x)$$
$$u_1^1(x)=\phi_1(x)+\int_0^x K_1[x,\xi,\phi_1(\xi),\ldots,\phi_n(\xi)]d\xi$$
$$u_1^2(x)=\phi_1(x)+\int_0^x K_1[x,\xi,u_1^{(1)}(\xi),\ldots,u_n^{(1)}(\xi)]d\xi$$
$$\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots$$
$$u_2^{(0)}(x)=\phi_2(x)$$
$$u_2^{(1)}(x)=\phi_2(x)+\int_0^x K_2[x,\xi,\phi_1(\xi),\ldots,\phi_n(\xi)]d\xi$$
$$u_2^{(1)}(x)=\phi_2(x)+\int_0^x K_2[x,\xi,u_1^{(1)}(\xi),\ldots,u_n^{(1)}(\xi)]d\xi$$
$$\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots$$
$$\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots$$
$$u_n^{(0)}(x)=\phi_n(x)$$
$$u_n^{(1)}(x)=\phi_n(x)+\int_0^x K_n[x,\xi,\phi_1(\xi),\ldots,\phi_n(\xi)]d\xi$$
$$u_n^{(2)}(x)=\phi_n(x)+\int_0 K_n[x,\xi,u_1^{(1)}(\xi),\ldots,u_n^{(1)}(\xi)]d\xi$$
$$\cdots\cdots\cdots\cdots\cdots\cdots\cdots\cdots \qquad (42)$$

This method, in general, fails due to complexity, unless the K_i are nearly linear functions or unless the solution is known from experience or physical considerations to be monotone increasing or decreasing.

An application is to dynamic braking of synchronous machines. The differential equations of dynamic braking of a synchronous machine are

$$\frac{dI}{dt}=\frac{(E-IR)}{L}\frac{\left[\left(\frac{rs_0}{s}\right)^2+x_dx_q\right]}{\left[\left(\frac{rs_0}{s}\right)^2+x_d'x_q\right]}-$$
$$\frac{2KPr^3I^3}{JI_0^2s^4}\frac{x_qs_0^2(x_d-x_d')\left[\left(\frac{rs_0}{s}\right)^2+x_q^2\right]}{\left[\left(\frac{rs_0}{s}\right)^2+x_d'x_q\right]\left[\left(\frac{rs_0}{s}\right)^2+x_dx_q\right]^2}$$

$$\frac{ds}{dt}=-\frac{KPrI^2}{JsI_0^2}\frac{\left[\left(\frac{rs_0}{s}\right)^2+x_q^2\right]}{\left[\left(\frac{rs_0}{r}\right)^2+x_dx_q\right]^2}$$

By change of dependent variables $s=s_0\epsilon^{-z}$, $I=E/R+I_1\epsilon^{-y}$ (suggested by an oscillogram of the field current and by a speed curve) the differential equations are reducible to the non-linear integral equations

$$y=\frac{Rt}{L}+\int_0^t\frac{Rdt}{A_0^2+(r\epsilon^z)^2}+\frac{2KPr^3\mu}{Js_0^2I_1I^2}\times$$
$$\int_0^t\frac{[x_q^2+(r\epsilon^z)^2]\left[\frac{E}{R}+I_1\epsilon^{-y}\right]^2\epsilon^ydt}{[A^2+(r\epsilon^z)^2]^2[A_0^2+(r\epsilon^z)^2]\epsilon^{-4z}}$$

$$z=\frac{KPr}{JI_0^2s_0^2}\int_0^t\frac{\left[\frac{E}{R}+I_1\epsilon^y\right]^2}{\epsilon^{-2z}}\frac{[x_q^2+(r\epsilon^z)]^2}{[A^2+(r\epsilon^z)^2]^2}dt$$

where $\mu=x_q(x_d-x_d')$, $A^2=x_dx_q$, $A_0^2=x_d'x_q$, I and s are the instantaneous field current and speed respectively and t is the time in seconds. For the meaning of the remaining symbols (mostly reactances) the reader is referred elsewhere.[12]

Once z has been found the number of revolutions before the rotor of the machine comes to rest is given by

$$N=\frac{s_0}{2\pi}\int_0^\infty\epsilon^{-z}dt$$

The start of the solution of the equations above is the identification

$$u_1(x)=y_1=\phi_1(x)=\frac{R}{L}t,$$
$$u_2(x)=z_1=\phi_2(x)=0, \text{ etc.}$$

It is evident that the complexity of the successive approximations u_1^1, u_1^2, .. increases much too rapidly to afford an accurate solution. An upper limit to the number of revolutions will suffice as an answer provided the upper limit is not much in excess of the actual number. Since both I and s are known to be monotone functions (figure 5) this useful upper limit is easily obtained by replacing functions of the time within the integrands of the successive integrals by appropriately chosen constants.

6. Method of Galerkin

Galerkin's method resembles in certain features the method of Ritz[13] for linear partial differential equations. Essentially, the method consists of setting up a sequence (sometimes series) of functions which satisfy precisely the boundary conditions of a system of differential equations and which satisfy the differential equations themselves very closely. The method is primarily one of solving systems of linear equations, but it will in certain cases attack successfully non-linear problems. In the interest of brevity, we shall examine it relative to a most trivial exercise and refer elsewhere[14] for the theory. However, a gist of the method is evident from the exercise. The equation $di/dt=Ri^2$ can be considered the differential equation of a non-linear d-c circuit with non-linear resistance. Let the initial conditions be $i=1$ for $t=0$. By Galerkin's method choose

$$i=1+c_1t+c_2t^2$$

for the interval (0, 1). Denote the result of substituting i in the differential equation by ϵ. Galerkin imposes the condition

$$\frac{\partial}{\partial c_i}\int_0^a\epsilon^2dt=0$$

which, in the present exercise, yields

$$\int_0^1[(c_1+2c_2t)-R(1+c_1t+c_2t^2)^2]\times[1-2R(1+c_1t+c_2t^2)t]dt=0$$
$$\int_0^1[(c_1+2c_2t)-R(1+c_1t+c_2t^2)^2]\times[2t-2R(1+c_1t+c_2t^2)t^2]dt=0$$

Values of c_1 and c_2, which satisfy the last equations, can be found by means of implicit function theory.[15] The accurate solution of the differential equation is $i=1/(1-Rt)$. Graphs of the accurate and approximate solutions (for $R=1/2$) are shown in figure 6.

Concluding Remarks

In the non-linear discrete problems of industry the author has found the six methods given above the most useful. References to the methods of differential variations, successive approximations, series solutions in independent variables, and collocation which also have been of great value are found in the bibliography.

Transient Torques in Squirrel-Cage Induction Motors, With Special Reference to Plugging

E. S. GILFILLAN, JR.
NONMEMBER AIEE

E. L. KAPLAN
NONMEMBER AIEE

WHEN a squirrel-cage motor is switched in any way, whether while running or at rest, transient torques, which are usually several times the steady-state torque, occur and must be considered in design. It was desired to obtain a general semi-quantitative view of these torques by considering a limiting case which is accessible analytically with the expectation that a simple rule would be apparent for estimating the magnitude of these torques from design data. No such rule was found, and we must be content to exhibit limiting transient torque curves for certain types of motors in the commercial range and to provide accurate formulas for calculating such limiting torques for types not considered here.

The limiting case studied involves the following assumptions:

1. The windings of stator and rotor are sinusoidally distributed.
2. The iron is worked on the straight portion of the *B-H* curve (constant reluctance of the magnetic circuit).
3. There are no losses in the iron.
4. The applied voltage is sinusoidal.
5. The moment of inertia of the rotor and attached apparatus is large, so that in the limit there is no change of rotor speed during the interval of time considered.

Differential equations appropriate to this case have been derived by H. C. Stanley.[1] We shall use those for the two-phase motor.

$$\left(R+L\frac{d}{dt}\right)I_\alpha+M\frac{di_\alpha}{dt}=E\sin 2\pi ft$$

$$\left(R+L\frac{d}{dt}\right)I_\beta+M\frac{di_\beta}{dt}=E\cos 2\pi ft$$

$$M\frac{dI_\alpha}{dt}+MnI_\beta+\left(r+l\frac{d}{dt}\right)i_\alpha+lni_\beta=0$$

$$-MnI_\alpha+M\frac{dI_\beta}{dt}-lni_\alpha+\left(r+l\frac{d}{dt}\right)i_\beta=0 \quad (1)$$

I_α and I_β are the stator currents. i_α and i_β are currents flowing in the face of the rotor under the corresponding stator phases. They are not the instantaneous currents flowing through fixed points in the rotor face. R and r are the ohmic resistances of stator and rotor phases. L and l are the corresponding self-inductances and M is the maximum mutual inductance between a rotor and a stator phase. n is the rotor speed in electrical radians per second. In order that the limiting case be the best approximation to an actual case, R, r, L, l, and M should be the effective values at the supply voltage and frequency for the stator windings, and at the frequency actually occurring in the rotor windings.

In terms of these quantities, the torque (in watt-seconds) is

$$T=M(I_\beta i_\alpha-I_\alpha i_\beta)$$

The quantity of interest is the ratio of instantaneous torque to steady-state torque. The form of equation 1 has the disadvantage that many different combinations of $R, r, L, l, M, n, E,$ and f give the same relation between torque-ratio and the time in cycles. A fractional horsepower motor may have just the same transient characteristics as a much larger motor, for which all the above design parameters are different. To clarify this situation it is desirable to introduce new parameters and variables having identical values for motors of identical torque ratio characteristics, as follows:

$$I=\frac{E}{R}$$

$$x_1=\frac{I_\alpha}{I}\quad x_2=\frac{I_\beta}{I}\quad x_3=\frac{i_\alpha}{I}\quad x_4=\frac{i_\beta}{I}$$

$$A=\frac{2\pi fL}{R}\quad B=\frac{2\pi fM}{R}\quad C=\frac{2\pi fl}{R}$$

$D=\frac{r}{R}\quad \rho=-\frac{n}{2\pi f}$[*] $\quad u=2\pi ft$

The number of independent design parameters has been reduced to five, and these and the variables have become dimensionless. Substituting those, and introducing a phase-shifting parameter kappa (κ) which we shall need later, we obtain

$$\left.\begin{aligned}
&\frac{d}{du}(Ax_1+Bx_3)+x_1=\sin(u+\kappa)\\
&\frac{d}{du}(Ax_2+Bx_4)+x_2=\cos(u+\kappa)\\
&\frac{d}{du}(Bx_1+Cx_3)-\rho(Bx_2+Cx_4)+Dx_3=0\\
&\frac{d}{du}(Bx_2+Cx_4)+\rho(Bx_1+Cx_3)+Dx_4=0
\end{aligned}\right\}\quad (2)$$

Further modification of these equations to bring out maximum symmetry is desirable. The necessary transformation, with its inverse, is given below.

$$\left.\begin{aligned}
&Z_1=Ax_1+Bx_3 && Z_3=Bx_1+Cx_3\\
&Z_2=Ax_2+Bx_4 && Z_4=Bx_2+Cx_4\\
&x_1=cZ_1-bZ_3 && x_3=-bZ_1+aZ_3\\
&x_2=cZ_2-bZ_4 && x_4=-bZ_2+aZ_4
\end{aligned}\right\}\quad (2a)$$

$$a=\frac{A}{AC-B^2}\qquad b=\frac{B}{AC-B^2}\qquad c=\frac{C}{AC-B^2}$$

Paper 41-126, recommended by the AIEE committee on electrical machinery, and presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941. Manuscript submitted April 15, 1941; made available for preprinting May 14, 1941.

E. S. Gilfillan, Jr. and Edward Kaplan are both with the naval ordnance laboratory, Navy Yard, Washington, D. C. Mr. Gilfillan is a member of the American Chemical Society. Mr. Kaplan is a member of the Mathematical Association of America.

The authors gratefully acknowledge the assistance of Dr. A. M. Wahl and R. E. Peterson who suggested the problem and participated in many helpful discussions; the Massachusetts Institute of Technology and Professor S. H. Caldwell who placed the differential analyzer at their disposal; J. L. C. Löf, Perry Crawford, Jr., and Robert Plunckett who assisted in operating the differential analyzer, and J. Kaye, A. H. Willis, P. R. Toolin, and A. C. Hagg, who carried out the greater part of the numerical work.

[1] For all numbered references, see list at end of paper.

[*] Rotation of the rotor from the positive axis of the stator coil of phase β toward the positive axis of α has been taken as making ρ positive, which is the opposite of Stanley's convention for n. Since the voltage $E\sin(u+\kappa)$ applied to stator phase α lags the voltage $E\cos(u+\kappa)$ applied to phase β, the field of the stator windings also rotates from β toward α, and with our convention $\rho=+1$ for synchronous speed.

which gives

$$\left.\begin{aligned}
&\left(c+\frac{d}{du}\right)Z_1-bZ_3=\sin(u+\kappa)\\
&\left(c+\frac{d}{du}\right)Z_2-bZ_4=\cos(u+\kappa)\\
&-DbZ_1+\left(Da+\frac{d}{du}\right)Z_3-\rho Z_4=0\\
&-DbZ_2+\rho Z_3+\left(Da+\frac{d}{du}\right)Z_4=0\\
&T=MI^2(ac-b^2)(Z_2Z_3-Z_1Z_4)
\end{aligned}\right\}\qquad(3)$$

Since $L\ l-M^2$ is necessarily positive, $AC-B^2$ is necessarily positive, as are a, b, and c.

Equations 3 can be solved by straightforward methods. The solution is:

$$\left.\begin{aligned}
Z_1={}&(F_1\cos h_1u+F_2\sin h_1u)e^{g_1u}+\\
&(F_3\cos h_2u+F_4\sin h_2u)e^{g_2u}+\\
&\alpha\sin(u+\kappa+\lambda)\\
Z_2={}&(-F_2\cos h_1u+F_1\sin h_1u)e^{g_1u}+\\
&(-F_4\cos h_2u+F_3\sin h_2u)e^{g_2u}+\\
&\alpha\cos(u+\kappa+\lambda)\\
Z_3={}&(F_5\cos h_1u+F_6\sin h_1u)e^{g_1u}+\\
&(F_7\cos h_2u+F_8\sin h_2u)e^{g_2u}+\\
&\beta\sin(u+\kappa+\mu)\\
Z_4={}&(-F_6\cos h_1u+F_5\sin h_1u)e^{g_1u}+\\
&(-F_8\cos h_2u+F_7\sin h_2u)e^{g_2u}+\\
&\beta\cos(u+\kappa+\mu)
\end{aligned}\right\}\qquad(4)$$

where

$$2g_1=-c-aD+\sqrt{\frac{q_1+\sqrt{q_1^2+q_2^2}}{2}}$$

$$2g_2=-c-aD-\sqrt{\frac{q_1+\sqrt{q_1^2+q_2^2}}{2}}$$

$$2h_1=-\rho-\sqrt{\frac{-q_1+\sqrt{q_1^2+q_2^2}}{2}}$$

$$2h_2=-\rho+\sqrt{\frac{-q_1+\sqrt{q_1^2+q_2^2}}{2}}$$

$$q_1=(c-aD)^2-\rho^2+4b^2D$$
$$q_2=2\rho(c-aD)$$

When q_2 is negative interchange h_1 and h_2.

$$\begin{aligned}
(k_3-k_5)F_1&=-k_5\Gamma_1-k_4\Gamma_2-k_7\Gamma_3-k_6\Gamma_4\\
(k_3-k_5)F_2&=-k_4\Gamma_1+k_5\Gamma_2-k_6\Gamma_3+k_7\Gamma_4\\
(k_3-k_5)F_3&=+k_3\Gamma_1+k_4\Gamma_2+k_7\Gamma_3+k_6\Gamma_4\\
(k_3-k_5)F_4&=+k_4\Gamma_1-k_3\Gamma_2+k_6\Gamma_3-k_7\Gamma_4\\
(k_3-k_5)F_5&=-k_2\Gamma_1-k_1\Gamma_2+k_5\Gamma_3+k_4\Gamma_4\\
(k_3-k_5)F_6&=-k_1\Gamma_1+k_2\Gamma_2+k_4\Gamma_3-k_5\Gamma_4\\
(k_3-k_5)F_7&=+k_2\Gamma_1+k_1\Gamma_2-k_3\Gamma_3-k_4\Gamma_4\\
(k_3-k_5)F_8&=+k_1\Gamma_1-k_2\Gamma_2-k_4\Gamma_3+k_3\Gamma_4\\
\Gamma_1&=Z_1^{(0)}-\alpha\sin(\kappa+\lambda)\\
\Gamma_2&=Z_2^{(0)}-\alpha\cos(\kappa+\lambda)\\
\Gamma_3&=Z_3^{(0)}-\beta\sin(\kappa+\mu)\\
\Gamma_4&=Z_4^{(0)}-\beta\cos(\kappa+\mu)
\end{aligned}$$

$Z_i^{(0)}$ is the value of Z_i when $u=0$

The k's are functions of the g's, and h's, and b and c as follows:

$$\begin{aligned}
k_1={}&[-h_2(g_1+c)^2+h_1(g_2+c)^2-\\
&h_1h_2(h_1-h_2)]+b\\
k_2={}&[+(g_1+c)(g_2+c)(g_1-g_2)+h_1^2(g_2+c)-\\
&h_2^2(g_1+c)]+b\\
k_3={}&h_1(h_1-h_2)+(g_1+c)(g_1-g_2)\\
k_4={}&h_1(g_2+c)-h_2(g_1+c)\\
k_5={}&h_2(h_1-h_2)+(g_2+c)(g_1-g_2)\\
k_6={}&-b(h_1-h_2)\\
k_7={}&-b(g_1-g_2)
\end{aligned}$$

The relation

$$k_4(k_3+k_5)+k_1k_7+k_2k_6\equiv0$$

may be used as a check on the numerical work.

$$\alpha=\left(\frac{a^2+\sigma^2}{G^2+H^2}\right)^{1/2}\qquad\beta=\frac{b}{(G^2+H^2)^{1/2}}$$

$$\sin\lambda=\frac{-aG+\sigma H}{(a^2+\sigma^2)^{1/2}(G^2+H^2)^{1/2}}$$

$$\cos\lambda=\frac{aH+\sigma G}{(a^2+\sigma^2)^{1/2}(G^2+H^2)^{1/2}}$$

$$\sin\mu=-\frac{G}{(G^2+H^2)^{1/2}}\qquad\cos\mu=\frac{H}{(G^2+H^2)^{1/2}}$$

$$G=a+c\sigma\quad\sigma=\frac{1-\rho}{D}\quad H=ac-b^2-\sigma$$

It is worthwhile to form the expression for the torque as certain terms cancel. The result is:

$$\begin{aligned}
Z_2Z_3-Z_1Z_4={}&\alpha\beta\sin(\mu-\lambda)+\\
&L_1e^{2g_1u}+L_2e^{2g_2u}+\\
&[L_3\cos(h_1-h_2)u+L_4\sin(h_1-h_2)u]e^{(g_1+g_2)u}+\\
&[L_5\cos(h_1+1)u+L_6\sin(h_1+1)u]e^{g_1u}+\\
&[L_7\cos(h_2+1)u+L_8\sin(h_2+1)u]e^{g_2u}
\end{aligned}\qquad(5)$$

where

$$\begin{aligned}
L_1={}&F_1F_6-F_2F_5\\
L_2={}&F_3F_8-F_4F_7\\
L_3={}&F_3F_6-F_2F_7+F_1F_8-F_4F_5\\
L_4={}&F_1F_7-F_3F_5+F_2F_8-F_4F_6\\
L_5={}&+F_6\alpha\sin(\kappa+\lambda)+F_5\alpha\cos(\kappa+\lambda)-\\
&F_2\beta\sin(\kappa+\mu)-F_1\beta\cos(\kappa+\mu)\\
L_6={}&-F_5\alpha\sin(\kappa+\lambda)+F_6\alpha\cos(\kappa+\lambda)+\\
&F_1\beta\sin(\kappa+\mu)-F_2\beta\cos(\kappa+\mu)\\
L_7={}&+F_8\alpha\sin(\kappa+\lambda)+F_7\alpha\cos(\kappa+\lambda)-\\
&F_4\beta\sin(\kappa+\mu)-F_3\beta\cos(\kappa+\mu)\\
L_8={}&-F_7\alpha\sin(\kappa+\lambda)+F_8\alpha\cos(\kappa+\lambda)+\\
&F_3\beta\sin(\kappa+\mu)-F_4\beta\cos(\kappa+\mu)
\end{aligned}$$

When $Z_i^{(0)}=0$ (no currents flowing in motor at the instant of switching) the torque is independent of the phase κ of the voltage at which the motor is thrown in the line. This was to be expected from the complete symmetry of the squirrel-cage motor and the polyphase field.

When $q_2=2\rho(c-aD)=0$, in which case the burden of computation is considerably reduced, interesting special cases occur.

Case 1:

$c=aD$
$\rho\neq0$
$U^2\equiv\rho^2/_4-b^2D>0$
$g_1=g_2=-c$
$h_1=-\frac{\rho}{2}-U$
$h_2=-\frac{\rho}{2}+U$

This is the case in which rotor and stator windings have the same phase-angle when each is energized at the supply frequency with the other open circuited, and in which the absolute speed of rotation is at or near synchronous speed. In this case the formulae for the k's are simplified as follows:

$k_1=+2bDU$
$k_3=+\rho U+2U^2$
$k_5=+\rho U-2U^2$
$k_6=+2bU$
$k_2=k_4=k_7=0$

Case 2:

$c=aD$
$\rho\neq0$
$V^2\equiv b^2D-\rho^2/_4>0$
$g_1=-c+V$
$g_2=-c-V$
$h_1=h_2=-\frac{\rho}{2}$

This case has the same phase-angle relation as case 1, but the absolute speed of rotation, while not zero, differs considerably from synchronous speed. The k's simplify to

$k_2=-2bDV$
$k_3=2V^2$
$k_4=\rho V$
$k_5=-2V^2$
$k_7=-2bV$
$k_1=k_6=0$

Case 3:

$c=aD$
$\rho\neq0$
$b^2D=\rho^2/_4$
$g_1=g_2=-c$
$h_1=h_2=-\frac{\rho}{2}$

This is the transition case between case 1 and case 2. The Z's are

$$\begin{aligned}
Z_1={}&[(\Gamma_1+\Gamma_5u)\cos b\sqrt{D}u+(-\Gamma_2+\Gamma_6u)\times\\
&\sin b\sqrt{D}u]e^{-cu}+\alpha\sin(u+\kappa+\lambda)\\
Z_2={}&[(\Gamma_2-\Gamma_6u)\cos b\sqrt{D}u+(\Gamma_1+\Gamma_5u)\times\\
&\sin b\sqrt{D}u]e^{-cu}+\alpha\cos(u+\kappa+\lambda)\\
Z_3={}&[(\Gamma_3+\sqrt{D}\Gamma_5u)\cos b\sqrt{D}u+(-\Gamma_4-\\
&\sqrt{D}\Gamma_6u)\sin b\sqrt{D}u]e^{-cu}+\beta\sin(u+\kappa+\mu)\\
Z_4={}&[(\Gamma_4+\sqrt{D}\Gamma_6u)\cos b\sqrt{D}u+(\Gamma_3+\\
&\sqrt{D}\Gamma_5u)\sin b\sqrt{D}u]e^{-cu}+\beta\cos(u+\kappa+\mu)
\end{aligned}$$

where

$$\Gamma_5=b(\sqrt{D}\Gamma_2+\Gamma_3),\quad\Gamma_6=b(\sqrt{D}\Gamma_1-\Gamma_4)$$

$$\begin{aligned}
Z_2Z_3-Z_1Z_4={}&\alpha\beta\sin(\mu-\lambda)+\\
&(N_0+N_1u+N_2u^2)e^{-2cu}+\\
&e^{-cu}[(N_3+N_4u)\cos(b\sqrt{D}+1)u+\\
&(N_5+N_6u)\sin(b\sqrt{D}+1)u]
\end{aligned}$$

where

$$N_0=\Gamma_2\Gamma_3-\Gamma_1\Gamma_4 \quad N_3=-\sqrt{D}(\Gamma_5^2+\Gamma_6^2)$$
$$N_1=-\Gamma_3\Gamma_6-\Gamma_4\Gamma_5+\sqrt{D}\Gamma_2\Gamma_6-\sqrt{D}\Gamma_1\Gamma_5$$
$$N_2=-\Gamma_4\alpha\sin(\kappa+\lambda)+\Gamma_3\alpha\cos(\kappa+\lambda)+\Gamma_2\beta\sin(\kappa+\mu)-\Gamma_1\beta\cos(\kappa+\mu)$$
$$N_4=-\sqrt{D}\Gamma_5\alpha\sin(\kappa+\lambda)+\sqrt{D}\Gamma_6\alpha\cos(\kappa+\lambda)-\Gamma_6\beta\sin(\kappa+\mu)-\Gamma_5\beta\cos(\kappa+\mu)$$
$$N_5=-\Gamma_3\alpha\sin(\kappa+\lambda)-\Gamma_4\alpha\cos(\kappa+\lambda)+\Gamma_1\beta\sin(\kappa+\mu)+\Gamma_2\beta\cos(\kappa+\mu)$$
$$N_6=-\sqrt{D}\Gamma_6\alpha\sin(\kappa+\lambda)-\sqrt{D}\Gamma_5\alpha\cos(\kappa+\lambda)+\Gamma_5\beta\sin(\kappa+\mu)-\Gamma_6\beta\cos(\kappa+\mu)$$

The above formulae are valid when $\rho=-2b\sqrt{D}$. When $\rho=+2b\sqrt{D}$ change the sign of $\sqrt{D}$ wherever it occurs. α, β, λ, μ, and the Γ's have the same values as before.

Case 4: $\rho=0$. Here the equations are as follows:

$$Z_1=J_1\epsilon^{\omega_1 u}+J_2\epsilon^{\omega_2 u}+\alpha\sin(u+\kappa+\lambda)$$
$$Z_2=J_3\epsilon^{\omega_1 u}+J_4\epsilon^{\omega_2 u}+\alpha\cos(u+\kappa+\lambda)$$
$$Z_3=J_5\epsilon^{\omega_1 u}+J_6\epsilon^{\omega_2 u}+\beta\sin(u+\kappa+\mu)$$
$$Z_4=J_7\epsilon^{\omega_1 u}+J_8\epsilon^{\omega_2 u}+\beta\cos(u+\kappa+\mu)$$

where

$$J_1=\frac{(c+\omega_2)\Gamma_1-b\Gamma_3}{\omega_2-\omega_1} \qquad J_2=\frac{-(c+\omega_1)\Gamma_1+b\Gamma_3}{\omega_2-\omega_1}$$

$$J_3=\frac{(c+\omega_2)\Gamma_2-b\Gamma_4}{\omega_2-\omega_1} \qquad J_4=\frac{-(c+\omega_1)\Gamma_2+b\Gamma_4}{\omega_2-\omega_1}$$

$$J_5=\frac{c+\omega_1}{b}J_1 \qquad J_6=\frac{c+\omega_2}{b}J_2$$

$$J_7=\frac{c+\omega_1}{b}J_3 \qquad J_8=\frac{c+\omega_2}{b}J_4$$

α, β, λ, μ, and the Γ's have the same values as before, and ω_1 and ω_2 are the roots of

$$(\omega+c)(\omega+aD)-Db^2=0$$

These roots are always real and unequal.

$$Z_2Z_3-Z_1Z_4=\alpha\beta\sin(\mu-\lambda)+K_0\epsilon^{(\omega_1+\omega_2)u}+\epsilon^{\omega_1 u}(K_1\cos u+K_2\sin u)+\epsilon^{\omega_2 u}(K_3\cos u+K_4\sin u)$$

where

$$K_0=\frac{\omega_2-\omega_1}{b}(J_2J_3-J_1J_4)$$
$$=J_3J_6+J_4J_5-J_1J_8-J_2J_7$$
$$K_1=-J_7\alpha\sin(\kappa+\lambda)+J_5\alpha\cos(\kappa+\lambda)+J_3\beta\sin(\kappa+\mu)-J_1\beta\cos(\kappa+\mu)$$
$$K_2=-J_5\alpha\sin(\kappa+\lambda)-J_7\alpha\cos(\kappa+\lambda)+J_1\beta\sin(\kappa+\mu)+J_3\beta\cos(\kappa+\mu)$$
$$K_3=-J_8\alpha\sin(\kappa+\lambda)+J_6\alpha\cos(\kappa+\lambda)+J_4\beta\sin(\kappa+\mu)-J_2\beta\cos(\kappa+\mu)$$
$$K_4=-J_6\alpha\sin(\kappa+\lambda)-J_8\alpha\cos(\kappa+\lambda)+J_2\beta\sin(\kappa+\mu)+J_4\beta\cos(\kappa+\mu)$$

The foregoing sections apply only to the case where the two phases are switched simultaneously. Larger transient torques are found when the switching (plugging) is done one phase at a time. To compute these it is necessary to solve the equation for the case of only one phase closed and the case of no phase closed.

Single-Phase Case

Here, if we assume that it is the β phase which is opened, the second of equations 3 becomes indeterminate and the condition $x_2\equiv 0$ is substituted for it. The solution is

$$\left.\begin{aligned}Z_1&=E_1\epsilon^{su}+\epsilon^{gu}(E_2\cos hu+E_3\sin hu)+\alpha'\sin(u+\kappa+\lambda')\\Z_2&=b[E_7\epsilon^{su}+\epsilon^{gu}(E_8\cos hu+E_9\sin hu)+\gamma'\cos(u+\kappa+\nu')]\\Z_3&=E_4\epsilon^{su}+\epsilon^{gu}(E_5\cos hu+E_6\sin hu)+\beta'\sin(u+\kappa+\mu')\\Z_4&=c[E_7\epsilon^{su}+\epsilon^{gu}(E_8\cos hu+E_9\sin hu)+\gamma'\cos(u+\kappa+\nu')]\end{aligned}\right\}\quad(6)$$

where s is the real root of the equation

$$cs^3+p_1s^2+p_2s+p_3=0$$

and g and h are coefficients in the form of complex roots $g\pm hi$. Here

$$p_1=D(2ac-b^2)+c^2$$

$$p_2=D(ac-b^2)(Da+2c)+\rho^2c$$

$$p_3=D^2(ac-b^2)^2+\rho^2c^2$$

$$E_1=\frac{[(c+g)^2+h^2+Db^2]\Sigma_1-b(2g+Da+c)\Sigma_3+\rho bc\Sigma_2}{(g-s)^2+h^2}$$

$$E_2=\Sigma_1-E_1$$

$$\left.E_3=\frac{[(g-s)(s+c)(g+c)+Db^2(g-s)-h^2(s+c)]\Sigma_1+Pbc(g-s)\Sigma_2+b[h^2-(g-s)(c+Da+s+g)]\Sigma_3}{h[(g-s)^2+h^2]}\right\}$$

$$E_4=\frac{E_1(c+s)}{b}$$

$$E_5=\frac{E_2(c+g)+E_3h}{b}$$

$$E_6=\frac{-E_2h+E_3(c+g)}{b}$$

$$\rho bcE_7=E_1[(c+s)(Da+s)-Db^2]$$

$$\rho bcE_8=E_2[(c+g)(Da+g)-h^2-Db^2]+E_3h(Da+c+2g)$$

$$\rho bcE_9=-E_2h(Da+c+2g)+E_3[(c+g)(Da+g)-h^2-Db^2]$$

Checks:

$$E_4+E_5=\Sigma_2$$
$$E_7+E_8=\Sigma_3$$
$$DbE_3+hE_5-(Da+g)E_6+\rho cE_9=0$$
$$DbE_2-(Da+g)E_5-hE_6+\rho cE_8=0$$

where

$$\Sigma_1=Z_1^{(0)}-\alpha'\sin(\kappa+\lambda')$$

$$\Sigma_2=Z_3^{(0)}-\beta'\sin(\kappa+\mu')$$

$$\Sigma_3=\frac{-bZ_2^{(0)}+aZ_4^{(0)}}{ac-b^2}-\gamma'\cos(\kappa+\nu')$$

and

$$P_1=c(1-\rho^2)-D^2a(ac-b^2)$$
$$P_2=D^2b(ac-b^2)$$
$$G'=c-p_2$$
$$Q_1=D(2ac-b^2)$$
$$Q_2=Dbc$$
$$H'=p_1-p_3$$

$$\alpha'=\left(\frac{P_1^2+Q_1^2}{G'^2+H'^2}\right)^{1/2}$$

$$\beta'=\left(\frac{P_2^2+Q_2^2}{G'^2+H'^2}\right)^{1/2}$$

$$\gamma'=\frac{Db|\rho|}{(G'^2+H'^2)^{1/2}}$$

$$\sin\lambda'=-\frac{P_1G'+Q_1H'}{(G'^2+H'^2)^{1/2}(P_1^2+Q_1^2)^{1/2}}$$

$$\cos\lambda'=\frac{-Q_1G'+P_1H'}{(G'^2+H'^2)^{1/2}(P_1^2+Q_1^2)^{1/2}}$$

$$\sin\mu'=\frac{P_2G'-Q_2H'}{(G'^2+H'^2)^{1/2}(P_2^2+Q_2^2)^{1/2}}$$

$$\cos\mu'=-\frac{Q_2G'+P_2H'}{(G'^2+H'^2)^{1/2}(P_2^2+Q_2^2)^{1/2}}$$

$$\sin\nu'=\frac{-H'}{(G'^2+H'^2)^{1/2}}$$

$$\cos\nu'=\frac{-G'}{(G'^2+H'^2)^{1/2}}$$

The above formulae for $\sin\nu'$ and $\cos\nu''$ hold when ρ is positive. When $\rho<0$ the signs should be reversed.

For the single phase case

$$Z_2Z_3-Z_1Z_4={}^1/_2c\alpha'\gamma'\sin(\lambda'-\nu')-{}^1/_2b\beta'\gamma'\sin(\mu'-\nu')+{}^1/_2c\alpha'\gamma'\sin(2u+2\kappa+\lambda'+\nu')-{}^1/_2b\beta'\gamma'\sin(2u+2\kappa+\mu'+\nu')$$

in the steady state.

In the case that the roots of the cubic $cs^3+p_1s^2+p_2s+p_3=0$ are all real the formulas are

$$Z_1=\rho bc[f_1\epsilon^{s_1u}+f_2\epsilon^{s_2u}+f_3\epsilon^{s_3u}]+\alpha'\sin(u+\kappa+\lambda')$$

$$Z_3=f_1\rho c(c+s_1)\epsilon^{s_1u}+f_2\rho c(c+s_2)\epsilon^{s_2u}+f_3\rho c(c+s_3)\epsilon^{s_3u}+\beta'\sin(u+\kappa+\mu')$$

$$\frac{Z_2}{b}=\frac{Z_4}{c}=f_1[-Db^2+(c+s_1)(Da+s_1)]\epsilon^{s_1u}+f_2[-Db^2+(c+s_2)(Da+s_2)]\epsilon^{s_2u}+f_3[-Db^2+(c+s_3)(Da+s_3)]\epsilon^{s_3u}+\gamma'\cos(u+\kappa+\nu')$$

where

$$f_1=\frac{+[Db^2+(c+s_2)(c+s_3)]\Sigma_1-b(c+Da+s_2+s_3)\Sigma_3+\rho bc\Sigma_2}{\rho bc(s_1-s_2)(s_1-s_3)}$$

$$f_2=\frac{+[Db^2+(c+s_1)(c+s_3)]\Sigma_1-b(c+Da+s_1+s_3)\Sigma_3+\rho bc\Sigma_2}{\rho bc(s_2-s_1)(s_2-s_3)}$$

$$f_3=\frac{+[Db^2+(c+s_1)(c+s_2)]\Sigma_1-b(c+Da+s_1+s_2)\Sigma_3+\rho bc\Sigma_2}{\rho bc(s_3-s_1)(s_3-s_2)}$$

When $\rho=0$ the formulas are

$$Z_1=m_1be^{s_1u}+m_2be^{s_2u}+\alpha'\sin(u+\kappa+\lambda')$$

$$Z_2=m_1(c+s_1)e^{s_1u}+m_2(c+s_2)e^{s_2u}+\beta'\sin(u+\kappa+\mu')$$

$$\frac{Z_3}{b}=\frac{Z_4}{c}=\Sigma_3e^{s_3u}+\gamma'\cos(u+\kappa+\nu')$$

where

$$m_1=\frac{-(c+s_2)\Sigma_1+b\Sigma_2}{b(s_1-s_2)}$$

$$m_2=\frac{(c+s_1)\Sigma_1-b\Sigma_2}{b(s_1-s_2)}$$

In this case s_1, s_2, s_3 reduce to

$$2s_1,2s_2=-c-Da\pm\sqrt{(c-Da)^2+4Db^2}$$

$$s_3=-\frac{D}{c}(ac-b^2)$$

α', λ', Σ, etc., have the same meanings as in general.

"No-Phase" Case

When both stator phases are open, we have

$$\left.\begin{aligned}&x_1=x_2\equiv0\\&C\frac{dx_3}{du}+Dx_3-C\rho x_4=0\\&C\frac{dx_4}{du}+Dx_4+C\rho x_3=0\\&x_3=\delta e^{-Du/C}\sin(\rho u+\epsilon)\\&x_4=\delta e^{-Du/C}\cos(\rho u+\epsilon)\end{aligned}\right\}\qquad(7)$$

where δ and ϵ are determined by the initial values of x_3 and x_4 when $u=0$. The torque is, of course, identically zero in this case.

Transformation of Formulas

For computational purposes it is generally necessary to be able to modify the preceding formulae by means of the following rules. They should be understood as mere devices to obviate the necessity of writing down new sets of formulae; the *formulae* are to be transformed as described, while the significance of the *letters* remains unchanged. E_α and E_β denote the voltages applied to the stator α and β phases, respectively.

To make the one-phase formulae for stator phase α closed ($E_\alpha=E\sin(u+\kappa)$), β open apply for α open, β closed($E_\beta=E\times\cos(u+\kappa)$), interchange Z_1 and Z_2 (also $Z_1^{(0)}$ and $Z_2^{(0)}$); interchange Z_3 and Z_4 (also $Z_3^{(0)}$ and $Z_4^{(0)}$); change the sign of ρ in the formulae; and increase the phase constants λ', μ', ν', calculated from the transformed formulae, by $\pi/2$. Thus we obtain

$$\Sigma_1=Z_2^{(0)}-\alpha'\sin\left(\kappa+\lambda'+\frac{\pi}{2}\right)$$

and so on. The actual numerical value of ρ to be used in the new formula must be determined by the convention adopted, that ρ is positive when the rotor turns from the positive axis of stator-phase β toward the positive axis of stator-phase α.

To reverse the polarity of stator-phase α, that is, to make the two-phase formulae which are valid when $E_\alpha=E\sin(u+\kappa)$, $E_\beta=E\cos(u+\kappa)$, apply to the case when $E_\alpha=-E\sin(u+\kappa)$, $E_\beta=E\cos(u+\kappa)$, the procedure is exactly the same as in the preceding paragraph, except that here there are only the two phase constants λ, μ to be increased by $\pi/2$. A specimen transformed formula is

$$\Gamma_1=Z_1^{(0)}-\alpha\sin\left(\kappa+\lambda+\frac{\pi}{2}\right)$$

Formulae applicable when E_α, E_β are given by still other expressions are obtainable from the foregoing by assigning a suitable value to κ. It may be mentioned, however, that the polarity of the β phase may also be reversed by means of the procedure above, except that the phase constants λ, μ are to be decreased (not increased) by $\pi/2$.

Sequential Switching

As an example of the use of the above formulae consider the case of a motor which has been running forward long enough to have reached a steady condition. The general method is to switch one phase out at a selected phase of the voltage and consider the motor as running single-phase in the transient condition. At a second selected instant and phase, the second phase is switched out. The stator currents (i.e. x_1 and x_2) are zero during the "no phase" interval but the rotor currents die away slowly in the manner described by equations 7. Before the rotor currents are gone one stator phase is switched in with the polarity which it had originally and the motor runs single phase again in the transient condition. Before the steady state is established the second phase is switched in with reversed polarity and the motor runs "plugged" through the transient condition into the steady state. The computation details are as follows:

The Z's are computed from equations 4 for the particular phase of u at which one phase is to be switched out, bearing in mind that the absolute value of u is so large that the exponential terms drop. From the values of the Z's at the instant at which one phase is switched out the Σ's of equations 6 are computed. These are substituted in equations 6 for the instant the second phase is switched out and the corresponding Z's are computed. x_3 and x_4 are now computed from equations 2*a*. (Note that the values of x_1 and x_2 so computed are not zero in general; in practice the energy accruing from their annihilation is dissipated in arcs at the contacts.) δ and ϵ are computed from these values and substituted in equations 7 and x_3 and x_4 computed for the end of the "no phase" interval. These are translated into Z's via equations 2*a* with x_1 and x_2 zero, new values of the Σ's of equations 6 are worked out and the Z's computed for the instant the second phase is reclosed reversed. Equations 4 are transformed as described above, new Γ's computed for these equations and the transient followed as far as desired. Since the coefficients of explicit formulae for the Z's have been evaluated for each interval, it is possible to compute the instantaneous torque at any time before, during, and after the switching sequence.

The changes necessary for the computation of other switching sequences are fairly obvious. There are in all ten different switching sequences by means of which a motor can be plugged, the two phases being regarded as distinct. In reality it can be shown that from the computational point of view they may be regarded as interchangeable, so that the number is reduced to five. These five appear to be distinct.

In the cases we have investigated numerically, the maximum transient torques occur when the switching is done at voltage zero and the minimum transient torques occur when the switching is done at voltage maxima. In the limiting case considered here there appears to be no upper limit to the transient torques obtained from arbitrary switching sequences. In practice, of course, saturation of the iron would intervene. In one case we computed opening and closing at voltage zero, and leaving one phase in throughout the switching, a transient torque twenty times the steady state plugging torque was computed.

Solutions From the Differential Analyzer

To obtain a general view of transient plugging torques resulting from simultaneous switching equations 3 were solved on the Massachusetts Institute of Technology differential analyzer.[2]

The use of gears for multiplying constants into the machine restricted us to simple rational fractional values of a, b, and c. The results are shown graphically in the accompanying illustrations. The ordinates are ratios of instantaneous

torque to steady plugging torque. The abscissas are cycles.

The accuracy of the instantaneous torques from the differential analyzer was expected to be of the order of two percent of the steady-state torque based on the machine constants. All curves were run until a steady state set in and the value compared with the first term of equation 5. They always agreed within two percent. In many cases the curves were integrated graphically and the results substituted directly in equations 3 for a value of u near the maximum of the instantaneous torque. The discrepancies were never greater than three and usually less than two percent. This agreement between two totally different methods of solving equations 3 amounts to proof that both solutions are correct.

It will be observed that the highest transient plugging torque is 5.9 and the lowest 1.9 times the steady state plugging torque. As the parameters used sweep out the commercial range these numbers represent approximate limits between which maximum theoretical torques will lie for motors of any number of phases provided the rotor currents are initially zero and all phases are switched simultaneously. The best results we have on actual motors lie in this range. In general, the effect of sequential switching will be to spread the torques outside this range.

It is interesting to note that the torques for simultaneous switching never fell below zero by more than the error of the machine, though many of them came very close to zero following the maximum. In sequential switching negative torques are usually found at some points.

It will assist in the interpretation of the curves to remember that large values of A and C correspond to circuits of high inductance-to-resistance ratio, and, in ordinary commercial practice, to large motors. D, it will be remembered, is the ratio of rotor to stator resistance. The difference between B and the mean of A and C is the measure of the leakage reactance of the machine.

For several cases the magnetizing currents x_1+x_3 and x_2+x_4 were computed and plotted with the torque curve. It will be seen that the transient torque maxima are due more to shift of phase than to shift of amplitude.

Electric Locomotive Application

E. W. BRANDENSTEIN
MEMBER AIEE (Deceased)

D. R. MacLEOD
ASSOCIATE AIEE

ELECTRIC locomotives were first used for the movement of main-line traffic over 45 years ago. This early application was for tunnel work but it may be taken as the beginning of a new era in main-line transportation. In this era the steam locomotive has been transformed in appearance and characteristics. More recently the Diesel engine has been applied to passenger and freight trains. During all this period of development the characteristics of the electric locomotive have continued to be superior to those of either the steam or the diesel-electric locomotive. Many of the early ideas with regard to the application of electric locomotives are still valid today, but progress in transportation engineering has become so accelerated that a periodic review of each type of motive power must be made by those who are responsible for their application.

A discussion of the engineering fundamentals which enter into the selection of an electric motive power unit for main-line work will be presented. An understanding of these fundamentals is essential to the specification of a balanced design. A locomotive which is specified on this basis will give all of the advantages of momentum operation augmented by high electrical horsepower at high speed. This is one of the unique advantages of the electric locomotive.

Development

Great as have been the advances in steam and diesel-electric motive power, the developments in the electrification of main-line railroads are still more spectacular. Figure 1 depicts the tremendous improvement which has been made in electric motive power during the last 20 years. This advance is due in no small measure to the pooling of the engineering talent of the two leading electrical manufacturers and to the pioneering spirit of the Pennsylvania Railroad. This railroad has in service approximately 900,000 horsepower of electric locomotives capable of delivering peaks of over 1,500,000 horsepower at the wheels. These locomotives consume approximately one billion kilowatt-hours per year. The power is supplied from 364,000 kva of single-phase 25-cycle generators over 1,100 miles of 132-kv single-phase transmission line.

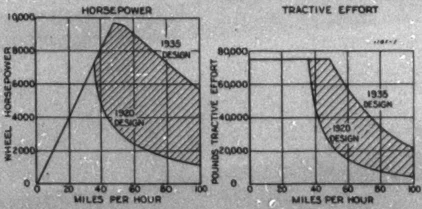

Figure 1. Comparison of 1920 and 1935 designs of electric locomotives

There are several 3,000-volt d-c systems in successful operation in this country. During the last decade steady advances have been made in d-c motive power and substation equipment, but all of the new 3,000-volt d-c applications have been in foreign countries. This discussion will, therefore, be confined to the 25-cycle single-phase system of electrification.

The *Electrical World* records that during 1939 consumption of electric power by the electrified railroads and transit systems was more than four per cent of the total amount of power consumed in the United States. Railroad electrification is, therefore, of great importance to every electrical engineer who has anything to do with power generation and distribution. Many of the problems associated with electrification have to do with getting power to the pantograph. A knowledge of the requirements of the locomotives and an appreciation of what is expected of them are essential for an economic design of that part of the system.

Types of Electric Locomotives

During the last ten years a great deal has been learned about the tracking qualities of high-speed electric locomotives. Extensive tests were made with different wheel arrangements, different weights on drivers, different degrees of restraint, different amounts of lateral in the drivers, and so on. The results of these tests have been printed in the technical press.

The most successful wheel arrangement used in this country for high-speed passenger service is classified as the 2-C+C-2 type. (The C+C means that there are two articulated driving trucks each having three axles. The figure 2 on each end of the 2-C+C-2 classification means that each driving truck is equipped with a two-axle guiding truck.) This type of locomotive operates successfully at speeds somewhat above 100 miles per hour with driving axle loads of 50,000 to 55,000 pounds. For freight service, where speeds do not exceed 70 miles per hour, the axle loading can probably be increased to 70,000 pounds without destroying the excellent tracking qualities of the locomotive. The 2-C+C-2 type of locomotive may, therefore, be used for a 150-ton (on drivers) locomotive for passenger service or a 210-ton (on drivers) locomotive for freight service. If a larger freight locomotive is desired one additional driving axle can be added to each driving truck, making a 2-D+D-2 classification and providing 280 tons on drivers.

Locomotive Characteristics

The speed-tractive effort characteristics of three locomotives of the 2-C+C-2 type are shown in figure 2. All three locomotives have the same wheel arrangement the only differences being in the motor and equipment capacity and the weight on drivers. It should be understood that all horsepower ratings are given in wheel horsepower, which is contrary to the usual practice for steam and diesel locomotives. Steam ratings are often given in terms of indicated horsepower, and diesel locomotive ratings in terms of engine output. Neither the steamer nor the diesel-electric includes transmission losses in its nominal horsepower rating.

Experience has taught us that at least 21 per cent adhesion can ordinarily be maintained on limiting grades with heavy rails and good ballast. The short-time maximum horsepower rating available at this adhesion is, therefore, quite important because it is used to accelerate trains not only from stops but also from every slow down. The overall schedule speed depends to a considerable extent on the

1. For all numbered references, see list at end of paper.

short-time rating. The rating corresponding to 21 per cent adhesion on the 6,000-horsepower locomotive is 69,300 pounds tractive effort at 56 miles per hour representing 10,350 horsepower at the wheels. For the 7,500-horsepower freight locomotive the short-time rating for 21 per cent adhesion is 88,200 pounds at 49 miles per hour representing 11,500 horsepower at the wheels. This is about twice as much power as is obtainable from the largest steam locomotive, and five to six times as much as has been installed in a single-cab diesel-electric locomotive.

The advantage of having locomotives, with characteristics similar to those shown in figure 2*B*, which can be used interchangeably in freight or passenger service is obvious. The peak passenger traffic on most lines does not coincide with the peak freight traffic. The latter usually occurs in October while the peak passenger traffic usually occurs in the vicinity of the Christmas holidays. These peaks are difficult to predict. The passenger peak is particularly variable as was evidenced by the very great increase for 1940 over that for 1939. The greatest flexibility in operation with the smallest number of locomotives is obtained if an appreciable number can be used in either freight or passenger service. The pool of universal locomotives can then be used for freight service in October and for passenger service in December.

The ability of the electric locomotive to utilize its overload capacity, together with its high availability, makes it an ideal type of motive power for handling peak traffic conditions with a minimum interference with schedules and with a minimum number of units. The high horsepower at speed gives it the ability to speed up the freight and get more miles per locomotive. Similarly it is possible to add as much as 50 per cent to the average passenger train weight and make the same or better schedule than was made with steam operation.

A railroad gets the greatest use of its track capacity and other facilities if the daily freight movement avoids the peaks of the passenger movement. If a locomotive can come into a terminal on a freight train and go out on a passenger or vice versa, a much smaller number of locomotives will be required than would otherwise be the case. The number of extra locomotives required as "protect locomotives" is cut in half. Maintenance is simplified, shop facilities reduced, and training of personnel simplified by the universal type of locomotive.

The electric locomotive has a further advantage in that it can be double headed without an extra crew so that excess motive power at one terminal can be moved to another terminal in anticipation of the requirements at that end.

A careful analysis of the traffic must be made when selecting the motive power for the division of a railroad that is to be electrified. A peak day of passenger and a peak day of freight should be selected and the trains rearranged for electric operation. The rearrangement of traffic can only be done intelligently by one who is very familiar with the division. The weight of the locomotive that is selected will depend upon the sizes of trains to be hauled, the schedule speeds that are to be made, and by the characteristics of the limiting grade. The continuous rating of the locomotive should be in the neighborhood of 700 to 1,250 horsepower per driving axle, depending on whether the axle loading is 50,000 pounds or 70,000 pounds or between these limits.

Momentum Operation

One of the outstanding advantages of the modern electric locomotive is its performance in momentum operation on relatively short grades. The flexible control and high tractive effort that are available at high speeds enable the electric locomotive to reap much greater benefit from momentum operation than is possible with other forms of motive power. The principle involved is that of the conversion of the kinetic energy of the train into the potential energy required to lift the train up the grade. The relation is expressed by the formula

$$\text{Lb per ton} \times \text{miles} = \frac{V_1^2 - V_2^2}{72}$$

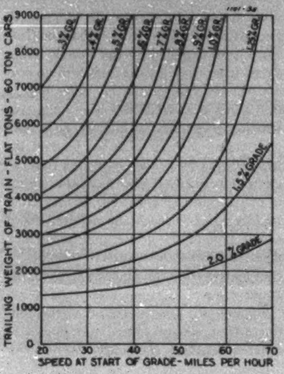
where V_1 and V_2 are the speeds in miles per hour at the beginning and the end, respectively, of the slow down. Thus a train that starts up a grade at 70 miles per hour and slows down to 20 miles per hour gives up energy equivalent to 62.5 pounds per ton-mile. If the train resistance (friction) is all supplied by the electric power taken from the line, the train will go over a 0.625 per cent grade five miles long, a 0.3125 per cent grade ten miles long, etc., starting at 70 miles per hour at the bottom and ending with 20 miles per hour at the top in each case. The advantage that the electric locomotive has over other forms of motive power is its ability to accelerate rapidly so as to reach the required speed at the foot of the grade, and in its high tractive effort at all speeds to supplement that gained from the kinetic energy of the train.

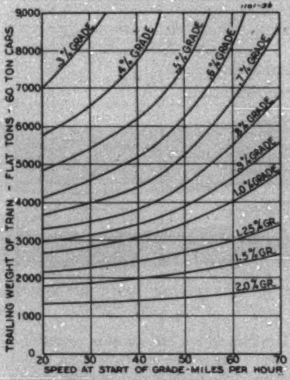
Figures 3*a*, *b*, *c*, and *d* show the tonnages that can be taken over grades of different lengths. The curves were calculated for 60-ton cars as these represent a good average weight of car for a loaded train. The 6,000-horsepower locomotive characteristic of figure 2*b* operating at 21 per cent adhesion up to 56 miles per hour was used for the tractive effort. The train resistance was calculated by the formula

$$TR = 1.5 + \frac{72.5}{W} + 0.015V + \frac{0.055V^2}{W} \quad \text{lb per ton}$$

where W is the weight of the car and V the speed in miles per hour. This formula gives values of train resistance more in line with the performance of modern equipment on a good road bed than does the conventional Davis formula.

An inspection of the curves reveals a useful criterion by means of which a momentum grade for a high-speed locomotive may be recognized. This criterion is that a momentum grade for an electric locomotive operating at high speed is one which has a characteristic of eight per cent grade-miles. Thus a two per cent grade four miles long, a one per cent grade eight miles long, etc., are momentum grades for

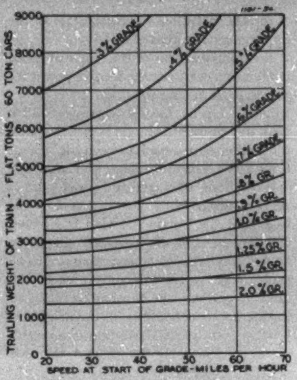




an electric locomotive. This characteristic would be considerably lower for a constant horsepower motive power unit having the same weight on drivers. The high tractive effort that is available at all speeds as the train slows down is a unique characteristic of the electric locomotive.

Heating and Commutation of Motors

Felix and Jungk[1] have presented a method for predetermining the temperature rise of an a-c traction motor. This enables the application engineer to take a train over the profile and determine the tonnage rating of a given locomotive on the basis of the heating of the motors. Ratings established in this way are then checked against the ratings permitted on the basis of momentum operation. In the case of relatively easy grades of the order of 15 miles or longer it may be necessary to provide greater thermal capacity to obtain the full benefit of the high short-time overload capacity of the electric equipment. The ventilation of the motors is, therefore, an important part of the motor design for a given application.[1] The maximum benefit with a given equipment will be obtained if the engine is brought up to speed soon enough to permit the blowers to cool the motors down before attacking the grade. Since the blowers on a locomotive consume an appreciable quantity of power, it can be seen that variable speed blowers have a definite advantage over those that operate at constant speed. Forced ventilation can then be provided when it is needed.



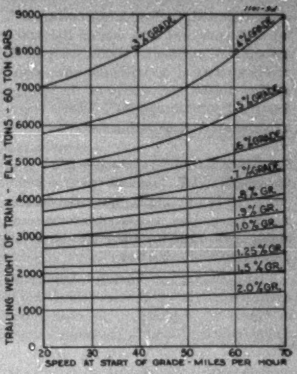


Figure 3. Momentum operation of 6,000-horsepower electric locomotive; 330,000 pounds on drivers; 21 per cent adhesion to 56 miles per hour

(*a*) Length of grade $2^1/_2$ miles
(*b*) Length of grade 5 miles
(*c*) Length of grade $7^1/_2$ miles
(*d*) Length of grade 10 miles

When an engine is limited in its tonnage rating by heating, the capacity can be increased by simply changing the gearing to lower the top speed. Thus if a 70-mile-per-hour engine is found to be limited by heating, consideration should be given to changing the gearing of some of the engines to 70 mile-per-hour gearing and assigning these permanently to freight service. The only difference between a freight locomotive and a passenger is the gearing if this plan is adopted.

On the other hand, it is possible to apply larger motors so that the continuous horsepower will be greater with only a slight increase in weight on drivers. Such a locomotive does not have the heating limitations of the usual 90-mile-per-hour passenger engine and can be used in freight service with no more restrictions than are applied to the 70-mile-per-hour freight engine. For instance, a 6,000-horsepower locomotive of the 2-C+C-2 type with characteristics as shown in figure 2*b* can be built without exceeding 55,000 pounds per driving axle. The continuous rating of this 6,000-horsepower locomotive is approximately 50,000 pounds tractive effort with 90-mile-per-hour gearing. The continuous rating of the 4,800-horsepower locomotive, figure 2*a*, when it is geared for 70 miles per hour is 43,000 pounds tractive effort. It is, therefore, evident that the universal 6,000-horsepower locomotive, which is good for either high-speed passenger service or for freight service, will have a higher tonnage rating than will the 4,800-horsepower locomotive when it is geared for 70 miles per hour. This 6,000-horsepower locomotive represents what is meant by a balanced design.

There are many details of motor design which must be considered for a given application. Such details are beyond the scope of this paper, but the following empirical relation, which has been borne out by operating experience, is of value when a preliminary study is being made.

Number of poles on motors per axle =
weight per driving axle in tons

Control

The adjustments of the main and interpole fields which are necessary for the best performance of an a-c series motor are under the control of relays.[1] Figure 4 shows the essential elements of the circuits by means of which the motors are controlled. There are two small preventive coils X_1X_2 and Y_1Y_2 and one large preventive coil X_3Y_3. This method of tap changing under load permits rapid operation of the control and is the most economical in weight and space of the available tap changing schemes. Since the motors are designed for relatively low voltage a number of armatures are connected in series.

When a wheel slips, the motors that are geared to the slipping axle consume most of the voltage and overspeed. Ogden[8] has proposed an autotransformer connection which equalizes the voltages across the slipping and working motors that are in series. This limits overspeeding and gives substantially the same performance as if the motors are connected in parallel. The practice at the present time is to notch back when slipping occurs rather than to add automatic anti-slip equipment. A slip relay tells the engineer of a locomotive when to notch back and the control is made fast enough to reapply power without complete loss of tractive effort. A slow control would be a disadvantage because there would be some loss of headway which might be sufficient to stall the locomotive when it is operating at very low speeds. Relatively slow controls have been built, but locomotive crews who have operated both types prefer the fast control.

The preventive coil method of tap changing under load has the disadvantage of causing high switching surge currents. The contactors all make and break load current and must be designed to make considerably higher currents than they have to break. When a contactor (figure 4) is opened, the load current passing through one leg of either X_1X_2 or Y_1Y_2 is not balanced by a corresponding current in the other leg so that one-half of the total load current saturates the core of the coil that is being switched. When a contactor is closed to change to the next notch the fluxes in the coils must change suddenly to new values determined by the main transformer tap voltages to which the terminals X_1, X_2, Y_1, and Y_2 are connected. This causes transient currents to flow in the preventive coil circuits and through the tapping contactors. The preventive coils are designed with certain densities and air cored reactances to keep the surge currents to a value which will be within the interrupting rating of the contactors.

The duty on the contactors is greatly reduced if a resistor is connected from X_1 to X_2 before the coil X_1X_2 is switched, or from Y_1 to Y_2 before Y_1Y_2 is switched. The resistor commutates the load current instantly so that the current, which was passing through the contactor before the switch opened, passes through the resistor immediately after the contactor opens. The direction and magnitude of the current in the leg of the preventive coil that is being switched is maintained so that the coil does not saturate. Additional contactors and some elaboration of the control are required to cut the resistor into circuit before the preventive coil contactors are opened and to cut it out after the transition is complete.

When one leg of a preventive coil is open the other half must carry twice the load current and is, therefore, subject to approximately four times the heating. The coils are usually of the forced air cooled type which does not have the thermal storage of an oil-insulated type. It is, therefore, desirable to keep the currents balanced in the legs of the preventive coils on all running notches.

The number of available notches may be multiplied three times by the addition of the small buck-boost transformer marked Z_1Z_2 in the diagram figure 4. The secondary is in series with the motor and the primary is connected in one direction or the other across a pair of taps on the main transformer. A Thyrite resistor is connected across the primary in order to hold down the voltage that would otherwise appear when the primary is open-circuited with the secondary carrying load current. This feature gives a very smooth control and is particularly useful in freight service when working near the limits of adhesion.

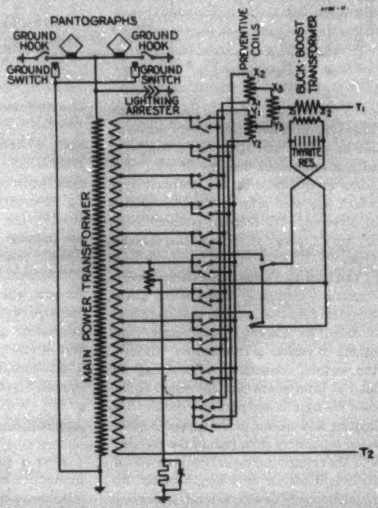

Figure 4. Main power transformer with low-voltage taps and auxiliaries for control of a-c series motors

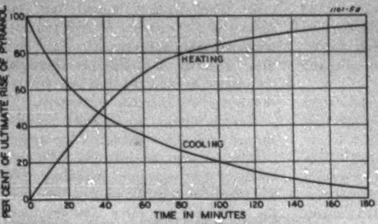
Transformer Heating

The preventive coils and buck-boost transformers are of the forced air cooled type. They have a thermal time constant (reach 63 per cent of their ultimate temperature) of approximately eight minutes. Their thermal design is, therefore, determined by the short-time performance that is required from the locomotive.

The main power transformer converts the relatively high voltage of the trolley (12,000 volts) to the relatively low motor voltage. The maximum secondary voltage that is used at the present time is of the order of 1,400 volts. The reactance of the transformer should be kept relatively low because it is in reality a part of the distribution system. The per cent reactances used on all locomotives should be approximately the same so that the notching curves will line up for multiple-unit operation. The impedance of the motor circuit adds vectorially to that of the transformer and preventive coils to give tractive effort-speed curves that are relatively steep. Increments of tractive effort equivalent to about one per cent of the weight on drivers are obtainable from zero speed until the top characteristic is reached.

Figures 5*a*, *b*, *c*, and *d* show characteristic heating and cooling curves of a 25-cycle locomotive transformer. The transformer is Pyranol-insulated. A motor-driven pump immersed in the transformer tank circulates the liquid through the coils and the radiator in series. The heat is removed by force ventilating the radiators. The time constant of the transformer is nearly one hour, whereas that of the cop-



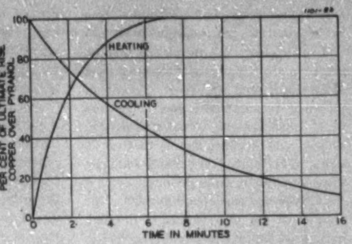


Figure 5. Pyranol insulated forced cooled locomotive transformer

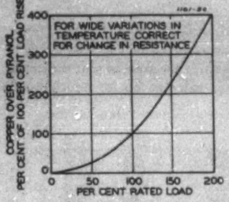
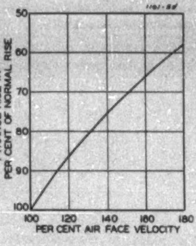
(*a*) Heating up and cooling down curves of Pyranol with pump and blower on

(*b*) Heating up and cooling down curves of windings—rise over Pyranol



(*c*) Winding rise over Pyranol for constant conditions and constant resistance



(*d*) Pyranol rise versus air velocity for constant conditions

per is of the order of two to three minutes. This type of transformer is very economical in weight and space when compared with a self-cooled design. It also compares favorably with the air-blast type which was used prior to the introduction of Pyranol. Its thermal characteristics are very superior to those of the air-blast type.

The load on a locomotive transformer is constantly changing. The heating can be calculated by the methods that have been outlined by Cooney, Montsinger,[4] and others in various AIEE papers. Briefly, the method consists in determining the load at intervals of time for which significant changes in temperature occur. The heating and cooling of the copper is calculated separately from that of the Pyranol, and the resultant temperatures are added. In freight service on a long haul the Pyranol may only be able to reach 50 per cent of its ultimate before it starts to cool down again. The required capacity of the transformer can be determined theoretically by taking a train, which can be handled by the motors and preventive coils, over the profile and calculating the temperature rise for an assumed rating. It is well known that liquid-cooled transformers will stand overheating for short intervals without appreciably affecting their life. It is, therefore, not necessary to make allowances for emergency operating conditions when selecting the rating for a given service.

High-Voltage Insulation

The insulation level of a locomotive is determined by that required for the primary of the transformer and the high-tension cable. The existing a-c electrifications in this country operate on a nominal 12-kv trolley and the prevailing practice is to use three insulators. These have an impulse flashover of approximately 355-kv crest on a 1.5 by 40 positive wave. The insulation level of the Pyranol transformers which have been in service on locomotives for more than five years is equivalent to a full wave AIEE impulse test of 120 kv. They are protected with 15-kv (max.) Thyrite lightning arresters mounted on the transformer.

Application

After a suitable rating and design of locomotive has been selected the next step is to make a more detailed study of the traffic than was made in the preliminary selection. An analysis can only be made after making a prolonged study of the movement of traffic over the divisions that are to be electrified as well as those that feed into the electrified zone but which will remain in steam operation. The delays that occur from day to day in steam operation must be studied to see to what extent these delays may be reduced or eliminated. Such details as track capacity in terminals may affect the possible length of passenger trains. Speed restrictions, cross-overs, passing sidings, and the like will affect the schedule speeds. The possibility of combining freight trains to take advantage of higher speed operation, made possible by the more powerful electric locomotives, will be affected by the facilities that are available in classification yards and by the service that is available on lines that feed into the yard. The combination of sections of passenger trains into larger sections will be affected by the origin of the cars, by the facilities for switching at terminals, and by the inclusion of mail or express cars with passenger cars. Finally, it is essential to examine the performance of all facilities that contribute to the make-up, dispatch, and movement of trains under peak traffic conditions.

When all the fundamental data have been assembled, a train sheet can be prepared for electric operation and compared with steam operation. The number of locomotives that are required for that day can be determined from the electric train sheet. The ratio of the number of steam locomotives that were required for the day that was studied to the maximum that had ever been used gives a factor by which the number of locomotives may have to be increased when a complete change-over has to be made. Electric operation often proves to have many nonpredictable operating advantages so that the number of locomotives actually required is less than the calculated figure. It is, therefore, advisable to make an initial purchase of less than the calculated requirements and buy added units as needed.

Conclusion

Single-cab electric locomotives with high horsepower at speed have been in successful operation for several years. They are maintaining high-speed passenger and freight schedules which would be impossible with any other type of motive power having the same horsepower rating. The universal type of locomotive is conservatively designed on the basis of this experience for use in either freight or passenger service. Its electrical characteristics are co-ordinated with its weight on drivers and it combines high horsepower at speed with high availability. It is, therefore, capable of moving more gross ton miles per train hour with fewer units than any other type of motive power.

E. M. WOOD
MEMBER AIEE

Introduction

AT the summer convention of the Institute in 1930, Mr. E. T. J. Brandon presented a paper under this same title,[1] describing the design of the initial components of this system, which had then been in operation approximately one and one-half years. At that time, one and one-half circuits, having a combined length of 350 miles, were in service, transmitting approximately 110,000 kw. to a receiving terminal station in the Toronto area of 180,000 kva. capacity. At the present time, the Commission is operating a total of 1,000 miles of single-circuit 220,000 volt construction, with one receiving terminal of 420,000 kva. rated capacity and is placing into service immediately 45 miles of double-circuit construction and a second receiving terminal of 150,000 kva. capacity.

This paper presents a brief history of the development of the system and places on record the experience gained in 8,400 circuit-mile-years of operation of the transmission circuits. Data are presented regarding lightning outages and the behavior of the circuits under sleet and conductor vibration.

These data are then used to indicate the reasons for certain revisions made in the design of new single-circuit construction carried out during 1940–41, and to indicate the factors that influenced the design of a new 45 mile double-circuit extension. The paper concludes with a discussion of the relay protection system and the improvements now being incorporated therein.

General System Arrangement

The 220,000 volt system under discussion forms part of the Commission's 25 cycle Niagara system, figure 1, which supplies a highly developed area of some 12,000 square miles in the peninsula formed by Lakes Huron, Erie, and Ontario. This system distributes power over approximately 1,350 miles of 110,000 volt lines. The total primary load, which equalled 710,000 kw. in December 1929, reached nearly 1,125,000 kw. in December 1940.

This 220 kv. system has been the channel over which all growth of load in the Niagara system has been supplied since 1928, from generating sources largely in the neighbouring Province of Quebec. An initial 60,000 kw. was transmitted over the first circuit in October 1928, increasing to 515,000 kw. transmitted over three such circuits in December 1940.

Table I. Lightning Outage Record

Classified According to the Type of Fault

Involving one wire and ground	56– 59%
Involving two wires and ground	25– 26%
Involving three wires	14– 15%
Total	95–100%
Involving one circuit only	95– 98%
Involving two circuits simultaneously	1– 1%
Involving three circuits simultaneously	1– 1%
Total outages due to lightning	97–100%

Until this summer, this supply has been delivered at the Leaside receiving terminal, adjacent to the City of Toronto, which it will be noted lies at the easterly extremity of the main 110,000 volt system. This fact has in itself created problems of distribution, the solution of which will be materially aided by the placing in service of the new terminal shown at Burlington.

Development of 220,000-Volt System

The 220,000 volt system was initially conceived as a two-circuit system, with a mid-point interswitching station, transmitting some 200,000 kw. purchased under contract from the Gatineau Power Company, from that Company's Paugan development some 230 miles east of Toronto. Later contractual undertakings and the construction of the Chats Falls development on the Ottawa River, brought the total capacity available from eastern sources to approximately 615,000 kw.

The third 220 kv. circuit was constructed in 1931, when the Chats Falls development was first brought into service. The connection shown from Beauharnois to MacLaren to Chats Falls was built during the depression years, to deliver the power which became available from the former sources to Chats Falls for transmission over the three-circuit system. This was an expedient, adopted as the most economical means of effecting this delivery, following an analysis of the transmission capacity of these three circuits in the light of the then existing knowledge of stability problems. This analysis indicated that, even without a mid-point interswitching station, the dependable capacity of these circuits, given proper fault clearance times, could be increased from an earlier rating of 330,000 kw. to approximately 450,000 kw.

The terminal capacity at Leaside has been increased progressively, by the addition of four 45,000 kva. banks, duplicate of the two banks originally installed, and two 75,000 kva. banks, making a total installed rating of 420,000 kva.

Until the outbreak of hostilities in September 1939, it was planned that this system would need to be extended for service in the fall of 1942. The outbreak of hostilities, however, brought the expectation of rapidly accelerated power demands and the construction of a fourth circuit from the Beauharnois development of the Beauharnois Light, Heat and Power Company, in the Quebec section of

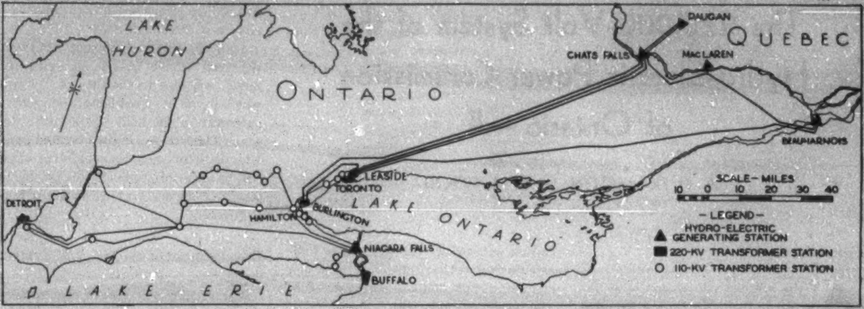

Figure 1. The Niagara system of the Hydro-Electric Power Commission of Ontario, showing major generating and transformer stations and 220-kv and 110-kv lines

the St. Lawrence River, was immediately undertaken. The selection of a westerly terminus for that line presented a problem upon which considerable time and study has been expended.

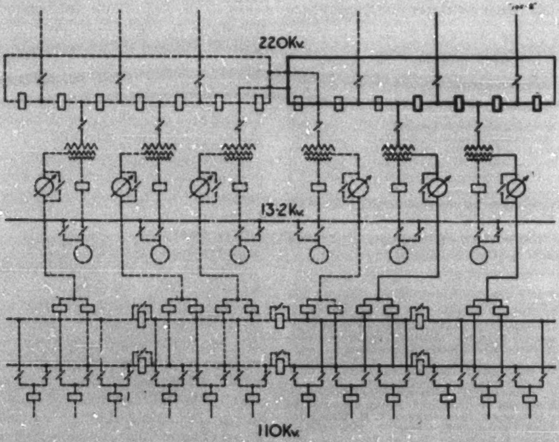
The Leaside terminal, being located in the metropolitan area of the City of Toronto, in which approximately 40 per cent of the total primary demand of the Niagara system occurs, provided a convenient point of distribution for the power delivered during the building-up years. In later years, however, Leaside has been expanded beyond the capacity originally contemplated, so as to make the most efficient use of the transmission system, thereby creating an increasing distribution problem.

Furthermore, as is obviously desirable, the power transmitted over this system was purchased under contracts which require high load-factor deliveries, much higher, in fact, than the load-factor of the demands within the immediate vicinity of the receiving terminal.

For these reasons it has been necessary to distribute from Leaside, to gradually increasing distances, power and energy delivered in excess of the Toronto area demands. This distribution distance increases and decreases daily, with the variations of local demand, and is considerably greater in the summer than in the winter. During recent summer months power generated 250 miles east of Toronto has actually been delivered to the immediate vicinity of Niagara Falls.

Figure 2. Burlington 220-kv receiving terminal

Proposed ultimate diagram for six 220-kv circuits and six 75,000-kva transformer banks. Initial (1941) installation in heavy lines



It had been planned that the second 220 kv. terminal would also be in the Toronto area, but on its westerly outskirts. Further study, in the light of the increased capacity of Leaside, has resulted in the new terminal being located at Burlington, some thirty miles west of Toronto. At that point the new station is adjacent to the rapidly expanding load area of the city of Hamilton and also is situated where a number of existing 110 kv. circuits intersect.

This new terminal is supplied by diverting to it the shortest of the existing 220 kv. circuits, namely, one originating at the Chats Falls development, thus holding the longer Beauharnois circuit to its minimum length by terminating it at Leaside. In addition, a 220 kv. tie-circuit between Burlington and Leaside is provided, interconnecting the 220 kv. lines so that they operate as a four-circuit system. These two circuits are carried around the metropolitan area of Toronto and to Burlington

Table II. Lightning Outage Record

Classified According to Tower-Footing Resistance

Average Tower-Footing Resistance—Ohms	Number of Outages	Circuit-Mile-Years of Operation	Outages Per 100 Circuit-Mile-Years
(a) For 70 located faults on the Leaside-Chats Falls Circuits			
Under 25	3	2,150	0.14
25–50	6	1,950	0.31
50–200	16	2,000	0.8
Above 200	45	1,100	4.1
	70	7,200	0.97
(b) For all outages due to lightning			
Under 25	5	2,600	0.19
25–50	9	2,200	0.41
50–200	27	2,500	1.08
Over 200	56	1,100	5.1
	97	8,400	1.15

(b) Corresponding outline of revised 1940 tower

on double-circuit structures, the first of such construction adopted by the Commission.

The Burlington transformer station is being constructed on a sixty-acre site, designed to accommodate ultimately six banks of three-25,000 kva., single phase, 220/110/13.2 kv., forced-air-cooled transformers. Two banks totalling 150,000 kva. are being installed initially. A schematic diagram of the proposed ultimate station is shown in figure 2, on which the initial installation is indicated in heavy full lines. The addition of a third bank at this station will complete the existing phase of development, providing for the delivery of some 675,000 kw. over the four 220 kv. circuits. Beyond that point further delivery at Burlington will depend upon the development of new power resources, as for example, upon the Ottawa or St. Lawrence rivers.

Summary of Operating Experience

The first of these 220 kv. circuits was placed in service on October 1, 1928, since when a total of 560 circuit-miles has been added, making a total of 790 circuit-miles in service as of March 31, 1941. Of this mileage some 85 circuit-miles are not actually operated by the Commission, being located in the Province of Quebec, but are included in the following record. The whole of this construction in general conforms to the designs described in the earlier paper, the standard suspension tower being shown in figure 3*a*.

In approximately thirteen years, 8,400 circuit-mile-years of operating experience have been secured and a total of 111 faults due to all causes have been experienced. Of these, four were occasioned by various construction hazards in the early years and eight were due to miscellaneous causes, chiefly external interference. Each of these faults involved only one wire and ground and, except in the period when only one circuit was in service, created no serious disturbance. It is of interest to discuss the salient features arising out of the remainder of this extensive operating record.

(a) LIGHTNING

Of the remaining 99 faults experienced in this period, 97 are attributed to lightning, equal to an average of 1.15 lightning outages per 100-circuit-miles per year, in a territory in which the thunderstorm frequency is between thirty-five and forty storms per year. The classification of these lightning faults as to single-wire-to-ground, two-wire-to-ground, and three-wire and as to those involving one, two, or three circuits is given in table I. The frequency of occurrence of such faults has varied tremendously; for example, three outages have been experienced within ten minutes; on another occasion, four within an hour and again five in one day and yet one period of eighteen months passed without a single outage.

These averaged data do not give a complete picture of the performance of these circuits. The three Chats Falls-Leaside circuits are constructed over terrain varying from rich farm land to rocky undeveloped bush country. The latter section, which extends almost continuously for a distance of about 90 miles, is characterized by surface rock formations with pockets of muskeg in the rock depressions. Towers are frequently erected on the rock outcrops. Low footing resistances are, therefore, difficult to obtain. In figure 4 an approximate footing-resistance profile for the Chats Falls-Leaside section is given, as compared to the known location of 70 of a total of 89 outages in this section attributed to lightning. It will be seen that some 90 per cent of the located lightning outages occurred in the section of high footing resistance.

In table II is presented an attempt to co-relate the lightning outage record with footing resistance. The data are presented first for the 70 located faults in the Chats Falls-Leaside section and then for all 97 faults, based on locations for those not traced, as estimated from relay target and oscillograph records. It will be observed that, in the territory where footing resistances are considered to be below 25 ohms, the actual outage record approximates 0.2 outage per 100-circuit-miles per year.

Reference to figure 3*a* shows that the tower design in these lines provides a shielding angle of 42 degrees and a ratio of "height of ground wire above power conductor to total height of ground wire" of 0.182. The experimental results of Wagner, McCann, and MacLane[2] and the data presented by Waldorf[3] would indicate that good lightning performance could be expected and the record proves, that given low footing resistances, such has been the case.

Some crowfoot counterpoise work was done in the rock section along these three circuits during 1934–35. Short sections of highest footing resistance were so treated, with some success in lowering the measured values, but presumably the distances the crowfoot wires were carried to reach good grounds were too great to secure any considerable benefit.

(b) MECHANICAL—SLEET AND WIND

In the southern part of the Province of Ontario sleet storms of varying intensity may be anticipated both in the early and late winter seasons. December and March are the two worst months, though infrequently sleet may occur in any month from November to April. Storms have been experienced which have disrupted communication circuits and taken down wood pole construction. The phenomenon of "galloping conductors" has been

observed, at not infrequent intervals, on various sizes and spans of conductors up to 605,000 c.m., A.c.s.r. at a span of 880 feet. Consideration must therefore be given to sleet conditions for all lines designed or constructed in this territory.

Two outages in the period under review are attributed directly to sleet, and these, incidentally, occurred within a few minutes of one another. Heavy sleet had formed on both power conductors and ground cables on certain hill tops, but only lightly on an intervening long valley span. As a result, the power conductors in the long span were pulled up by the unbalanced loading on the two sides of the adjacent suspension insulation, so that the ground cables, sagged to their normal loaded positions, appeared below the plane of the power conductors at mid-span. Two flashovers occurred, the second of which burned down a ground cable, resulting, on account of inaccessibility, in 27-circuit-hours of outage. In two other similar cases, a condition of unbalanced sleet loading was set-up, greatly increasing the sag of the ground cables without compensating sag of the power conductors, resulting in inadequate clearances. Fortunately, in these cases, the conductors were not distributed by wind.

(c) MECHANICAL—VIBRATION

At the time of the construction of the first of these circuits (1927–28), the then relatively recent adoption of much longer spans and higher conductor tensions had brought the problem of conductor vibration strongly to the attention of transmission engineers. Remedial or palliative measures were as yet under investigation. In the original design this problem was recognized by providing, at suspension points, a reinforcement consisting of a 6-foot length of the conductor fastened at its outer extremities and supported above the main conductor in a double-seated suspension clamp, figure 5*a*. In the second and third circuits this form of reinforcement was replaced by the standard armour rods.

Each of these circuits was designed for a maximum conductor tension, at $^{1}/_{2}$ inch ice, 8 pound wind, and 32 degrees F, of 10,000 pounds, conductors being 795,000 c.m., A.c.s.r having an ultimate strength of 28,500 pounds. This represents a maximum tension of 35 per cent of ultimate and also represents a tension at 60 degrees F of 16 per cent of ultimate. These figures will be recognized as indicating a design in which conductor fatigue due to vibration might be anticipated.

Actually a considerable record of vibration has accumulated in operation, though nothing approaching a serious condition has been observed to date. Quite early a loosening of tower members was experienced, but this was remedied by the use of locknuts or their equivalent at all one and two bolt positions. Careful periodic examination of the conductors has revealed a few broken strands though such damage does not indicate the need for any further palliative measures for some years.

Revisions in Design Incorporated in the 1940–41 Single-Circuit Construction

The recent extensive additions to this system were naturally not undertaken without re-consideration of the various design factors in the light of the experience enumerated above. It is of interest therefore to review such revisions as were made and to discuss the reasons associated therewith. The discussion is perhaps best arranged under the previous headings, though it is difficult to separate those adopted for improved lightning design from those which aimed at improvement in the mechanical performance.

(a) LIGHTNING

The record indicates that good lightning performance can be expected of the original single-circuit tower, so long as footing resistances are kept sufficiently low. Perhaps, therefore, no change would have been made in the tower design were this the only factor, but as it was decided to raise the ground cables primarily for sleet operation, this revision may also be taken as improving the expectation of good lightning performance.

As illustrated in figure 3*b*, the two ground cables were raised eight feet above their original location, to a point of support 21 feet above the point of support of the power conductor in the suspension tower. This has had the result of decreasing the shielding angle to 29 degrees, while increasing the ratio of "height of ground cable above power conductors to total height of ground cable" to 0.263.

Measurements made by the Meg-Earth tester shortly after tower erection indicated that, in the earth sections, after consolidation of the back-fill, tower footing resistances generally would not exceed 15 ohms. In these sections, no treatment beyond the occasional crowfoot is contemplated. In the rock section, it was decided to lay a continuous counterpoise, consisting of $^{5}/_{16}$ inch steel conductors available in salvage stores. These cables are in general buried to an average depth of 18 inches under the outer phase wires. Occasionally, however, they are taken around rock outcrops, when by so doing they could be buried, and, in isolated cases, are actually carried over the top of the rock. The performance of this new circuit will be carefully compared to that of the existing circuits as such performance will largely dictate whether counterpoise should be added to the older construction.

(b) MECHANICAL—SLEET AND WIND

Our experience would seem to indicate that, under the operating conditions existing, sleet is more liable to form on the ground cables than on the power conductors and under such conditions, the vertical separation provided between ground cables and power conductors has proven insufficient. Mr. A. E. Davison, transmission engineer for the Commission, has actively studied this problem of conductor clearances. These studies are based on Lissajous figures[4] and the locus of motion of the conductor under "galloping" conditions is taken as the criterion. The axes of this motion have been determined empirically from recorded field observations and from analyses of motion picture records of a number of actual occurrences. It is possible to at least approximately delineate the various loci. A tower design in which these approximate loci indicate adequate clearance between all conductors is considered much more satisfactory than one in which overlapping loci occur.

However, the extent to which this method should be applied to heavy conductor, long-span construction is still somewhat of an open question, being largely based on the behaviour of smaller conductors and shorter span construction than is involved in this case. No conclusive data are available indicating that 795,000 c.m., A.c.s.r. at 1,056 foot spans will "gallop" at all, and, even if it does, whether it will be in one continuous loop between the points of support or in something of a wave motion raising not more than one-half the span above its normal position at one time (that is, in half-loops). Messrs. Oldacre and Wollaston,[5] in describing the Powerton-Crawford line, illustrated the use of Lissajous figures and assumed the movement of the conductor in one loop.

In our case, however, a substantial mileage of towers was available in stock and much quicker deliveries could be obtained if the basic original design was not changed. This design was based on a longitudinal loading equivalent to $^{1}/_{2}$ inch ice and 8 pound wind, but with the transverse loading increased to $^{3}/_{4}$ inch and 11 pound wind, the latter increase an added factor of safety since considered unnecessary. It was decided that part of this excess strength could be utilized to provide greater vertical separation between ground cables and power conductors, though in designing this improvement it was considered sufficient to assume movement of the conductors in half-loops only. It will be noted in figure 6*a* that the redesign has removed the loci of motion of the ground cables from those of the phase conductors, providing adequate clearances under the assumed conditions. The ice-loaded mid-span position of the ground cable at rest, as compared to the corresponding position of the unloaded phase conductor, is also shown, indicating the maintenance of substantial clearances even with a $^{3}/_{4}$ in. ice differential.

(c) Mechanical—Vibration

The balance of the excess strength in the original tower design has been utilized to increase the ruling span from 1,056 feet to 1,150 feet. In order to maintain the same ground clearance at this longer span, the higher strength 26x7 strand, 795,000 c.m., A.c.s.r. has been used, strung to a maximum designed tension of 12,000 pounds. Based on an ultimate strength of 30,900 pounds, the designed maximum and "60 degree" tensions therefore approximate 39 per cent and 17.6 per cent of ultimate strength respectively.

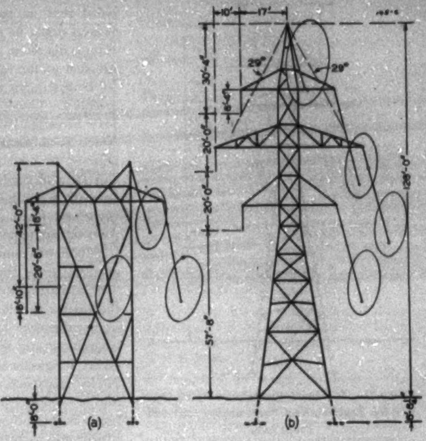

Figure 6. (a) Clearance diagram (Lissajous figures) for 1940–41 single-circuit construction

Loci based on half-loops, i.e., movement of quarter-point in suspension span. Note also mid-span positions of $^{3}/_{4}$-inch ice-loaded ground cable and unloaded phase conductor

(b) Corresponding diagram for 1941 double-circuit construction

Note full loop movement of ground wires assumed at 880-foot span

The lengthening of the span in the new circuit was based partly upon the vibration record of the existing circuits and partly upon the favourable results obtained from an extensive laboratory and field investigation of damper design and performance.[6] It is felt that the development in this field now safely permits securing the economy inherent in longer spans and higher conductor tensions. The full possibilities in this connection were not realized in this case, due to the decision to retain the basic original tower design, but had a completely new design been permitted, spans as great as those encountered in some other recent construction would have been given serious consideration.

Associated with this increased span length the application of vibration absorbers was decided upon, rather than the previously used armour rods. Approximately one-half the line is equipped with the Stockbridge damper and one-half with the torsional damper, figure 5*b*, developed in the Commission's laboratory and described in a companion paper by Mr. G. B. Tebo.[6] Both dampers are used singly, that is, two per span. Vibration of the ground wires is protected against by the use of festoons, figure 5*c*.

Double-Circuit Construction—Leaside to Burlington

In considering the two-circuit extension of these 220 kv. lines, from the existing terminal at Leaside to the new terminal at Burlington, a number of factors were brought into consideration. Single-circuit construction was initially considered, the Commission not having previously operated any double-circuit construction at 220 kv. In fact, there had been evident in the Commission's engineering a tendency to avoid such construction at all voltages, in favour of various single-circuit configurations. However, as some twenty miles of the Burlington extension necessarily encircled the metropolitan area of Toronto, this viewpoint was brought sharply into conflict with the question of right-of-way costs. The final decision was in favour of the double-circuit construction, though it will be noted that a relatively conservative design has been adopted.

The initial decision was to adopt a span of 880 ft., utilizing 795,000 c.m., A.c.s.r. at a maximum designed tension of 10,000 pounds. However, a change in this decision was brought about by the exigencies of the present situation and the line is actually being constructed utilizing the type HH segmental, hollow-core, copper conductors, 500,000 c.m., 1.02 inch outside diameter, seven segments, having an ultimate strength of 21,200 pounds. At the 880 ft. ruling span the maximum designed tension, at $^{1}/_{2}$ in. ice, 8 pound wind, and 32 degrees F, is 9,500 pounds, the 60 degree tension being 4,700 pounds, equivalent to 45 per cent and 22 per cent of ultimate respectively.

The tower design adopted is shown in figure 6*b*. It will be noted that a single ground cable is used, located at the tower peak, 30 ft. above the point of support of the upper phase conductor in the suspen-

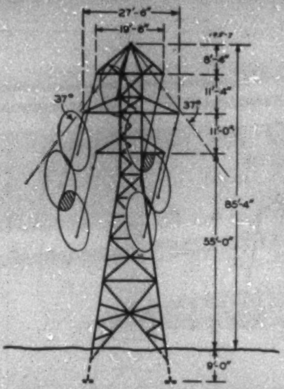

Figure 7. Clearance diagram for 1920-type 110-kv double-circuit construction—one-half loops only

Note overlapping loci indicating anticipation of sleet outages

sion position. A shielding angle of 29 degrees and a ratio of "height of ground wire above power conductors to total height of ground wire" of 0.236 results. Footing resistance data on this construction are not yet available, but the line being all in good agricultural land it is not anticipated any particular treatment of the footings will be found necessary

Again in the new double-circuit construction the same principles of design for sleet operation were used. It has been found more difficult to provide adequate clearances economically in this type of structure than in the single-circuit design. For example, in an earlier 110 kv. design, utilizing 605,000 c.m., A.c.s.r. conductors at 880 ft. spans and providing a 4-foot offset of the centre phase wire, figure 7, actual outages due to "galloping" have been experienced. That these outages might be anticipated, however, is indicated when the design is analyzed by means of Lissajous figures, though it will be seen that rather extensive revisions will be needed to effect full clearances. The clearance diagram for the 220 kv. design finally adopted is shown in figure 6*b*, based on half-loop movement of heavy copper power conductors but full loop movement of the relatively light ground cable.

No special precautions are being taken to protect this double-circuit construction against conductor vibration. The extensive studies reported by other authors are interpreted as indicating that, except perhaps in certain cases, no such precautions are necessary. Furthermore, it was decided that no particularly special provisions would be made in the suspension clamp, figure 8*a*, and that copper compression joints, figure 8*b*, would be used for both straight joints and dead-end assemblies. Time has not permitted complete investigation of this latter practice, which is at variance with the practice adopted in certain other lines utilizing this form of conductor,[7] but, as the full strength of the conductor is developed in these new joints and as the mass of all parts subject to possible vibratory stresses is reduced to a minimum, no objectionable operating experience is anticipated.

A structural revision incorporated in the double-circuit tower consists of designing the lower panel so that all diagonal connections are made above grade. In earlier designs, including the single-circuit 220 kv. construction, the point of connection of the lower diagonals and the main legs is located below ground level. In this climate and particularly in clay soils, frost heaving has been found to occur which reacts against this below-grade diagonal, causing bending and in some cases actual failure.

Relay Protection and System Stability

It is finally of interest to describe briefly the relay protection provided on this 220 kv. system and to discuss the improvements being made, both in the existing protection and in the protection of the newer construction, associating these improvements with the operating record and with the data obtained from network calculator analysis of the system.

For "phase" faults, the earlier relaying consists of directional, two-stage impedance distance type. The instantaneous range of such relays is set to cover 85 to 90 per cent of the line length, the overlapping second range set to cover the remainder of the line and being given a definite time delay of 0.6 to 0.8 second. This protection effects simultaneous clearance of all faults in the mid-section of any line, but results in delayed opening of the distant breaker for end-zone faults.

For "ground" faults, similar protection is used, except that the relays are supplied with line residual current and phase to ground voltage and the instantaneous range is set to cover the whole length of the line, with some margin if the remote end is open. This results in simultaneous clearance of mid-section faults, though it also effects sequential clearance of faults in the end zones, that is, clearance without the delay associated with the timed second range.

Certain of the line sections terminate in breakers of earlier design, which originally gave a clearance time, with instantaneous tripping, as high as 0.5 to 0.6 second. The more modern equipment clears within 0.2 to 0.25 second. Improvements have been made from time to time, in the original relaying and in the older circuit breakers, so that total clearance times now vary from 4.5 to 10 cycles, with an average of about 6 cycles (based on 25 cycles) for all faults except those cleared by the second ranges.

This protection, though admittedly below present-day standards, has nevertheless given adequate service during the building-up period on this system. Fortunately, all but a very few of the 39 multi-

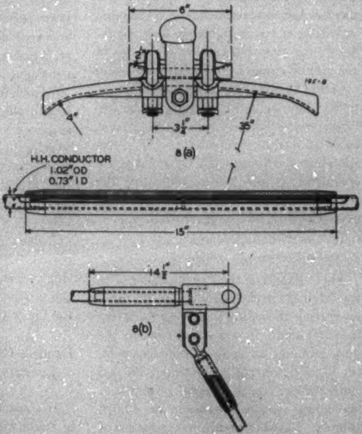

Figure 8. (a) Suspension clamp adopted for type HH segmental copper cable, 500,000 circular mils, 1.02 inches outside diameter

(b) Jointing and dead-end assemblies for type HH copper conductors

phase faults have occurred in the high-footing-resistance territory in the mid-section of the Chats Falls-Leaside lines, where this protection effects simultaneous clearance.

Improvement necessary in the protective equipment, when operating at the higher recent loadings, has been the subject of several network calculator studies. These studies bring out quite clearly the inherent stability of a 25-cycle system. Assuming simultaneous clearance times of 0.2 to 0.25 second, as would be obtained with standard modern equipment, it is found that the three-phase fault may be adopted as the stability criterion, rather than the two-wire-to-ground fault usually adopted in 60-cycle systems.

In figure 9 is presented a family of curves obtained in such analysis, which indicate the relative severity of different types and locations of faults. At a loading of approximately 150,000 kw. per circuit, curves *A* and *B* indicate that three-phase faults near the generating sources must be cleared simultaneously in approximately 0.2 second, if stability is to be maintained. If such faults occur away from the generating sources, curve *C* indicates that the increased loading of generators thereby created is sufficient to maintain stability with simultaneous clearance at 0.25 second. Curve *D* shows the relatively lesser severity of the two-wire-to-ground fault, which does not disturb the system stability with sequential clearance as long as 0.2 and 0.5 second. These results are taken to indicate that, with protective equipment effecting simultaneous clearance of all faults in 0.2 to 0.25 second, loss of system stability at loadings of 150,000 kw. to 170,000 kw. per circuit need not be anticipated.

It is proposed to attain this aim by superimposing carrier pilot control on existing and on all new two-stage impedance relaying. With the exception of the new Leaside-Burlington line, where standard "transfer-block" carrier relaying is proposed, a system of transfer-trip carrier control is being developed. The first of this equipment is being installed on the Beauharnois-MacLaren-Chats Falls connection and on the new Beauharnois-Leaside circuit. It consists of 400 watt carrier communication transmitters, single-frequency voice-actuated the speech frequency range being limited to a band of 200 to 2,500 cycles. Tone generators will be used to transmit relay control signals, which operate to remove the time-delay feature of the distant-end second-range relays. Thus simultaneous clearance is obtained over the full line length, the speed of clearance being limited to that of the various terminal breaker equipments. This protection is as yet experimental and its performance in service will form an interesting study.

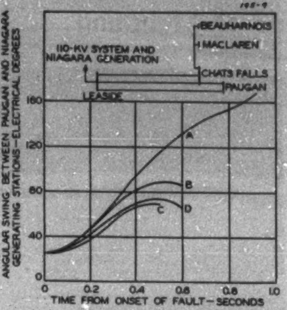

Figure 9. Stability curves for three-circuit 220-kv system, at loadings of approximately 150,000 kw per circuit

A. Three-phase fault at Chats Falls, cleared sequentially in 0.2–0.5 second—unstable

B. Three-phase fault at Chats Falls, cleared simultaneously in 0.2 second—stable

C. Three-phase fault 30 miles west of Chats Falls, cleared simultaneously in 0.25 second—stable

D. Two-wire-to-ground fault at Chats Falls, cleared sequentially in 0.2–0.5 second—stable

Conclusions

1. Operating experience with some 8,400 circuit-mile years of 220 kv. single-circuit overhead line construction is submitted, which to a high degree confirms conclusions which may be drawn from the application to designs of published principles derived from theoretical and experimental analysis.

2. Changes made in the latest designs of towers to provide improved operation under sleet conditions also provide desirable improvements in design against lightning.

3. Counterpoise on towers of high-footing-resistance which has largely been omitted on earlier construction is being installed on 1940–41 lines.

4. Standard two-stage impedance type relay protection has given good satisfaction on these lines. To provide the best operation under heavy line loadings, carrier-current features are being superimposed on both new and old relaying to extend high-speed simultaneous fault clearance to cover the full length of each line

Synopsis: In the investigation described in this paper, measurements have been made and statistical data obtained on the multiple character and wave shape of the currents in direct strokes and the currents discharged by lightning arresters. These data, in conjunction with other data on the field performance of arresters, have revealed definite differences between the nature of direct strokes and the currents they produce in arresters.

1. Arrester discharge currents have fewer components than found in direct strokes. Only about 30 per cent were found to be multiple and not over 8 components were recorded, while from 50 to 70 per cent of direct strokes were multiple with as many as 32 components recorded.

2. Components of arrester discharges are of lower crest magnitude. Only 30 per cent of those measured exceeded 1,000 amperes, while for direct strokes 50 per cent exceeded 5,000 amperes.

3. The initial high current portions of the components of arrester discharges do not vary greatly in wave shape and are similar to those of direct strokes, having for both types of discharges times to half value which, in general, lie between 25 and 100 microseconds and average about 50 microseconds.

4. The long duration low magnitude portions of direct strokes vary over wide limits, both in magnitude and duration. However, for arrester discharges they are seldom present to any appreciable degree. This portion of the discharge may have current magnitudes as high as 1,000 amperes and measurable durations from 50 to 20,000 microseconds in direct strokes, while lightning discharges through arresters seldom last more than 300 microseconds.

5. There is definite evidence that system neutral ground conditions influence the currents discharged by arresters on systems, and that the most severe duty is imposed on arresters on ungrounded systems, while the least severe service conditions appear on four-wire grounded neutral circuits. This is shown by the fact that no long duration surge components have been recorded on four-wire circuits, while about 50 per cent of the records obtained on ungrounded circuits had components of long duration. It is also shown by the performance record of the new Autovalve lightning arrester. With over 40,000 arrester years service this arrester has experienced only 18 lightning failures or a lightning failure rate of 0.045 of one per cent. Of 27,000 arrester years experience on four-wire systems there have been no failures, while of 4,500 arrester years of service on ungrounded circuits there have been 11 lightning failures.

6. There is indication that one of the factors influencing the nature of a lightning stroke is earth resistivity or geological structure. Observations lead to the inference that lightning discharges of long duration are more prevalent in regions of high earth resistivity and ancient geological structure than elsewhere. Thirteen of the 14 long duration arrester current records and 16 of the 18 arrester failures due to lightning occurred on four systems in two regions of high earth resistivity for which there was only 1,078 arrester years experience.

7. These data indicate that it is only with a combination of high earth resistivity and type of system for which the transformers cannot absorb the long duration portion, that appreciable long duration arrester discharges and accompanying severe duty on arresters is obtained. The data on which this is based are not yet conclusive, but the indications are sufficiently definite that this probability should not be overlooked.

Introduction

IN spite of the concentrated efforts of many years of lightning investigations, there still remains much to learn regarding the nature of the lightning discharge proper and its effects in power systems. The greatest dearth of information pertains to the wave shape of individual components of discharge currents, the number and time intervals between components, the total duration of the discharge, and the factors which may affect these quantities. The purpose of the investigation in progress is to collect statistical information regarding the foregoing characteristics, not only with regard to the lightning stroke itself, but also with regard to the discharge currents of lightning arresters. The accumulation of statistical information of this nature has been hindered heretofore by the lack of adequate instruments which were sufficiently low in cost and maintenance to permit their distribution in large quantities, yet with sufficient resolving power with respect to time to record the wave shape. The present investigation has been in progress for the past two years with instruments of new types which meet these requirements. Among these are the fulchronograph, the magnetic surge front recorder, and the magnetic surge integrator, which have been described elsewhere.[1]

The investigation has been made possible through the cooperation of a number of utilities and other organizations, reference to which will be found in the paper.

Recognizing the probable difference in character of currents in the lightning channel and those produced in power systems, this investigation has been divided into two major parts; first, the measurement of lightning strokes to tall objects and to open ground and, second, the measurement of lightning arrester discharge currents. The performance record of arresters in the field has provided additional information which coordinates with the data obtained by the instruments.

In order to clarify the nomenclature, some of the terms will be defined. The entire phenomenon associated with current flowing in a given lightning channel will be referred to as the lightning stroke

or discharge. A multiple stroke or a multiple discharge is one having more than one component. It is important to distinguish between the individual components of a multiple stroke and the two distinguishing portions of a single component, the high current short duration portion and the low current longer duration portion. These are sometimes referred to as "cold" and "hot" lightning.[2] The high current portion produces high voltage on systems and is important from the insulation standpoint. The low current long duration portion is not important from an insulation standpoint, but can impose severe duty on the arrester. In the case of arrester installations involving more than one arrester pole, the group of records obtained is called a composite record. The data associated with the surge current in each or any arrester pole is called an arrester discharge record. For example, if three arrester phase legs discharge on one stroke, they will be regarded as three arrester discharges. Similarly, the failure of two arresters in a bank will be reckoned as two failures. As in the case of direct strokes, an arrester discharge with more than one component will be classified as one discharge.

Direct-Stroke Stations

The most direct manner in which to measure the current in a lightning channel is to connect the instruments in a circuit which intercepts the stroke itself. This suggests the use of tall objects in order to enhance the probability of obtaining a stroke to the object. On the other hand, it is known, not only from field work, such as the investigation on the Empire State Building,[3] but also from laboratory work,[4] that a large projection from a plane alters the nature of the discharge. The investigator, therefore, faces the dilemma of choosing between a small amount of data of unquestionable character and a larger quantity which may be questionable in regard to being representative of strokes to power systems. In the present investigation objects of different heights have been chosen and it is hoped that with time, sufficient information may be collected to determine the extent to which height affects the results.

Seven direct stroke stations have now been established, at each of which a "high speed" and a "low speed" fulchronograph, a surge front recorder, and a number of surge crest ammeter links have been installed. These stations vary in height as enumerated in table I.

Stations in Power Systems

The stations established on power systems are summarized in table II. There are 44; 42 in lightning arrester and protector tube ground leads and two on transmission line towers. Thirteen of the arrester installations are on three-phase arrester banks in stations with circuit voltages varying from 12 to 132 kv. Except for the two installations on the system of the Duquesne Light Company, these are of the general type shown schematically in figure 1 and in the photograph of figure 2. They consist of a high speed fulchronograph in the ground lead of each arrester and a slow speed fulchronograph and surge front recorder in the common lead to ground. In addition, surge crest ammeter links and surge indicators are installed in each phase and the neutral. The surge indicator consists of a surge crest ammeter link in a magnetic iron circuit surrounding the conductor. It is sensitive enough to measure currents as low as 50 amperes and provides a simple means of checking for records.

There are 29 single-phase installations at arresters on systems of voltage ratings from 4 to 7 kv. Twenty-two of these have high speed fulchronographs installed either in the arrester ground lead of a single arrester protecting a transformer connected phase to neutral or in the individual ground lead of one of the two arresters protecting a single-phase transformer connected phase to phase. Figure 3 is a photograph of a typical fulchronograph single-phase installation. Seven of the single-phase stations consist of surge integrators and surge crest ammeter links installed in the arrester ground leads.

Camera Studies

Photographic studies have also been carried on by means of modified motion picture cameras, in which the shutter and claw have been removed, thus permitting the film to move across the open lens at uniform speed. The lightning stroke constitutes its own shutter and the motion of the film imparts the time element. By this means certain properties of multiple strokes can be determined. A number of these cameras have been constructed and interesting records have been contributed by D. D. Clarke of the Kansas City Power and Light Company and C. M. Lear of the Westinghouse Electric and Manufacturing Company.

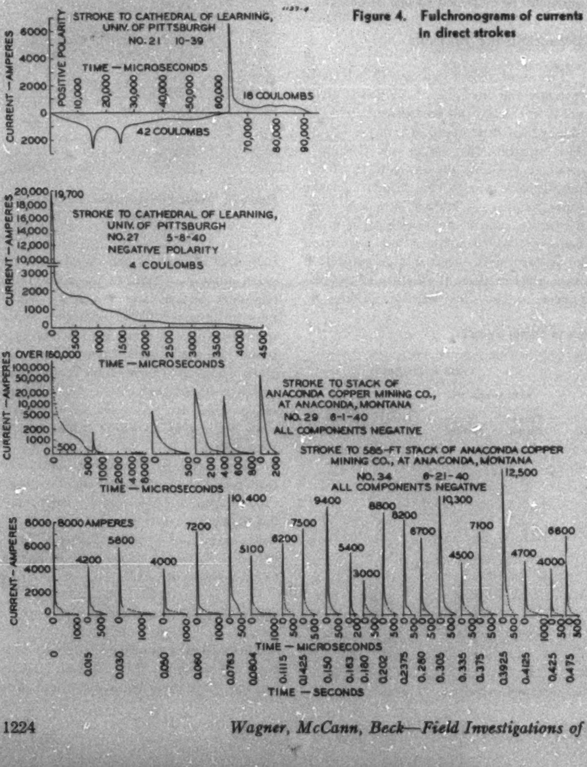

Figure 4. Fulchronograms of currents in direct strokes

Number of Records Obtained

Records have now been obtained of 12 direct strokes having a total of 57 components. Representative fulchronograms of these records are shown in figure 4. Fifty-three composite records have been obtained at the arrester installations. Thirty-two of the composite records were obtained on three-phase installations and comprise 54 arrester discharges having a total of 78 individual components. At the single-phase fulchronograph stations 9 arrester discharges were recorded and at the single-phase surge integrator stations 12 composite records were obtained of 19 arrester discharges. Fulchronograms of several of the arrester currents are shown in figure 5. With the surge front recorder, data were obtained on the character of the fronts of four of the direct strokes, 11 of the arrester surges, and one transmission line tower current. During 1940, the first full season of operation of most of the installations, surges were recorded at 20 of the 44 arrester stations. The number at any one station varied from 1 to 6. Seventy-three of the individual arresters were studied during all of the 1940 lightning season. The duty on these arresters is given in figure 6. As shown by this figure, 46 per cent of the arresters discharged no surges, 54 per cent had at least one surge, 26 per cent had two, and 1.4 per cent had 6, the highest number recorded. This may not be typical of duty on an average group of arresters, since the locations were chosen because experience indicated that they were subject to severe lightning conditions.

Thirty-seven direct strokes to open ground have been photographed with the modified motion picture cameras. Three of these are shown in figure 7 and the statistical data obtained by this means are shown in figures 10, 11, and 12. An analysis of the statistical data on both direct stroke and arrester discharge currents recorded with the fulchronograph is given in figures 9 to 14. The surge front recorder data are summarized in table III and the surge integrator records in table IV.

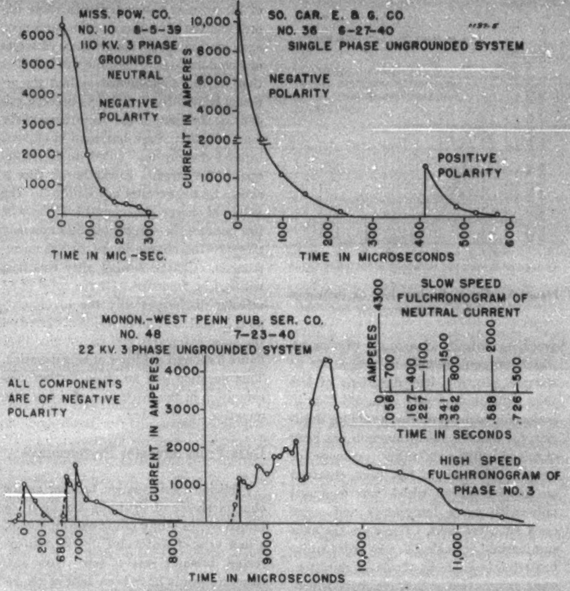
Direct-Stroke Records

Six strokes occurred to the Cathedral of Learning of the University of Pittsburgh during 1939 and 1940, three of which were recorded during operation of the fulchronographs. These records are of two types; first, single-component strokes in which the current can be divided into a high-current short-duration and a low-current long-duration portion of which record No. 27 of figure 4 is typical; and second, one in which the current is more or less continuous with peaks of relatively small magnitudes, such as record No. 21 of figure 4. The latter record, with its relatively low initial current, is similar to those obtained by McEachron in his investigation of the Empire State Building where most of the strokes were initiated at the building and propagated to the cloud. This initially low current represents the streamer formation current. It is believed that at the Cathedral of Learning with a height of 530 feet, strokes can be obtained which are initiated either from the building and propagate skyward or which are initiated from the cloud and propagate earthward. The two records of the first type were of negative polarity with crest magnitudes of the order of 20,000 amperes and long duration tails. They lowered to ground charge of the order of four to six coulombs. The third record (No. 21) consisted of several components having crest values of only a few thousand amperes and discharged 60 coulombs. It had a total duration of 92,000 microseconds, for all of which time considerable current was flowing. To obtain measurements of the thermal effect of the strokes fusible copper wires of varying sizes and a one-inch gap with one blunt electrode and one pointed electrode are installed at the Cathedral station. Information regarding fusion is given in the caption of figure 8. Of the three strokes which occurred while the fulchronographs were not in operation, surge integrator, surge crest ammeter, and fusion data indicate that they probably lie in one of the two groups mentioned above.

An Autovalve distribution arrester connected in the circuit withstood without damage a discharge of the type of record No. 27, but another was damaged by a discharge of the type of record No. 21.

During 1940, the first year that the station on the Anaconda Copper Mining Company's stack at Anaconda, Montana, was in service, four strokes were recorded. Fulchronograms of all of these were obtained, of which two are shown in figure 4. Although enough strokes have not yet been recorded to draw any definite conclusions, there appear to be marked differences between the strokes to this stack and to the Cathedral of Learning. All of the Anaconda strokes were multiple, having from four to 22 components. Only one of all 52 individual components had a measurable duration greater than 1,500 microseconds and only 14 over 500 microseconds. The magnitude of the long duration portion of all these components is considerably smaller than those for strokes to the Cathedral. One of the four components of the first stroke at Anaconda (record No. 29 of figure 4) exceeded 160,000 amperes, the maximum range of the equipment. This represents the highest known magnitude in which the total current was measured at one point, as contrasted with measurements obtained by summing up currents in parallel paths. Record No. 34 of figure 4 is of interest because of the large number of components and its total duration.

All the recorded direct strokes were negative, that is, lowered negative charge to ground, except two to the Cathedral which were oscillatory but initially negative.



PHASES NOS 1 & 2 HAD SINGLE COMPONENT NEGATIVE DISCHARGES OF ABOUT 300 AMPERES AND NEGLIGIBLE DURATION.

Figure 5. Fulchronograms of lightning-arrester discharge currents

Arrester Discharge Currents

Of the 32 composite records on three-phase arrester installations, 25 permitted analysis of current distribution between phases. Of these, nine showed current in only one phase, eight in two phases, and eight in three phases. In only one of the cases in which a surge was recorded in more than one phase was the current predominately greater in one phase than the others. This is record No. 48 of figure 5. In 21 of the 25 cases the maximum current recorded in the neutral was, within the accuracy of the instruments, the sum of the phase currents; in three, it was more; and in one, less. In a few cases of multiple strokes the number of components was not the same in each phase. Twenty-three per cent of the surges were positive polarity and only three surges were oscillatory. Nineteen per cent of the station arrester surges were positive as compared to 29 per cent for the distribution arresters.

The analysis of the individual components of the arrester currents given in figures 9 to 14 show that neglecting record No. 48, the times to half value vary from 25 to 80 microseconds with an average value of 47 microseconds, and none of the measurable durations exceed 300 microseconds. Thirty additional fulchrono-

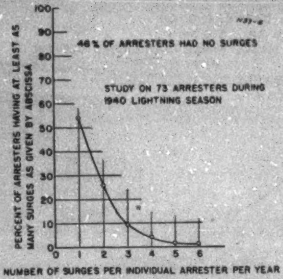


Figure 6. Curve showing duty on individual arresters

graph records of 48 arrester discharges, which were of insufficient magnitude to warrant plotting, had durations of less than 100 microseconds. Record No. 48 is the only arrester discharge of long duration for which a fulchronogram has been obtained, although other evidence of long duration surges has been obtained on another circuit which was equipped only with surge integrators and surge crest ammeter links. These are the data summarized in table IV. In order to interpret this table in terms of duration, some assumption as to wave shape is necessary. For example, if it is assumed that the discharge drops quickly to a constant current of 100 amperes, then a charge of one-half coulomb would correspond to a duration of 5,000 microseconds. While lack of definite data on wave shape precludes the possibility of drawing definite conclusions, it does appear that these charges are considerably greater than those determined elsewhere in this investigation. Further, the failure of the arrester associated with these records and the appearance of the parts upon examination verify the presence of surges of long duration. This table also indicates that on this ungrounded system the arrester failure did not always become evident at the time of the occurrence of the long duration surge but may have been injured thereby and failed in the subsequent discharge. Evidence of this is shown by the arrester at location 5. The values of charge given in table IV may be low because the surge integrator can only measure the charge up to 10,000 microseconds. Charge flowing after this time will not be recorded. Of the total of 82 arrester discharges only the 13 enumerated in table IV, all of which occurred on the same extension, and record No. 48 of figure 5 showed evidence of long duration. This question will be given further consideration in the discussion of the service record of the arresters.

Data From Arrester Performance

Additional information bearing on the characteristics of lightning has been obtained by the study of the performance of a new type of Autovalve distribution arrester, brought out a few years ago. Careful records have been kept of the locations and performance of this arrester. Laboratory tests had indicated that this new arrester has greater ability to handle the severe surges experienced on rural distribution systems than arresters available heretofore. The field experience has borne this out. For some years arresters have been able to withstand discharges of high current and short duration, but the new type has also greater capacity for moderate currents of long duration. It had been concluded from theoretical considerations and certain evidence from the field, that surges of this type were the principal cause of lightning failures of arresters on rural distribution circuits.[5] This has been confirmed by those discharge current records which were obtained at the time of arrester failure. Seven of these recorded by surge integrators are shown in table IV. The eighth such case so far recorded is record No. 48 which was accompanied by the failure of a 25 kv line type arrester of obsolete construction.

One of the factors affecting arrester discharge currents is the nature of system grounding. By providing a path to ground paralleling the arrester the transformers of grounded neutral systems can to varying extents, depending upon the time constant and resistance of the parallel path, absorb the low magnitude long duration portions of surges and thus relieve the duty on the arresters.[6] In other words, the arresters protect the system against the high voltage high current portions of the discharge and the system protects the arresters for the low voltage low current and long duration portions. Ungrounded systems cannot perform this function. Table V analyzes the operating experience with the new arrester with regard to the type of system on which it was installed as well as other factors contributing to arrester damage.

Over 40,000 arrester years of experience have been accumulated with this arrester since the early part of 1938. During this time there has been a total of 28 failures from all causes, representing a failure rate of 0.07 of one per cent. Of these, 10 are attributed to dynamic overvoltage, leaving 18 failures caused by lightning, or a lightning failure rate of 0.045 of one per cent. All of the failures occurred in rural service.

Table V shows the importance of the type of system grounding. Although by far the greatest portion of the service has

Figure 7. Photographs of multiple strokes to open ground

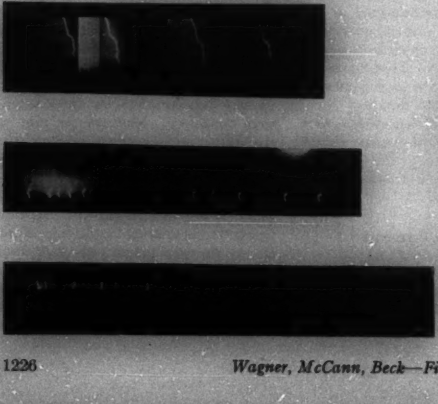

Figure 8. Fusion data on strokes to the Cathedral of Learning of the University of Pittsburgh

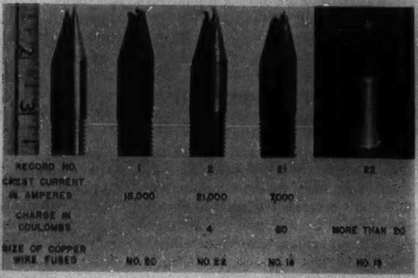

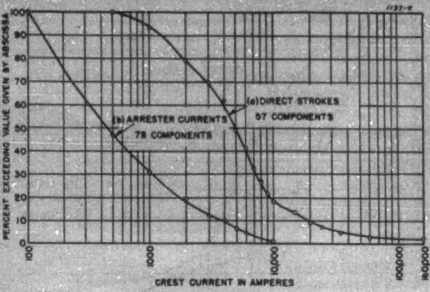

Figure 9. Percentage distribution of crest magnitude of individual components of surge currents

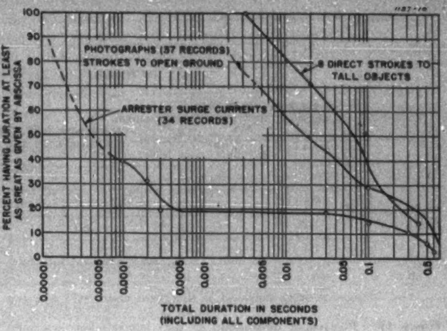

Figure 10. Percentage distribution of total duration of lightning surges

been accumulated on four-wire grounded neutral systems, no arrester failures have been reported on such circuits. This type of system provides the maximum amount of surge current drainage, because both the substation and distribution transformers constitute paths to ground in parallel with the arresters. At the other extreme are the delta connected or ungrounded systems, which provide no parallel drainage path, so that arresters must bear the full brunt of the surge, unless the line flashes to ground. Table V shows that on delta systems, although the service experience was much less, the failure rate was 0.24 of one per cent. Intermediate between these extremes is the type of system fed from a grounded neutral substation transformer but in which no neutral wire is carried out. The distribution transformers being connected phase to phase, the only drainage path to ground is that provided by the substation transformer. The effectiveness of this path decreases with increasing distance between the substation and the arresters involved in the discharge. In 8,500 arrester years of service on such systems, only seven lightning failures have occurred, indicating a rate of 0.08 of one per cent. All of these occurred at points remote from the substation transformers, a fact which corroborates the theory that arresters close to the grounded neutral substation transformers are relieved of discharge current.

This effect of system grounding upon the nature of the arrester discharge is also shown by the current records which have been obtained. Of the 82 arrester discharge currents recorded, 30 were on four-wire circuits, 21 on three-wire circuits, and 31 on ungrounded circuits. However, all 14 of the surges with long duration components were obtained on ungrounded circuits. All of the rest had measurable durations of less than 300 microseconds. It might be argued that, since about 70 per cent of the arrester currents measured had crest magnitudes less than 1,000 amperes, the presence of a long duration component of proportionate magnitude to that appearing in direct stroke currents would be indistinguishable in most of the records. However, of the 24 discharges with crest magnitudes exceeding 1,000 amperes only 12 were recorded on ungrounded circuits and nine of these showed evidence of long duration portions.

Another factor in the performance of arresters appears to be the earth resistivity in the region of the installations. Surveys[6] indicate that in certain regions in which the arresters are installed the earth resistivity is high, 1,000 meter ohms or more. Only two arresters were damaged in regions where the resistivity is thought to be low; both occurred on delta systems; while 16 were damaged by lightning in regions where the resistivity is known to be high. These 16 cases occurred on four systems representing only 1,078 of the 40,000 arrester years of service. The 16 failures have been further broken down in table VI, according to type of system and earth resistivity. Because of difficulty of securing accurate data, the segregation of arrester years of service according to earth resistivity is very approximate. However, a very considerable error in these is permissible without vitiating the qualitative character of the results and conservative figures are used. The 13 long duration discharges recorded with the surge integrator were obtained on one of the four systems in a region of high earth resistivity which gives further evidence of this effect.

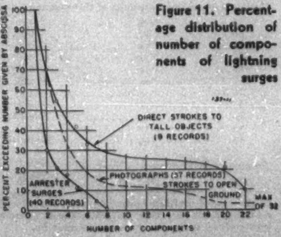

Figure 11. Percentage distribution of number of components of lightning surges

While the data are still meager, it appears from table VI that earth resistivity influences the character of arrester discharge currents and that a combination of high earth resistivity and delta or three-wire grounded system is required to produce appreciable rates of arrester failure, whereas four-wire grounded systems appear to be the most satisfactory from the arrester standpoint regardless of earth resistivity. This is important from the operating standpoint.

Discussion of Results

The foregoing data show that there are marked differences between the currents in direct strokes to tall objects and the currents discharged by protective devices on power systems.

MAGNITUDE

As shown by figure 9, the maximum measured value of crest current discharged by an arrester is about 10,000 amperes (record No. 36 of figure 5), and only 50 per cent of the crest magnitudes exceed 450 amperes, whereas the maximum measured value of crest current obtained in a direct stroke exceeded 160,000 amperes and 50 per cent of the components had crest values exceeding 5,000 amperes. These data differ from those

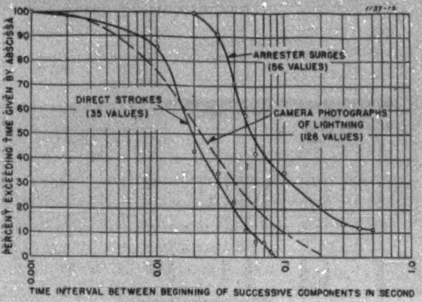

Figure 12. Percentage distribution of time intervals between components of multiple strokes

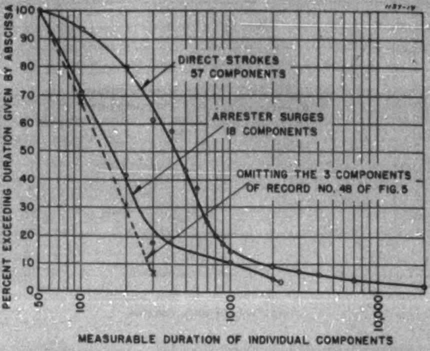

Figure 14. Per cent distribution of duration of individual components of lightning-surge currents

previously published by other investigators in that the quantity plotted is the crest magnitude of the individual components in distinction to the maximum crest magnitude of all the components in a stroke, the value measured by a surge crest ammeter. In common with the results published by others, the arrester currents are less than those in direct strokes. This may be attributed to three primary causes. One, all of the direct stroke current is not likely to pass through an arrester because more than one arrester may operate thus dividing the current, or flashovers may occur on the lines thereby limiting the arrester discharge current. Two, the arrester may be operated by attenuated surges reaching the arrester from strokes to the system at remote points. Three, the arresters may be discharged by induced surges.

POLARITY

Although all of the direct strokes recorded in this investigation, as well as those published by Stekolnikov[7] and McEachron,[8] were either negative or oscillatory, but initially negative, an appreciable number of positive discharges were recorded on arrester installations. It is thought that this is so because most of the positive discharges are produced by induced strokes, which, although relatively low in magnitude may yet be sufficiently high to discharge arresters. This is further substantiated by the fact that the proportion of positive discharges increases with decreasing discharge voltage of the arresters. The station arresters, which varied in ratings from 12 to 109 kv, showed 19 per cent positive discharges, while the distribution arresters, which varied in ratings from 3 to 9 kv, showed 29 per cent positive discharges.

MULTIPLE CHARACTER OF STROKES

In figures 10, 11, and 12 are plotted curves giving statistical data on the total duration, the number of components, and the time intervals between successive components of lightning currents. These curves present data of three general types, arrester discharge currents, strokes to open country, as given by the photographic records, and strokes to tall objects. More components and longer durations were recorded in strokes to tall objects than to open ground. Of practical importance is the indication that arrester discharge currents have fewer components and shorter durations. This is probably caused by the diminution of the magnitude of the components from the original magnitudes in the stroke for the reasons enumerated under "Magnitude." Thus, some of the smaller components may be reduced to such an extent that they are below the recording range of the equipment, or have associated voltages below the operating voltage of the arresters. Consequently, arresters and other

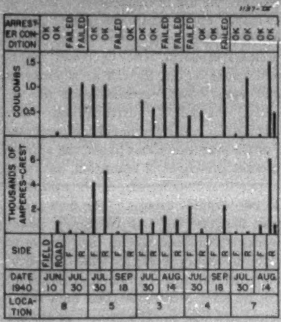
24	Neg.	19,000	2.5	7,600
34	Neg.	Multiple See ful'grams	0.5– 9.9	1,300–6,000
59	Neg.		0.5–19	174–2,000
60	Neg.		0.5– 6	1,140–2,000
Currents in common grounds of three-phase arrester banks				
5	Neg.	100	More 10	Less 10
55	Neg.	1,600	2	800
30	Pos.	500	1	500
41	Neg.	500	1.1	450
31	Pos.	600	More 6	Less 100
42	Pos.	825	More 20	Less 40
38	Pos.	1,100	3.9	280
47	Neg.	2,300	6	380
45	Neg.	200	More 10	Less 20
58	Neg.	5,100	1.6	3,200
48	Neg.	Multiple	Less 0.5 to 20	500–2,600
Transmission-line tower current				
66	Neg.	50,400	1.16	43,600

In the case of multiple strokes, because of interference between the indications upon the magnetic recorder resulting from successive impulses, the surge-front recorder provides only a range within which all of the fronts of the successive components must lie.

Table IV. Summary of Discharge Records Obtained by Surge Integrators on 6,900-Volt Ungrounded Circuit of the Wisconsin Public Service Corporation



The recorded data on coulombs of charge may be less than the actual because the surge integrator does not record charge flowing after 10,000 microseconds.

terminal equipment are exposed to less severe duty than would be indicated by the data on direct strokes to tall objects or to open country. The curves of figure 12 indicate that the time intervals between successive components of strokes to tall objects and open ground are approximately the same. The time intervals between components in arrester discharges, on the other hand, are appreciably greater. This would be expected from the reduction of some of the components as mentioned above. It is also possible that some of the multiple fulchronograph records which were regarded as the result of a single stroke are actually the result of more than one stroke occurring between inspections of the instruments. The data of figure 12 shows that there is seldom more than one component discharged in a period equivalent to one-half cycle of 60 cycles.

Wave Shape

The data obtained on wave fronts by means of the surge front recorder summarized in table III show that of the four direct strokes for which records of the front were obtained only one had a single component. This record (No. 24) had a crest value of 19,000 amperes, a front of 2.5 microseconds, and an average rate of rise of 7,600 amperes per microsecond. The three strokes of multiple character indicated a possible range of fronts between 0.5 and 19 microseconds, and a possible rate of rise of between 174 and 6,000 amperes per microsecond. The highest rate of current rise which has been recorded is that of the one transmission line tower current. This value (43,000 amperes per microsecond for a current with a crest value of 50,400 amperes) is also the highest rate of rise which is known to have been measured in natural lightning surges. However, this value was determined by instruments on only one leg of a tower and the result of this leg multiplied by four.

Of the arrester discharge current records, the times to crest varied from about 1 to 20 microseconds. The highest rate of rise is 3,200 amperes per microsecond obtained, however, for a surge of only 5,100 amperes crest.

Low earth resistivity	4,000*	2	0.05
High earth resistivity	500*	9	2

* Approximate estimate.

The times to half value of the high current portions of the direct strokes and arrester discharges, as shown by figure 13, range from 25 to 100 microseconds with an average of about 50 if record No. 48 is excepted. The total duration of the individual components including the long duration portions, however, as shown by figure 14, varied over a wide range. Direct strokes show a range of from 50 to 20,000 microseconds, while arrester discharges varied from less than 50 to 2,300 microseconds.

McEachron in his investigations on the Empire State Building shows that most of the strokes to it are initiated from the building and propagate upward to the cloud. The current measured in the building in such cases may persist at relatively small values between successive peaks. No doubt this tendency increases with the height of the object. On the other hand, the fulchronograms obtained in the present investigation show that such low currents can follow high current peaks even to lower objects. There is nothing in the mechanism of stroke propagation as proposed and developed by Schonland that precludes the possibility of lower currents of long duration following high current peaks in strokes to ground. The only direct evidence that this characteristic is present in strokes to open ground is provided by the fulchronogram (record No. 48 of figure 5) and the magnetic surge integrator records of table V, although there has been indirect evidence to this effect provided by the markings left on arresters returned from the field and by camera studies, notably those of Schonland.

In general, there is considerably less evidence of long duration portions of the current in arrester discharges than in di-

Power-Circuit Instruments for the Higher Range of Audio Frequencies

L. J. LUNAS
MEMBER AIEE

PAUL MacGAHAN
MEMBER AIEE

Synopsis: The extending use being made of frequencies from 900 to 12,000 for special purposes such as induction furnaces, etc., introduces new problems in instrument design and calibration. Previous practical a-c instruments were either of the electrodynamic or moving iron types designed for low power frequencies or thermal and rectifier types for audio and radio frequencies, these latter usually being confined to measurements of only current and voltage.

The ordinary low frequency electromagnetic instruments have such high coil reactance and losses that they are unsuitable for the higher power frequencies in question without special arrangements, which are described in the paper. Furthermore, the usual calibration methods and standards as previously used for low frequencies are not adequate, and therefore, new methods of calibration were introduced.

Introductory

FOR many years, the frequency range within which measurements were required, was within the scope of ordinary power application requirements. This range was in general below 150 cycles. Then there followed certain higher frequencies for high speed motors, as in metal working and spinning, which involved the use of frequencies up to 600 or 1,000. The higher frequencies gave rise to no new serious instrument problems, except that they disqualified the induction principle of operation which was used in earlier instruments designed for low frequencies.

Higher frequencies than those ordinarily used for operating motors were used largely in communication work and were therefore termed "audio frequencies." This name has prevailed for want of a more exact term. It is, of course, somewhat inexact since it does not distinguish from frequencies such as 60 cycles, which are also audible. Moreover, the higher frequencies in the audio range were also used for long wave radio communication. Likewise, the range of audio frequencies overlaps the range of radio frequencies, which begins at 10 kilocycles and extends in practice to 60,000 kilocycles or higher.

Principles of Operation

Electrical instruments may be classified by applicability in various frequency groups, roughly as follows:

1. Direct current.
2. Low frequency power (up to several hundred cycles).
3. High frequency power, including the complete audio-frequency range.
4. Radio frequencies.

Practical indicating instruments required in the radio and upper audio-band communication activities are well covered by instruments which measure currents and voltages. Requirements for measuring power, energy, or reactive power or power factor are not insistent for these fields.

The extension of industrial power applications to induction electric furnaces requires the use of frequencies within the so-called upper audio-frequency range, involving the usual power supply measurement of watts, reactive power (vars) and power factor, as well as of amperes and volts. Such measurements are required not only for investigation work, but also for control or operating purposes. For the purposes of this paper, the various present principles of operation, as found in practical instruments, can be said to be of two distinct groups. The first group was designed for low frequency power work, and the second, for high audio- or radio-frequency work, for which the ordinary instruments of the first group could not be used because of their high reactances and losses. The second group has other inherent limitations which generally restrict its use to measurement work where the more sturdy, less sensitive types cannot be used.

Until recently, the instrument requirements for higher audio-frequency measurements have been taken care of by the use of thermal instruments for current and voltage measurements in the same manner as for radio frequencies. However, the development of power equipment for heat-treating equipment has

---

rect strokes. This is to be expected from the consideration of the absorption of these portions in varying degrees on grounded neutral systems, and is confirmed by the results of the investigation, which so far has shown evidence of long duration portions only on ungrounded circuits. It is indicated that there is a considerably greater prevalence of the long duration portions in strokes in regions of high earth resistivity, since at least 13 and possibly all of the 14 long duration discharges were obtained in such regions, which comprise only a small part of the scope of the investigation. This is given additional weight by the fact that 16 of the 18 cases of lightning damage to arresters occurred in two regions of high earth resistivity, although they represent only a small part of the total arrester experience.

given rise to the necessity for instruments having heavy overload capacity, quick response, and other characteristics found in industrial power instruments. The necessity for measuring power and power factor also has made it necessary to extend the use of wattmeters and reactive meters to include this audio-frequency band.

The electrical measurements involved include (*a*) current, (*b*) voltage, (*c*) true power, (*d*) vars (reactive power), (*e*) power factor. In any particular installation, one of the last two measurements is usually sufficient in any electrical circuit.

AMMETERS

The magnitude of an alternating current usually is measured by moving iron vane, electrodynamic, or electrothermic type ammeters. The electrothermic type ammeter, which utilizes the thermocouple principle in measuring a current by its heating effect, is entirely free from frequency errors over the audio-frequency range. However, the disadvantages of this type, such as low overload capacity, delicacy of mechanism, and uneven scale distribution, render it undesirable for power work, or in fact, for any source where the measurement can be made accurately by other indicating means. Likewise, the electrodynamic ammeter has relatively low overload capacity, and furthermore, the usual parallel connection of the moving and stationary coils introduces difficulties in matching circuit branch impedances as required in order to minimize frequency errors. This narrows the choice down to the moving iron vane type ammeter. This type is characterized by inherently high overload capacity and simplicity. The frequency influence is relatively small and no particular difficulty is involved in calibration.

The frequency error of the repulsion moving iron ammeter is shown in the curve, figure 1. In the higher audio-frequency range, the eddy current losses in metal framework parts, damping chamber parts, and even the jewel screws and nuts of the conventional low frequency forms, cause excessive temperature rise, making it necessary to fabricate these parts from special low-conductivity materials having suitable physical characteristics. Temperature rises are thus kept within permissible limits. Further points of interest in this connection are the necessity of laminating the iron vanes to sufficiently thin sheets to limit temperature rise caused by eddy currents in the vanes themselves, and the fact that at least in five- or ten-ampere ammeters, there appears to be no necessity for subdividing the conductors used in the coils. Calibration of ammeters is accomplished by using the thermocouple type standard, with current obtained from an oscillator source adjusted to the desired frequency.

VOLTMETERS

The value of an alternating voltage is ordinarily measured by electrodynamic, moving iron, thermocouple, or rectifier type instruments. For high voltage work, electrostatic types have been used. Electrodynamic voltmeters readily may be built for frequencies up to about 3,000 cycles by designing the windings with the requisite low inductance. For higher frequencies, the necessary further decrease in inductance which is accompanied by increase in energy consumption, causes the coils to operate near their safe maximum temperature, thus limiting overload capacity. Moving iron type voltmeters inherently have a high ratio of inductance to resistance which limits their use to commercial power frequencies. For example, a well-designed repulsion iron vane type voltmeter calibrated for 60-cycle service may indicate 12 percent low at 500 cycles. This inductance varies with the angular position of the moving element for different parts of the scale, and therefore the compensating means for wattmeters (which will be described further) cannot be employed readily for voltmeters.

The overload capacity of voltmeters must be greater than is provided by thermocouple type instruments, since induction furnace generators usually have poor regulation. The no-load voltage may be 20 to 30 percent higher than full-load voltage, and this no-load overvoltage condition may exist for prolonged periods under operating conditions. Also, there exists a possibility of surges when the load is applied or removed, which would damage thermocouple type instruments. Therefore, thermocouple voltmeters would seem to be undesirable for this application.

Another inherent disadvantage of the thermocouple type voltmeter, as well as of the ammeter, is that the scale distribution is a function approximately of the square of the applied quantity.

Electrostatic voltmeters would seem to have the ideal electrical characteristics, but are far from satisfactory from the viewpoint of mechanical requirements in practical operating instruments.

The remaining practical possibility for voltmeters is the rectifier type principle. Rectifier voltmeters, as is well known, consist of a permanent magnet moving coil mechanism with a copper-oxide rectifying unit. All rectifier types measure the average value of the a-c wave, but in practice, they are calibrated on a sine wave to read the rms value. Thus, on other wave forms, errors are introduced. It is necessary to provide a filter to eliminate errors which arise from variable harmonics present in the distorted wave forms usually present in high frequency furnace circuits. The importance of a suitable filter is further emphasized by the fact that the wave form changes with various load conditions. Recent improvements in Rectox units used with rectifier voltmeters vir-

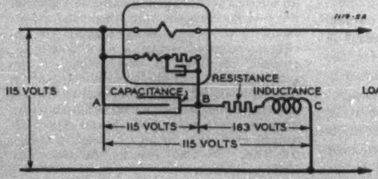

Figure 2a (left). Phase-shifting network for varmeter

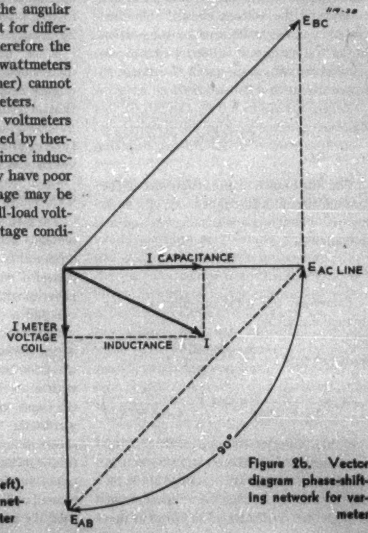

Figure 2b. Vector diagram phase-shifting network for varmeter

tually have eliminated the frequency error within the audio range and reduced the temperature error to commercially allowable limits.

WATTMETERS

The measurement of power is accomplished by a conventional electrodynamic type instrument provided with a simple method of compensating for the voltage circuit inductance. Since the inductance of the voltage circuit causes the current in that circuit to lag the impressed voltage, an uncompensated instrument will read low at high frequencies because the deflection is proportional to the in-phase components of current and voltage. Actually, the inductance of the voltage circuit can be made very low. At power frequencies, the voltage circuit current lags the impressed voltage only 10 to 20 minutes, and this is therefore negligible. At higher audio frequencies, however, this angle of lag assumes very large proportions; for example, if the angle of lag at 60 cycles is 18 minutes, it becomes almost 40 degrees at 9,600 cycles. This would correspond to an error of 23 percent in the reading. It is therefore necessary to provide compensation for the voltage circuit inductance.

Compensation for the inductance of the voltage circuit is accomplished by a simple method which makes the instrument practically free of frequency error. This is done by connecting a capacitor of suitable value in parallel with the non-inductive resistor of the voltage circuit. The impedance of the resistor capacitor portion of the voltage circuit is the impedance of a parallel circuit composed of resistance R_1 in parallel with a capacitor C.

$$Z_{\text{Res.}}=\frac{1}{\frac{1}{R_1}+jWC}=\frac{R_1}{1+jWCR_1}=\frac{R_1-jWCR_1^2}{1+W^2C^2R_1^2}$$

The impedance of the remainder of the voltage circuit is the impedance of a moving coil which has a resistance R_2 and inductance L.

$$Z_{MC}=R_2+jWL$$

Therefore, the total impedance of the voltage circuit is:

$$Z_{\text{total}}=R_2+jWL+\frac{R_1-jWCR_1^2}{1+W^2C^2R_1^2}$$
$$=R_2+\frac{R_1}{1+W^2C^2R_1^2}+jW\left(L-\frac{CR_1^2}{1+W^2C^2R_1^2}\right)$$

At 10,000 cycles, the value of $W^2C^2R_1^2$ for a well-designed wattmeter is $(2\pi 10{,}000)^2 \times (0.002\times 10^{-6})^2(2{,}500)^2 = 9.88\times 10^8\times 4\times 10^{-18}\times 2.5\times 10^6 = 9.85\times 10^{-3}$, which may be neglected with respect to unity so that approximate impedance $Z_{\text{total}}=R_2+R_1+jW(L-CR_1^2)$. If R_1 is adjusted so that $L=CR_1^2$, then $Z_{AC}=R_1+R_2$ which is the same as the measured resistance.

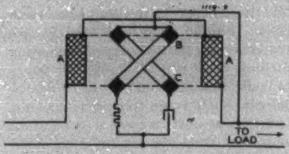

Figure 3. Schematic diagram power-factor meter

VARMETERS

A wattmeter equipped with suitable frequency compensation, as described, may be used for the measurement of vars by providing a phase-shifting network in the voltage circuit to turn the voltage circuit vector 90 degrees in a lagging direction. The instrument will then read zero at unity power factor and full scale at zero power factor of the measured circuit, assuming a sinusoidal wave condition. It is customary to build varmeters with zero center scales to provide indications for both leading and lagging reactive power. The phase-shifting network consists of a circuit with capacitance, inductance, and resistance paths arranged as shown in figure 2*a*. The vector diagram is shown in figure 2*b*. In practice, the 90-degree lag of the current in the moving coil behind the applied voltage is accomplished by adjusting the value of inductance until I_M lags E by exactly 90 degrees.

While thermal wattmeters and varmeters also could be applied to the frequency ranges in question, it is believed that in view of the practicability of the modified conventional electrodynamic type as above described, their use would not be justified.

POWER-FACTOR METERS

The measurement of single-phase power factor is accomplished by a conventional cross-coil type electrodynamic instrument provided with a non-inductive resistance in series with the horizontal cross-moving coil and a capacitance in series with the vertical cross-moving coil. The inductance of the horizontal moving coil is compensated for by a small capacitor in parallel with a portion of the series resistance in the same manner as described for the wattmeter. The circuit arrangement is shown in figure 3. The principle of operation is otherwise the same as for conventional single-phase electrodynamic type crossed coil power factor meters provided with the resistor-reactor network, except that, because of the high frequency, it is more practical to substitute a capacitor for the usual inductive reactance, the corresponding moving coil being reversed since the current in it leads instead of lags the voltage.

The production of resonant type frequency meters for the ranges involved is a much easier problem than that of the reactive meters. However, so far as the present types of induction furnace circuits are concerned, there seems to be no necessity for frequency indication, as the generators are motor-driven at a speed sufficiently constant for good performance. This speed is not ordinarily changed during operation.

If variable frequency systems are introduced later, they would be of the tube circuit type, in which case, frequency meters would be desirable. These might be of the wave meter type as used in radio applications.

Measurements for Induction-Furnace Circuits

Reactive measurements are important in the operation of an induction furnace or high frequency heating load for two reasons:

(1). The power factor of the load is quite low; approximately 10 percent in the case of an induction furnace. It is not practical to design a generator to supply, say, 100 kw of load and 900 kva of reactance. Power factor correction by means of capacitors is, therefore, used to bring the power factor up to unity, and in some cases, even to make it slightly leading.

It is important that the power factor of the circuit being supplied be checked at all times, because the physical conditions, such as permeability and resistivity of the charge, will vary with temperature, and the initial power factor will not be maintained. Adjustments, therefore, have to be made in the amount of corrective capacitance as the heating cycles proceed. In other words, the power factor meter tells the operator when it is necessary for him to make an adjustment in the number of capacitor units connected. This may not be so important in the case of the short time heating cycles because in that case, an average power factor must be used, since the time is too short to make any adjustments. However, the power factor meter is used in this case to predetermine the correct value.

(2). The generator usually is arranged with an automatic voltage regulator to maintain its voltage constant. If, then, the power factor becomes increasingly lagging, the excitation required would be very greatly increased, resulting in overheating of the generator field. If the generator voltage is not automatically regulated, then the kw input to the load would be reduced materially, since the voltage naturally would drop with a fixed excitation on an increasingly inductive load. For these reasons, the power factor is important.

In more recent installations, the use of varmeters has been recommended rather than power factor meters, because it is believed that a closer control of the tuning of the circuit can be obtained by the use of the former.

Electrodynamic wattmeters are a more accurate form of instrument than the corresponding power factor meter, as the accuracy of the latter is influenced by the constant but slight torque of the spiral strips used for conducting the current to the moving coil.

The power factor meter operates by a difference between two electrical torques, and thus the presence of a third torque, such as that of the connecting strips, introduces an error at light loads which cannot be calibrated out. The influence of wave form distortion caused by harmonics is present in both varmeters and power factor meters. However, the oscilloscope shows a somewhat better wave form on the power supply circuit than anticipated, especially when a large capacitance is connected.

A word of caution is necessary in the interpretation of readings of reactive quantities such as vars and power factor. Both varmeters and power factor meters operate on the assumption of a sinusoidal wave form, and only under this condition is power factor equal to the cosine of the angle of lag. Under conditions where harmonics are present, the power factor and reactive component calculated from the wattmeter readings and the voltamperes will not necessarily agree with the readings of the power factor meter or the varmeter. Thus the readings of the reactive instruments should be used for control rather than for exact measurement purposes. Their usefulness is principally for indicating the required resonance condition of the circuit. As between the choice of a power factor meter or a varmeter for this purpose, the authors are strongly in favor of the latter. Figure 4 shows the elementary instrument diagram of connections of a typical installation.

In order to simplify the metering diagram, the 60-cycle auxiliary control circuit for the generator is not shown. The elementary diagrams for measurement and control are virtually the same for frequencies from 960 to 11,520 cycles.

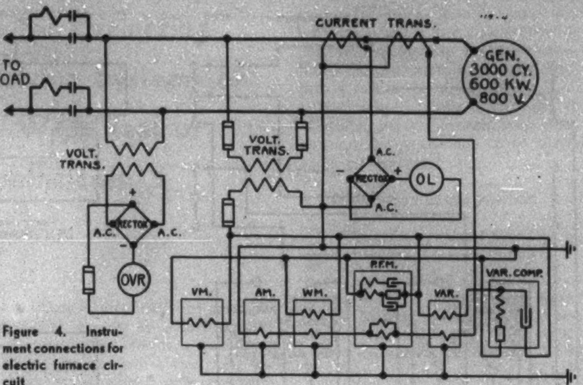

Figure 4. Instrument connections for electric furnace circuit

An important operating precaution in audio-frequency measurements involving instruments having both current and voltage circuits is to have the voltage terminal which is connected to the voltage coil, connected to the low potential or grounded line. This brings the moving and stationary coils to the same level of potential which eliminates errors due to capacitance effects which at the higher audio frequencies are by no means negligible. It is, of course, conventional practice to connect the voltage terminal from the resistor end of the voltage circuit to the opposite line from the current coil, even in power frequency applications. However, at the higher audio frequencies, the effects are so much more pronounced that this point must not be overlooked.

Calibration

The calibration of modified power type instruments for audio-frequency application required new equipment, including the adjustable frequency power sources having adequate capacity and calibration standards.

The schematic wiring diagram of the audio-frequency source is shown in figure 5. Taps are provided for various voltages and load impedances. The beat frequency oscillator is adjustable for frequencies from 20 to 20,000 cycles a second. This equipment provides a suitable power source for the calibration of ammeters, voltmeters, wattmeters, and varmeters. The calibration of power factor meters requires two separate audio-frequency sources (one for voltage and one for current), with provision for varying the phase angle between current and voltage.

Ammeters are calibrated by setting the oscillator for the desired frequency and using a thermocouple type instrument as a standard with the instrument under test. A tap is selected for proper impedance to maintain sine wave output.

The calibration of voltmeters is accomplished similarly, using a thermocouple voltmeter connected in parallel as a standard.

Wattmeters are adjusted and dials marked in the conventional manner on a 60-cycle source. Frequency compensation adjustment is accomplished by passing a current of the order of 12,000 cycles a second through the current coil and short circuiting the voltage circuit terminals. Any movement deflection resulting from this short circuit indicates the necessity of compensation. When the condenser is connected across the proper portion of the resistance, no deflection results from the short circuit, and the instrument is practically independent of frequency error over the complete frequency range to 12,000 cycles.

The varmeter instrument proper is identical to the wattmeters except for dial markings, so calibration adjustments and compensation are the same for both instruments. The varmeter compensator is adjusted to shift the voltage circuit current 90 degrees at the desired frequency by adjusting the value of inductance and resistance until I_M lags E by exactly 90 degrees and is of proper magnitude. The vector relationship of currents and voltage in the circuit are shown in vector diagram figure 2*b*. Phase shifter adjustments for obtaining proper phase angle and magnitude are made quite simply by the test and calibration circuit, figure 6. Since the current in the instrument voltage circuit must be in quadrature with the line voltage, the phase angle adjustment made by adjusting the phase shifter reactor will produce a quadrature shift in current which gives zero deflection on the voltmeter.

The magnitude of the voltage output of the phase shifter is made equal to the input voltage by adjusting resistance R_1. The calibration circuit for power factor meters is shown in figure 7. The voltage applied to the voltage coil of the power

A Short Method for Evaluating Determinants and Solving Systems of Linear Equations With Real or Complex Coefficients

PRESCOTT D. CROUT
NONMEMBER AIEE

THE purpose of this paper is to describe a short method for solving arbitrary systems of linear algebraic equations, and evaluating determinants, the quantities involved being either real or complex. For proofs and for treatment of complex systems whose symmetrical coefficients are conjugate, see appendix. The cases considered are:

1. Arbitrary systems with real coefficients, which occur in obtaining stresses in structures, in solving systems of linear differential equations with constant coefficients (transient problems), etc.

2. Symmetrical systems with real coefficients, which occur with d-c networks, undamped vibration, deflections in structures, least square processes, Ritz's method, etc.

3. Symmetrical systems with complex coefficients, which occur with a-c networks, and forced vibration with dissipation.

4. Arbitrary systems with complex coefficients, which occur in certain vibration problems involving gyroscopic action.

5. Systems involving two sets of variables, which occur when the currents in a network are to be found for a variety of impressed voltages, also in the approximate solution of integral equations arising in electric field problems.

The work of solving a system of equations (or evaluating a determinant) is largely concentrated in the determination of an "auxiliary matrix," and is roughly half that required by a matrix multiplication. The process is particularly adapted for use with a computing machine, for each element is determined by one continuous machine operation (sum of products with or without a final division). The setting down of this matrix and of the final solution is the only writing required by the process. The work involved is cut almost in half if the given equation (or determinant) is symmetrical, as very often happens. A "check column" can be carried along if desired.

The amount of work required to obtain a solution is considerably less than that required by Gauss's method,[1] even when there is symmetry and the coefficients are real, in which case Gauss's method has been considerably refined by Doolittle.[2] (Gauss's method is much shorter than a solution by determinants.)

The method as given is applicable to m equations in n unknowns, there being no restriction on the rank of the matrix of the coefficients.

2. Description of the Method

Let the given system of equations be specified by its *given matrix*,[2] thus

$$\begin{array}{ccccc} x_1 & x_2 & x_3 & x_4 & = \\ 12.1719 & 27.3941 & 1.9827 & 7.3757 & 6.6355 \\ 8.1163 & 23.3385 & 9.8397 & 4.9474 & 6.1304 \\ 3.0706 & 13.5434 & 15.5973 & 7.5172 & 4.6921 \\ 3.0581 & 3.1510 & 6.9841 & 13.1984 & 2.5393 \end{array} \tag{1}$$

the first equation being $12.1719x_1 + 27.3941x_2 + 1.9827x_3 + 7.3757x_4 = 6.6355$. The solution requires the formation of one matrix and a set of final results; thus we have an *auxiliary matrix*

$$\begin{array}{ccccc} x_1 & x_2 & x_3 & x_4 & = \\ 12.1719 & 2.2506 & 0.16289 & 0.60596 & 0.54515 \\ 8.1163 & 5.0720 & 1.6793 & 0.0057629 & 0.33632 \\ 3.0706 & 6.6327 & 3.9585 & 1.4193 & 0.19891 \\ 3.0581 & -3.7316 & 12.7526 & -6.7332 & 0.060806 \end{array} \tag{2}$$

and a *final matrix*

$$\begin{array}{l} x_1 = 0.15942 \\ x_2 = 0.14687 \\ x_3 = 0.11261 \\ x_4 = 0.060806 \end{array} \tag{3}$$

The procedure for obtaining the auxiliary matrix from the given matrix is contained in the following rules.

1. The various numbers, or *elements*, are determined in the following order: elements of first column, then elements of first row to right of first column; elements of second column below first row, then elements of second row to right of second column; elements of third column below second row, then elements of third row to right of third

factor meter is applied to one set of plates of a cathode ray oscilloscope, while a voltage drop in phase with the current in the current coil is applied to the other set of plates. The amplifiers in the cathode ray oscilloscope must have no phase shift. This readily can be checked by applying the same voltage to both plates and noting the image.

It is possible to determine the phase angle by measuring the areas of the elliptical image formed on the screen of the oscilloscope, but precise measurements are not possible, as it is difficult to read exact deflection values. A more accurate method of determining the phase angle is to bring the two voltages applied to the plates exactly in phase, which produces a precise straight-line image on the cathode ray screen. By means of vacuum tube voltmeters, it is then possible to measure the voltage in phase with the non-inductive resistance R, which is in phase with the current in the current circuit of the power factor meter, and to measure the voltage across the mutual inductance which is 90 degrees leading the current in the current circuit of the power factor meter. In bringing the image on the oscilloscope to a straight line, this latter voltage (the out-of-phase component) is adjusted in magnitude so that the vector sum of the two voltages is brought in phase with the voltage across the voltage coil of the power factor meter. The ratio of these two voltmeter readings is therefore a measure of the tangent of the phase angle from which the phase angle and power factor can be calculated accurately.

Figure 8 is a view of the calibrating outfit which is shown diagrammatically in figure 5.

column; and so on until all elements are determined.

2. The first column is identical with the first column of the given matrix. Each element of the first row except the first is obtained by dividing the corresponding element of the given matrix by that first element.

3. Each element on or below the principal diagonal is equal to the corresponding element of the given matrix minus the sum of those products of elements in its row and corresponding elements in its column (in the auxiliary matrix) which involve only previously computed elements.

4. Each element to the right of the principal diagonal is given by a calculation which differs from rule 3 only in that there is a final division by its diagonal element (in the auxiliary matrix) [3]

As examples we have the following typical calculations made in obtaining (2), the letters *R* and *C* representing the words "row" and "column," respectively.[4]

$$\begin{array}{lrl}
R1C3 & 0.16289 & = 1.9827 \div 12.1719 \\
R2C2 & 5.0720 & = 23.3385 - 8.1163\cdot 2.2506 \\
R4C2 & -3.7316 & = 3.1510 - 3.0581\cdot 2.2506 \\
R2C5 & 0.33632 & = (6.1304 - 8.1163\cdot 0.54515)\div 5.0720 \\
R3C3 & 3.9585 & = 15.5973 - 3.0706\cdot 0.16289 - 6.6327\cdot 1.6793 \\
R4C3 & 12.7526 & = 6.9841 - 3.0581\cdot 0.16289 + 3.7316\cdot 1.6793 \\
R3C4 & 1.4193 & = (7.5172 - 3.0706\cdot 0.60596 - 6.6327\cdot 0.0057629)\div 3.9585 \\
R4C4 & -6.7332 & = 13.1984 - 3.0581\cdot 0.60596 + 3.7316\cdot 0.0057629 - 12.7526\cdot 1.4193 \\
R4C5 & 0.060806 & = (2.5393 - 3.0581\cdot 0.54515 + 3.7316\cdot 0.33632 - 12.7526\cdot 0.19891)\div(-6.7332)
\end{array}$$

Since a modern computing machine gives in one continuous operation a sum or difference of products with or without a final division, we see that *each element of the auxiliary matrix is given by a single machine operation.*[5]

The procedure for obtaining the one-columned final matrix from the auxiliary matrix is contained in the following rules.

1. The elements are determined in the following order: last, next to last, second from last, third from last, etc.

2. The last element is equal to the corresponding element in the last column of the auxiliary matrix.

3. Each element is equal to the corresponding element of the last column of the auxiliary matrix minus the sum of those products of elements in its row in the auxiliary matrix and corresponding elements in its column in the final matrix which involve only previously computed elements.

We see that in forming products only those elements of the auxiliary matrix are used which lie to the right of the principal diagonal and to the left of the last column. The calculations made in obtaining (3) are

$$\begin{array}{ll}
R3C1 & 0.11261 = 0.19891 - 1.4193\cdot 0.060806 \\
R2C1 & 0.14687 = 0.33632 - 1.6793\cdot 0.11261 - 0.0057629\cdot 0.060806 \\
R1C1 & 0.15942 = 0.54515 - 2.2506\cdot 0.14678 - 0.16289\cdot 0.11261 - 0.60596\cdot 0.060806
\end{array}$$

It may be noted that *each element of the final matrix is given by a single machine operation.*

It is not necessary but is strongly recommended that the values of the unknowns, which compose the final matrix, be substituted in each of the given equations, the result being a number of checks equal to the number of equations. Since the satisfaction of these checks guarantees the correctness of the solution, *it is not necessary to check the calculations which gave the auxiliary matrix and the final matrix.*[6] The first of the four checks obtained from (1) and (3) is

$$12.1719\cdot 0.15942 + 27.3941\cdot 0.14687 + 1.9827\cdot 0.11261 + 7.3757\cdot 0.060806 = 6.6355$$

Evidently *each check requires but one machine operation.*

The above method is applicable as described to *n* equations in *n* unknowns. The only writing involved is that required in recording the auxiliary matrix and the final matrix.

3. Systems Having Symmetrical Coefficients

If there is symmetry, the work of computing the auxiliary matrix is cut almost in half by the fact that *if the coefficients of the unknowns (or the elements of the given matrix) are symmetrical about the principal diagonal; each element of the auxiliary matrix below the principal diagonal gives, if divided by its diagonal element, the symmetrically opposite element above this diagonal.*[3] Elements below the principal diagonal of the auxiliary matrix are thus obtained as by-products of calculations made in determining elements above this diagonal.

As an example the symmetrical set of equations

$$\begin{array}{rrrrr}
x_1 & x_2 & x_3 & x_4 & = \\
245.95 & 768.49 & 233.08 & 261.13 & 40.384 \\
768.49 & 2665.85 & 880.54 & 915.95 & 90.887 \\
233.08 & 880.54 & 688.91 & 458.17 & 6.5783 \\
261.13 & 915.95 & 458.17 & 652.85 & 24.471
\end{array} \qquad (4)$$

has the auxiliary matrix

$$\begin{array}{rrrrr}
x_1 & x_2 & x_3 & x_4 & = \\
245.95 & 3.1246 & 0.94769 & 1.0617 & 0.16420 \\
768.49 & 264.63 & 0.57536 & 0.37800 & -0.13338 \\
233.08 & 152.25 & 380.42 & 0.40259 & -0.029928 \\
261.13 & 100.03 & 153.15 & 276.13 & -0.0017367
\end{array} \qquad (5)$$

and the final matrix

$$\begin{array}{ll}
x_1 = 0.55591 & x_3 = -0.029229 \\
x_2 = -0.11591 & x_4 = -0.0017367
\end{array} \qquad (6)$$

In the auxiliary matrix the element in row 3 and column 4 is

$$\frac{(458.17 - 233.08\cdot 1.0617 - 152.25\cdot 0.37800)}{380.42} = \frac{153.15}{380.42} = 0.40259$$

---

[3] A *matrix* is a rectangular array of numbers, or *elements*. Those elements which have the same row and column index form the *principal diagonal* which slopes down to the right starting with the element in the upper left corner. The *diagonal element* of any element to the right of the principal diagonal is that element of this diagonal which lies in the same row as the given element. The diagonal element of any element below the principal diagonal is that element of this diagonal which lies in the same column as the given element.

[4] All numerical data (except where exact) were obtained by omitting a certain number of decimal places from the corresponding original data, which were obtained using a ten bank computing machine retaining ten decimal places throughout. This applies to the given equations as well as to other data, for the problems used here as illustrations were, for the most part, previously solved for other purposes.

[5] In carrying out such an operation it is not necessary to foresee whether the result is positive or negative.

[6] Since in solving a given set of equations only a limited number of decimal places can be carried, the question arises as to how much the error accumulated during the course of the calculations affects the final results. An answer to this question cannot be given, since it depends upon whether or not the determinant of the system is on the point of vanishing (or, more generally, upon whether the matrix is on the point of shifting rank). Nevertheless it will be mentioned that in solving each of six systems of four equations in four unknowns using a ten bank computing machine, the final checks showed the given equations to be satisfied except for errors numerically less than three units in the ninth digit. Also it is known (from a separate investigation) that the values (10) of the unknowns of the complex system (8) computed with a ten bank machine contain errors each of which is numerically smaller than four units in the tenth digit. Although no general statement can be made, it is believed that in the usual case the accuracy tends to remain high during the course of the calculations.

the numerator 153.15 being recorded in the symmetrically opposite position before the final division by the diagonal element 380.42 is carried out.[4] The final matrix is obtained in the usual manner.

4. Evaluation of Determinants

It is true that *the value of a determinant is equal to the product of the elements which form the principal diagonal of the auxiliary matrix.* The auxiliary matrix is computed as described in section 2, the elements of the determinant being treated in the same manner as the coefficients of the x's before. The auxiliary matrix is square, since there is no column corresponding to the last column in (2); also, there is no final matrix.

As an example, the determinant composed of the first four columns of (1) has an auxiliary matrix composed of the first four columns of (2); hence the value of the determinant is $(12.1719)(5.0720)\times(3.9585)(-6.7332)=-1645.4$.

If the determinant is symmetrical about the principal diagonal, the work of evaluating it is cut almost in half because of the smaller amount of work required in computing the auxiliary matrix. (See section 3.) For example, the determinant composed of the first four columns of (4) has an auxiliary matrix composed of the first four columns of (5). The value of the determinant is hence $(245.95)(264.63)(380.42)(276.13)=6.8368\cdot10^9$.[4]

5. Continuous Check on Calculations

If desired, a "check column" may be written at the right of the given matrix, each element of this column being the sum of the elements of the corresponding row in the matrix. This column is now treated in exactly the same manner as the last column of the given matrix, the calculations being carried along with those for the other columns, and the result being the addition of corresponding "check columns" to the auxiliary matrix and the final matrix. The check columns thus obtained for (1), (2), and (3) are, respectively,[4]

$$\begin{array}{l} 55.560 \\ 52.372 \\ 44.421 \\ 28.931 \end{array},\quad \begin{array}{l} 4.5646 \\ 3.0214 \\ 2.6182 \\ 1.0608 \end{array},\ \text{and}\ \begin{array}{l} 1.1594 \\ 1.1469 \\ 1.1126 \\ 1.0608 \end{array} \tag{7}$$

These columns provide checks at all stages of the computation, because

1. **In the auxiliary matrix any element in the check column is equal to one plus the sum of the other elements in its row which lie to the right of the principal diagonal.**
2. **In the final matrix any element in the check column is equal to one plus the sum of the other elements in its row.**

For example noting (2), (3), and (7), two of the checks are

$$1+1.6793+0.0057629+0.33632=3.0214$$
$$1+0.11261=1.1126$$

The above statements are true and the procedure the same for any number of equations and unknowns; also, for the evaluation of determinants, in which, however, only statement 1 is applicable.

6. Improvement in Accuracy

Since the number of decimal places in the computations is limited, the values obtained for the unknowns are in general not exact. However, if they are placed in the given equations and the differences between the two sides are obtained, and if these differences are then inserted in place of the right hand sides of the given equations, the resulting equations have as their solution the corrections to the values first obtained. Noting that the above differences are obtained in applying the final checks (see section 2), and that the auxiliary matrix for the modified equations is the same as that for the original equations except for the last column, it follows that *if the column of the differences[7] obtained in applying the final checks be annexed to the given matrix and then treated in the same manner as the last column, the corresponding column obtained in the final matrix is composed of the required corrections.*

Since the problem of solving the modified equations is similar to the original problem, the above process may be repeated; thus the final checks on the corrections give data for another column in the given matrix, which leads to a column in the final matrix composed of corrections to the first corrections, etc. In the usual case each application of this process increases the number of significant figures in the results by approximately the same number obtained with the original solution, the data in the given equations being considered exact.

7. Systems of Equations Having Complex Coefficients

Since the proofs which establish the above method do not require the quantities involved to be real, the method is applicable to complex equations. The only question is that of whether the required calculations can be easily performed on a computing machine.

Since $(a+jb)(c+jd)=(ac-bd)+j(ad+bc)$, we see that the real and imaginary parts of a sum of products of complex numbers are each a sum of products of real numbers, given by one machine operation. It follows that *each element of the final matrix and each element of the auxiliary matrix which lies on or below the principal diagonal can be obtained by two machine operations one of which gives the real part, the other, the imaginary part.* It also follows that *each check run on the final matrix consists of two machine operations.*

Each element of the auxiliary matrix which lies to the right of the principal diagonal is given by a sum of products with a final division. The sum is first computed and recorded, after which the final division by the diagonal element $A=a+jb$ is carried out as a separate *multiplication* by $1/A=a/(a^2+b^2)-jb/(a^2+b^2)$. Since the best form for recording the supplementary data depends upon how much of it there is, we shall consider separately the following two cases.

1. Symmetrical Equations

Noting section 3 we see that *if the coefficients in the given equations are symmetrical about the principal diagonal, the sum required for computing any element of the auxiliary matrix above the principal diagonal is already recorded as the symmetrically opposite element below this diagonal.* It follows that only the last column of the auxiliary matrix requires separately recorded sums, which may be written in a *right supplementary column.* Data on the final multipliers $1/A$ may be placed in *two left supplementary columns.* [See (9).] In determining the auxiliary matrix the elements in any row which lie in the supplementary columns are determined just before those in that row to the right of the principal diagonal.

As an example the given set of four equations

$$\begin{array}{rrrrr} x_1 & x_2 & x_3 & x_4 & = \\ 84.276 & -91.342 & 32.463 & -45.417 & 6558.50 \\ 71.184j & 10.741j & -12.142j & -32.984j & -\ \ 185.00j \\ -91.342 & 45.374 & -21.212 & 80.414 & -8780.75 \\ 10.741j & 52.741j & 74.342j & -20.732j & 670.75j \\ 32.463 & -21.212 & 72.713 & 37.642 & -3463.25 \\ -12.142j & 74.342j & -20.221j & -77.814j & -3535.41j \\ -45.417 & 80.414 & 37.642 & -20.114 & -4268.87 \\ -32.984j & -20.732j & -77.814j & -29.741j & 1449.04j \end{array} \tag{8}$$

---

[7] In recording the computed values of these differences, as many nonvanishing digits should be kept as can be handled in the subsequent machine calculations.

where the imaginary part of each element is written below the real part for compactness, has the auxiliary matrix

$$\begin{array}{cc|ccccc|c}
a^2+b^2 & 1/A & x_1 & x_2 & x_3 & x_4 & = & RS \\
12170. & 0.0069251 & 84.276 & -0.56973 & 0.15379 & -0.50745 & 44.336 & \\
 & -0.0058493j & 71.184j & 0.60867j & -0.27397j & 0.037241j & -39.644j & \\
13101. & -0.000009789 & -91.342 & -0.1282 & 0.41654 & -0.10413 & -29.887 & -5156.8 \\
 & -0.0087368j & 10.741j & 114.458j & 0.087841j & -0.30098j & 45.088j & -3426.6j \\
7119.4 & 0.0111588 & 32.463 & -10.107 & 79.444 & 0.75944 & -29.404 & -2574.2 \\
 & 0.0039928j & -12.142j & 47.665j & -28.426j & -0.77633j & -8.3789j & 170.19j \\
3284.5 & -0.00050088 & -45.417 & 34.462 & 38.265 & -1.6452 & -51.713 & 1369.5 \\
 & -0.0174415j & -32.984j & -11.880j & -83.263j & 57.287j & -22.421j & -2925.6j
\end{array} \qquad (9)$$

where the supplementary columns are partitioned off by vertical lines, and the final matrix[4]

$$\begin{array}{llll}
x_1 = & \begin{array}{l}20.471\\ 10.782j\end{array} & x_2 = & \begin{array}{l}27.275\\ -31.498j\end{array} \\
x_3 = & \begin{array}{l}-42.652\\ 37.913j\end{array} & x_4 = & \begin{array}{l}-51.713\\ -22.421j\end{array}
\end{array} \qquad (10)$$

The following are typical calculations made in obtaining the above solution. In each case the part computed is specified by "real" or "imag.," after which the letters *R*, *C*, *LS*, and *RS* are used in place of "row," "column," "left supplementary," and "right supplementary," respectively. In the auxiliary matrix[4]

Real, *R3C3* $\quad 79.444 = 72.713 - 32.463 \cdot 0.15379 + 12.142 \cdot 0.27397 + 10.107 \cdot 0.41654 + 47.665 \cdot 0.087841$

Imag., *R4C3* $\quad -83.263 = -77.814 - 45.417 \cdot 0.27397 + 32.984 \cdot 0.15379 - 34.462 \cdot 0.087841 + 11.880 \cdot 0.41654$

Real, *R3CRS* $\quad -2574.2 = -3463.25 - 32.463 \cdot 44.336 + 12.142 \cdot 39.644 - 10.107 \cdot 29.887 + 47.665 \cdot 45.088$

In the final matrix

Real, *R2C1* $\quad -42.652 = -29.887 - 0.41654 \cdot 27.275 - 0.087841 \cdot 31.498 - 0.10413 \cdot 51.713 + 0.30098 \cdot 22.421$

2. NONSYMMETRICAL EQUATIONS

In the general case where there is no symmetry, and a sum must be recorded for every element of the auxiliary matrix to the right of the principal diagonal, the supplementary data may be recorded in a *supplementary matrix* having the same number of rows and columns as the auxiliary matrix. Each element to the right of the principal diagonal is the sum required in computing the corresponding element of the auxiliary matrix; the diagonal elements are the final multipliers $1/A$; and values of a^2+b^2 may be placed in a left supplementary column.

Since to obtain any element of the auxiliary matrix or the final matrix a real and imaginary part must be obtained, and since the sums involved have twice as many terms as they would have in the case of real coefficients, we see that *the work involved in solving a set of equations with complex coefficients is a little more than four times that required in solving a similar set with real coefficients.*

The procedures just described under case 1 and case 2 can be used to obtain the square auxiliary matrix required in evaluating a determinant with complex elements. (See section 4.)

A check column can be carried along if desired, the entries being complex. (See section 5.)

8. Equations Involving Two Sets of Variables

If two sets of variables are involved, the above method may be used to obtain one set in terms of the other. For example the given set of equations[4]

$$\begin{array}{cccccccc}
x_1 & x_2 & x_3 & x_4 = & y_1 & y_2 & y_3 & y_4 \\
12.172 & 27.394 & 1.983 & 7.376 & 6.636 & 0 & 0 & 0 \\
8.116 & 23.339 & 9.840 & 4.947 & 0 & 6.636 & 0 & 0 \\
3.071 & 13.543 & 15.597 & 7.517 & 0 & 0 & 6.636 & 0 \\
3.058 & 3.151 & 6.984 & 13.198 & 0 & 0 & 0 & 6.636
\end{array} \qquad (11)$$

of which the first is $12.172x_1+27.394x_2+1.983x_3+7.376x_4=6.636y_1$, has the auxiliary matrix

$$\begin{array}{ccccccccc}
x_1 & x_2 & x_3 & x_4 & = & y_1 & y_2 & y_3 & y_4 \\
12.172 & 2.251 & 0.1629 & 0.6060 & & 0.5452 & 0 & 0 & 0 \\
8.116 & 5.072 & 1.679 & 0.00576 & & -0.8724 & 1.308 & 0 & 0 \\
3.071 & 6.633 & 3.958 & 1.419 & & 1.039 & -2.192 & 1.676 & 0 \\
3.058 & -3.732 & 12.753 & -6.733 & & 2.699 & -4.877 & 3.175 & -0.9855
\end{array} \qquad (12)$$

and the final matrix

$$\begin{array}{lcccc}
 & y_1 & y_2 & y_3 & y_4 \\
x_1 = & -9.187 & 17.053 & -12.117 & 5.643 \\
x_2 = & 3.800 & -6.607 & 4.734 & -2.343 \\
x_3 = & -2.791 & 4.730 & -2.830 & 1.399 \\
x_4 = & 2.699 & -4.877 & 3.175 & -0.9855
\end{array} \qquad (13)$$

from which we see that $x_1 = -9.187y_1 + 17.053y_2 - 12.117y_3 + 5.643y_4$, etc. Each *y* column of (11) is treated in the same manner as the last column of (1), the result being a corresponding column in the final matrix. Four final checks on each of these is obtained by equating the corresponding *y* to 1 and the other *y*'s to 0, and substituting (13) in (11). If a check column is not used, it is desirable to finish one *y* column and apply the final checks before filling in the other *y* columns. (The calculations for each *y* column are independent of those for the others.) If a check column is desired, the procedure and rules given in section 5 are worded so as to apply to the present case, the *y* columns being included with the others. There is no restriction on the number of equations or the number of *y*'s.

9. m Equations in n Unknowns. Unusual Cases

Let there be given *m* equations in *n* unknowns. These may be arbitrarily (in any order) labeled 1, 2, . . ., *m*, and 1, 2, . . ., *n*, respectively, and the above procedure followed as though the equations and unknowns were actually written in the orders indicated by the labels. We shall consider the rows and columns both numbered in the orders in which they are completed in the auxiliary matrix. In general these orders are those in which the equations and unknowns are actually written, so that the labels are superfluous; however, in determining the auxiliary matrix two unusual cases may arise, as follows:[8]

1. If in completing a column the diagonal element is found to vanish, the (unlabeled) row chosen to be completed and labeled is one which has a nonvanishing element in this column.
2. If in completing a column all of the newly computed elements are found to vanish, that column is left unlabeled; but is (with its zeros) in its final form, and requires no further calculations.

The calculation of the auxiliary matrix is continued until either the rows or the unfinished x columns are exhausted, the total number of labeled rows and columns then being R. (R is the *rank* of the matrix of the coefficients in the given equations.) The m-R unlabeled rows and n-R unlabeled x columns will be called *excess*. Either, both, or neither of the quantities m-R and n-R may vanish, depending upon the given equations.

The one column (or more if there are several y columns as in section 8) arising from the right hand sides of the equations is now completed, the procedure being identical with that used in completing the last labeled column. If in so doing the computed elements (which lie in excess rows) all vanish, the given equations are compatible; otherwise they are incompatible.

If the equations are found to be compatible, we next omit the excess rows (the equations corresponding to which are superfluous), and determine the final matrix from the remaining rows. Each excess column is treated like the last column, and contributes a column to the final matrix, in which it is labeled $-x$ with the appropriate subscript. We thus obtain R unknowns as linear combinations of the others.

As an example, the given equations[4]

$$\begin{array}{rrrrr} x_1 & x_2 & x_3 & x_4 & = \\ 47.126 & -74.150 & 14.222 & -64.372 & 27.304 \\ -29.312 & 54.332 & -37.998 & 70.028 & -80.476 \\ 32.470 & -46.984 & -4.7770 & -29.358 & -12.934 \\ -5.7490 & 17.257 & -30.887 & 37.842 & -66.824 \\ 8.9070 & -9.9090 & -11.888 & 2.8280 & -26.586 \end{array} \tag{14}$$

have the auxiliary matrix

$$\begin{array}{rrrrr} x_1 & x_2 & x_3 & x_4 & = \\ 47.126 & -1.5734 & 0.30179 & -1.3660 & 0.57938 \\ -29.312 & 8.2113 & -3.5502 & 3.6522 & -7.7324 \\ 32.470 & 4.1056 & 0 & 0 & 0 \\ -5.7490 & 8.2113 & 0 & 0 & 0 \\ 8.9070 & 4.1056 & 0 & 0 & 0 \end{array} \tag{15}$$

and the final matrix

$$\begin{array}{lrrr} & -x_3 & -x_4 & \\ x_1= & -5.2843 & 4.3805 & -11.5871 \\ x_2= & -3.5502 & 3.6522 & -7.7324 \end{array} \tag{16}$$

The first unknown is $x_1=5.2843x_3-4.3805x_4-11.5871$. Since the two labeled rows and columns of the auxiliary matrix are in consecutive order, the labels are omitted, the excess rows and columns being clearly indicated by the block of zeros. Here $R=2$.

m final checks can be obtained on each column of the final matrix by substituting the results in the given equations, the other columns in the final matrix and the corresponding columns in the given equations being omitted.

If a check column is desired, the procedure and rules given in section 5 are worded so as to apply to the present case. In addition it is true that in the auxiliary matrix those elements of the check column which lie in excess rows must vanish if the given equations are compatible.

If the given equations are homogeneous (right hand sides all zero), all columns of the final matrix arise from excess columns of the auxiliary matrix. In those systems ordinarily met in stability and vibration problems $m=n=R+l$.

Mathematical Appendix

1. Introduction

The purpose of this appendix is to give the proofs which established the method, but which were omitted in describing the technique. To avoid repetition, familiarity with this technique is assumed. The method was originally obtained by combining the various processes which compose Gauss's method, and adapting them for use with a computing machine; however, direct proofs of the induction type[9] (as opposed to proofs based on the evolution of the method) were found to be the only ones which are short, clear, and capable of disposing of unusual cases.

2. n Equations in n Unknowns

Denoting the given matrix, the auxiliary matrix, and the final matrix by $\|G_{ij}\|$, $\|A_{ij}\|$, and $\|F_{i1}\|$, respectively,[10] the method is contained in the following equations:

$$A_{ii}=G_{ii}-\sum_{k=1}^{i-1}A_{ik}A_{ki}$$

$$A_{ij}=G_{ij}-\sum_{k=1}^{j-1}A_{ik}A_{kj} \qquad \text{if } i>j \tag{17}$$

$$A_{ij}=\left[G_{ij}-\sum_{k=1}^{i-1}A_{ik}A_{kj}\right]\frac{1}{A_{ii}} \qquad \text{if } i<j$$

and

$$F_{i1}=A_{i,n+1}-\sum_{k=i+1}^{n}A_{ik}F_{k1} \tag{18}$$

where any Σ whose lower limit exceeds its upper vanishes. At present we consider the usual case where the diagonal elements $A_{ii}\neq 0$, in which case the final matrix has but one column.

It is true that *if in the auxiliary matrix the elements of the principal diagonal be replaced by 1's, and the elements below this diagonal be replaced by 0's, the resulting matrix is the augmented matrix of a set of equations entirely equivalent to the given set.*[10] More explicitly the set of equations having the augmented matrix

$$\left\|\begin{array}{lll} G_{11} & G_{12}\ldots & G_{1,n+1} \\ G_{21} & G_{22}\ldots & G_{2,n+1} \\ \ldots & \ldots & \ldots \\ G_{n1} & G_{n2}\ldots & G_{n,n+1} \end{array}\right\| \tag{19}$$

and that having the augmented matrix

$$\left\|\begin{array}{llllll} 1 & A_{12} & A_{13} & A_{14}\ldots & A_{1n} & A_{1,n+1} \\ 0 & 1 & A_{23} & A_{24}\ldots & A_{2n} & A_{2,n+1} \\ 0 & 0 & 1 & A_{34}\ldots & A_{3n} & A_{3,n+1} \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 & 0\ \ldots & 1 & A_{n,n+1} \end{array}\right\| \tag{20}$$

have the same solution. Since the solution of the equations corresponding to an augmented matrix is not altered if the rows are multiplied by any numbers, or if to any row there is added a linear combination of the other rows; the above statement will be proved by induction[9] if we note that the first row of (20) is $1/A_{11}$ times the first row of (19), and if we can show that the [i^{th} row of (20)] $=\frac{1}{A_{ii}}\{$[i^{th} row of (19)] $-A_{i1}$[1st row of (20)] $-A_{i2}$[2nd row of (20)] $-\ldots-A_{i,i-1}$[$(i-1)^{\text{th}}$ row of (20)]$\}$, or more explicitly

$$\left.\begin{array}{l} 1=\left[G_{ii}-\sum\limits_{k=1}^{i-1}A_{ik}A_{ki}\right]\dfrac{1}{A_{ii}} \\ 0=\left[G_{ij}-\sum\limits_{k=1}^{j-1}A_{ik}A_{kj}-A_{ij}\right]\dfrac{1}{A_{ii}}, \\ \qquad j=1,2,3,\ldots,i-1 \\ A_{ij}=\left[G_{ij}-\sum\limits_{k=1}^{i-1}A_{ik}A_{kj}\right]\dfrac{1}{A_{ii}} \\ \qquad j=i+1,i+2,i+3,\ldots,n+1 \end{array}\right\} \tag{21}$$

---

[8] These cases may also arise in evaluating a determinant. Should case 1 occur, the sign of the product of the diagonal elements must be reversed if the number of inversions of the row labels is odd; otherwise, left unaltered. Should case 2 occur, the value of the determinant is zero.

[9] A proof by *induction* establishes a relation for all positive integer values of n by verifying it for $n=1$ and then showing that if it is true for $n=1, 2, \ldots, i-1$, it is also true for $n=i$.

[10] The element in the i^{th} row and j^{th} column of the matrix $\|G_{ij}\|$ is G_{ij}. (See (3).) The *augmented matrix*, or given matrix, differs from the matrix of the coefficients of the unknowns only in that it has an additional column composed of the right hand sides of the equations. The usual matrix notation (double vertical bars) is used here, since we are concerned only with proofs.[9]

where any Σ whose upper limit is zero vanishes. But these equations follow directly from (17); hence the above statement is proved.

In a similar manner we can show that *the equations corresponding to the final matrix, whose augmented matrix is*

$$\left\|\begin{matrix} 1 & 0 & 0 \ldots 0 & F_{11} \\ 0 & 1 & 0 \ldots 0 & F_{21} \\ 0 & 0 & 1 \ldots 0 & F_{31} \\ \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 \ldots 1 & F_{n1} \end{matrix}\right\| \qquad (22)$$

are equivalent to those of (20), for the n^{th} rows of (20) and (22) are identical ($F_{n1}=A_{n,n+1}$), and the [i^{th} row of (22)] = [i^{th} row of (23)] $-$ $A_{i,i+1}$[$(i+1)^{th}$ row of (22)] $-$ $A_{i,i+2}$$(i+2)^{th}$ row of (22)] $- \ldots -$ A_{in} [n^{th} row of (22)], as is expressed by the relation

$$F_{i1}=A_{i,n+1}-\sum_{k=i+1}^{n} A_{ik}F_{k1}$$

which agrees with (18). The equations corresponding to (22), which constitute the result given by the final matrix, are thus equivalent to (20) and hence (19); and therefore express the required solution.

3. Evaluation of Determinants

To show that the value of a determinant is equal to the product of the elements of the principal diagonal of the auxiliary matrix we note that although augmented matrices and determinants are alike in that any row can be increased by a linear combination of the other rows, they differ in that division of a row of an augmented matrix by any number gives an equivalent matrix, whereas division of a row of a determinant by a number divides the value of the determinant by that number. The procedure used in section 2 for augmented matrices can hence be repeated for determinants; however, since the i^{th} row is divided by the diagonal element A_{ii}, we must compensate by retaining A_{ii} as an external factor. Corresponding to (20) we thus have

$$\begin{vmatrix} G_{11} & G_{12} \ldots G_{1n} \\ G_{21} & G_{22} \ldots G_{2n} \\ \ldots & \ldots \\ G_{n1} & G_{n2} \ldots G_{nn} \end{vmatrix} =$$

$$\begin{vmatrix} 1 & A_{12} & A_{13} & A_{14} \ldots A_{1n} \\ 0 & 1 & A_{23} & A_{24} \ldots A_{2n} \\ 0 & 0 & 1 & A_{34} \ldots A_{3n} \\ \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 & 0 \ldots 1 \end{vmatrix} A_{11}A_{22}A_{33} \ldots A_{nn}$$

But the determinant on the right hand side is 1, as can be seen by developing it by minors with respect to the first column, second column, and so on; hence the value of the given determinant is $A_{11}A_{22}A_{33} \ldots A_{nn}$.

4. Symmetrical Equations and Determinants

We shall now show that in the symmetrical case where

$$G_{ij}=G_{ji}, \quad i, j \leq n \qquad (23)$$

elements of the auxiliary matrix which lie in symmetrical positions on opposite sides of the principal diagonal are related by the equation

$$A_{ij}=\frac{A_{ji}}{A_{ii}}, \quad i<j\leq n \qquad (24)$$

Using induction[1] we note from (17) and (23) that (24) is true for the first row and column of the auxiliary matrix. Assuming it true for the first $i-1$ rows and columns, it follows from (17), (23), and (24) that

$$A_{ji}=G_{ji}-\sum_{k=1}^{i-1} A_{jk}A_{ki}$$

$$=G_{ij}-\sum_{k=1}^{i-1}(A_{kk}A_{kj})\left(\frac{A_{ik}}{A_{kk}}\right)$$

$$=G_{ij}-\sum_{k=1}^{i-1} A_{ik}A_{kj}=A_{ij}A_{ii}, \; i<j\leq n$$

Hence (24) is also true for the i^{th} row and column.

5. Check Columns

If in a matrix the last column is the sum of the other columns, this fact evidently remains true if a row be multiplied by a constant, or if to any row be added a constant times another row. Since (20) can be obtained from (19), and (22) from (20) by just such operations, we see that if a check column is annexed to (19), the corresponding columns obtained in the auxiliary matrix and the final matrix are the sums of the columns of (20) and of (22), respectively; and hence have the required properties.

6. Complex Equations Whose Symmetrical Coefficients Are Conjugate

It is true that *if in the given equations each coefficient below the principal diagonal is the conjugate of the symmetrically placed coefficient above this diagonal, those on the diagonal being real; then in the auxiliary matrix the elements of the principal diagonal are all real, and every element above this diagonal is obtained by dividing the conjugate of the symmetrically opposite element below this diagonal by its diagonal element.*[2] It follows that complex equations of this type, which occur in certain least square processes, are far easier to solve than any other type of complex equations, because in determining the auxiliary matrix

To prove the above statement we must show that if

$$G_{ij}=\overline{G}_{ji}, \quad i, j\leq n \qquad (25)$$

in which case G_{ii} is real (since $G_{ii}=\overline{G}_{ii}$), bars indicating conjugates; then

$$\begin{aligned} &A_{ii} \text{ is real}, \quad i\leq n \\ &A_{ij}=\frac{\overline{A}_{ji}}{A_{ii}}, \quad i<j\leq n \end{aligned} \qquad (26)$$

Using induction[1] we note from (17) and (25) that (26) is true for the first row and column of the auxiliary matrix. Assuming it true for the first $i-1$ rows and columns, it follows that

$$A_{ii}=G_{ii}-\sum_{k=1}^{i-1} A_{ik}A_{ki}$$

$$A_{ii}=G_{ii}-\sum_{k=1}^{i-1}(A_{kk}\overline{A}_{ki})\left(\frac{\overline{A}_{ik}}{A_{kk}}\right)$$

$$=\overline{G}_{ii}-\sum_{k=1}^{i-1} \overline{A}_{ik}\overline{A}_{ki}=\overline{A}_{ii}, \quad i\leq n$$

since the conjugate of a sum of products is the sum of products of the conjugates. A_{ii} is therefore real, since $A_{ii}=\overline{A}_{ii}$. Again, noting (17), (25), and (26),

$$A_{ij}=\frac{1}{A_{ii}}\left[G_{ij}-\sum_{k=1}^{i-1} A_{ik}A_{kj}\right]$$

$$A_{ij}=\frac{1}{A_{ii}}\left[\overline{G}_{ji}-\sum_{k=1}^{i-1}(A_{kk}\overline{A}_{ki})\left(\frac{\overline{A}_{jk}}{A_{kk}}\right)\right]$$

$$=\frac{1}{A_{ii}}\left[\overline{G}_{ji}-\sum_{k=1}^{i-1} \overline{A}_{jk}\overline{A}_{ki}\right]=\frac{\overline{A}_{ji}}{A_{ii}}, \quad i<j\leq n$$

Hence (26) is also true for the i^{th} row and column.

7. m Equations in n Unknowns

The justification of the procedure described for m equations in n unknowns follows from the statements

A. If one column of a matrix is a linear combination of certain other columns, it remains that same combination if a row be multiplied by a constant, if to any row be added a constant times another row, or if such operations be repeated any number of times.

B. If after determining i rows and i columns of the auxiliary matrix, the remaining elements are determined by the relation

$$A_{pq}'=G_{pq}-\sum_{k=1}^{i} A_{pk}A_{kq}, \quad p, q>i \qquad (27)$$

(ordinarily used only in completing the $(i+1)^{th}$ column) instead of (1); the resulting matrix has the property that if in the first i columns the elements of the principal diagonal be replaced by 1's, and the elements below this diagonal, by 0's, thus

$$\left\|\begin{matrix} 1 & A_{12} & A_{13} \ldots A_{1i} & A_{1,i+1} & A_{1,i+2} & \ldots A_{1,n+1} \\ 0 & 1 & A_{23} \ldots A_{2i} & A_{2,i+1} & A_{2,i+2} & \ldots A_{2,n+1} \\ 0 & 0 & 1 \ldots A_{3i} & A_{3,i+1} & A_{3,i+2} & \ldots A_{3,n+1} \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 \ldots 1 & A_{i,i+1} & A_{i,i+2} & \ldots A_{i,n+1} \\ 0 & 0 & 0 \ldots 0 & A_{i+1,i+1}' & A_{i+1,i+2}' & . A_{i+1,n+1}' \\ 0 & 0 & 0 \ldots 0 & A_{i+2,i+1}' & A_{i+2,i+2}' & . A_{i+2,n+1}' \\ \ldots & \ldots & \ldots & \ldots & \ldots & \ldots \\ 0 & 0 & 0 \ldots 0 & A_{m,i+1}' & A_{m,i+2}' & . A_{m,n+1}' \end{matrix}\right\| \qquad (28)$$

---

[1] Elements below the principal diagonal are obtained as by-products of calculations made in determining elements above this diagonal, the procedure being similar to that used with symmetrical equations.

[2] The divisions by the real diagonal elements can be performed directly as final divisions, no supplementary columns being required.

Self-Excitation of Induction Motors With Series Capacitors

C. F. WAGNER
FELLOW AIEE

INDUCTION motors with series capacitors connected in the supply circuit can under certain conditions become unstable. Upon application of the voltage the rotor will come up to partial speed and continue to rotate at this reduced speed. This phenomenon should not be confused with ferro-resonance which is accompanied by violent wave distortion, abnormally large magnetizing currents, and fluctuations in voltage. Both of these phenomena were analyzed as applied to induction motors by Butler and Concordia.[1] It is the purpose of this paper to present further thoughts regarding the stability problem. A new approach is utilized which is much simpler and at the same time provides a clearer conception of the physical processes involved. Somewhat different conclusions result with the use of this analysis than with the analysis of others. In this analysis conventional induction motor nomenclature and symbols will be used as it is believed that induction motor engineers will better understand the problem by this procedure.

Simple Analysis of Problem

Currents in circuits consisting of a capacitor, inductor, and resistor in series may originate in two ways. First, they may be forced by an externally applied voltage in which case the frequency of the currents corresponds to that of the applied voltage. Second, they may flow in accordance with the natural frequency of the circuit. In the latter case, the current flows in response to some change in the circuit and gradually decays to zero, the rate being dependent to a large extent upon the resistance. The smaller the resistance the longer will the currents persist. If a negative resistance, such as may be obtained by certain combinations of vacuum tubes, is inserted into the circuit and is of such characteristic as to just equal the positive resistance, then currents of the natural frequency of the circuit flow continuously. This is the kind of condition that may exist in an induction motor in which series capacitors are connected in the stator circuit.

The upper circuit of figure 1 shows the conventional schematic diagram of an induction motor in which

x_s = leakage reactance of the stator
x_r = leakage reactance of the rotor
x_m = reactance of the magnetizing branch
r_s = resistance of stator
r_r = resistance of rotor
x_c = capacitive reactance of series capacitor
s = slip, expressed as a fraction of synchronous speed

All impedances are expressed in per unit quantities which are the same as per cent, except that unity is taken as a base instead of 100. The loss in the resistor $\frac{1-s}{s}r_r$ represents the shaft power.

The lower circuit is the same as the upper one, except that it is resonant for a frequency f times the system frequency. It is assumed that the source has zero impedance, and since it has no emf of resonant frequency, this point of the circuit is merely represented by a line of zero impedance. After connection of the motor to the system voltage, the speed increases until it reaches a value equal to that corresponding to the synchronous speed associated with the frequency f. Beyond this speed, its slip, s_1, with respect to the synchronous speed of the resonant circuit becomes negative, and with regard to this circuit the motor begins to function as an induction generator. Since s_1 is negative, then the resistor $(1-s_1)r_r/s_1$ is negative and the shaft power, which is represented by the loss in this resistor, is also negative. Thus, s_1 so adjusts itself that the negative resistor $(1-s_1)r_r/s_1$ just annuls the effect of the two other positive resistors r_s and r_r; the circuit will self excite and the currents of frequency f will flow continuously. The resistor $(1-s_1)r_r/s_1$ corresponds to the vacuum tubes mentioned previously. The only connection between these otherwise independent circuits is

Paper 41-139, recommended by the AIEE committee on electrical machinery, and presented at the AIEE Pacific Coast convention, Yellowstone National Park, August 27–29, 1941. Manuscript submitted May 23, 1941; made available for preprinting July 2, 1941.

C. F. WAGNER is engineering manager of central station section, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

---

then each row of (28) differs from the corresponding row of the given matrix by a linear combination of the preceding rows of (28). The equations corresponding to (28) (considered as an augmented matrix) are thus equivalent to the original equations.

A is self-evident. The proof given with (20) and (21) is applicable to (28), and establishes B for the first i rows. For the p^{th} row, $p>i$, it is true that the [p^{th} row of (28)] = [p^{th} row of given matrix] $-A_{p1}$[1st row of (28)] $-A_{p2}$[2nd row of (28)] $-\ldots-$ A_{pi}[i^{th} row of (28)], or

$$0=G_{pq}-\sum_{k=1}^{q-1}A_{pk}A_{kq}-A_{pq}, \quad p>i,\ q\leq i$$

$$A_{pq}'=G_{pq}-\sum_{k=1}^{i}A_{pk}A_{kq}, \quad p>i,\ q>i$$

For here the first equation follows from the second of (17), and the second follows from (27); hence B is proved.

In solving a set of m equations in n unknowns two unusual cases may arise in determining the auxiliary matrix; however, case 1 requires no comment, and we lose nothing by supposing the equations to be written in such an order that this case does not occur. Turning to case 2, suppose that in completing the $(i+1)^{\text{th}}$ column of the auxiliary matrix the computed elements, which are identical with $A_{i+1,i+1}'$, $A_{i+2,i+1}'$, $\ldots$, $A_{m,i+1}'$, all vanish; then this column is evidently a linear combination of the first i columns of (28), whence it follows from A and B that the $(i+1)^{\text{th}}$ column of the *given* matrix is the same linear combination of the first i columns of that matrix. Were this excess $(i+1)^{\text{th}}$ column shifted to any other position to the right in the given matrix, and i or more rows and columns completed as usual in the auxiliary matrix before applying (27) to obtain a matrix similar to (28); then since the first i columns are the same as before, and since the same linear combination is involved, the corresponding excess column obtained is (with its zeros) identical with that obtained before. It is thus true that *each excess column in the auxiliary matrix is obtained in its final form when first calculated.*

Writing the excess columns together and just to the right of the R columns for the other unknowns, the finished auxiliary matrix differs from (28) only in that i is replaced by R. Since the last $m-R$ or more elements in each excess column in this matrix vanish, it follows from B that for compatibility the last $m-R$ elements of the $(n+1)^{\text{th}}$ column, which arises from the right hand sides of the equations, must also vanish; in which case the last $m-R$ elements of the check column (if one is used) must vanish due to A.

In determining the final matrix the excess columns are considered as transposed to the right hand side of the equations, which fact gives rise to minus signs in the column labels.

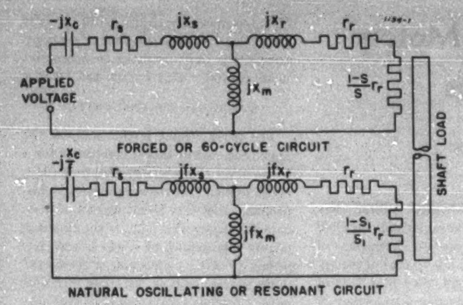

Figure 1. Schematic diagram of induction motor with series capacitor

the shaft. Power is taken by the shaft from the upper circuit and fed back into the lower circuit. The current flow in the lower circuit is limited only by the amount of power that can be drawn from the upper circuit at the particular speed necessary to make the resistance of the lower circuit zero. This power appears as a negative quantity in the branch which represents shaft loading and must equal the I^2R loss in the r_s and r_r branches of the resonating circuit.

The actual speed, p, of the rotor can be expressed in terms of both s and s_1. Thus, the speed is

$$p = 1 - s = (1 - s_1)f \qquad (1)$$

from which

$$s = 1 - (1 - s_1)f \qquad (2)$$

Quantitative Relations

Consider next the conditions which must be satisfied to permit natural oscillations. The resonant circuit of figure 1 must have an impedance equal to zero as viewed from any point in the network. It will be found more convenient for the present purpose to view the circuit from a point in the rotor circuit. For the sake of simplicity in deriving the following expressions f will first be assumed equal to unity. It will be reinserted in the final results by dividing x_c everywhere it appears by f and multiplying the inductive reactances by f. In this paper all reactances, both inductive and capacitive, will be given in terms of their values at system frequency. The two resistances in the rotor can be combined into the single resistor r_r/s_1. Upon paralleling the condensive branch with x_m and adding to the rotor impedances, the impedance as viewed from a point in the rotor becomes

$$\frac{jx_m[r_s + j(x_s - x_c)]}{r_s + j(x_m + x_s - x_c)} + \frac{r_r}{s_1} + jx_r = 0 \qquad (3)$$

or

$$\frac{jx_m[r_s + j(x_s - x_c)][r_s - j(x_m + x_s - x_c)]}{r_s^2 + (x_m + x_s - x_c)^2} + \frac{r_r}{s_1} + jx_r = 0 \qquad (4)$$

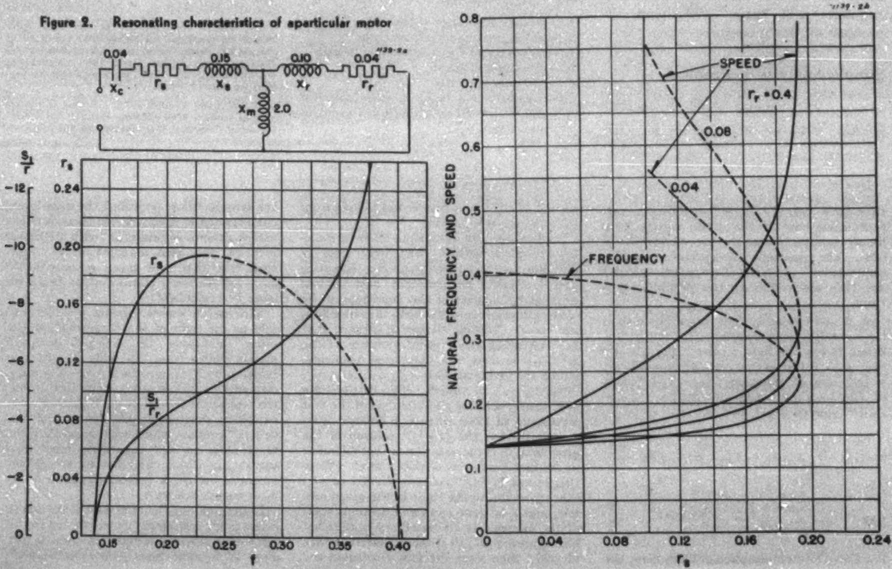
The condition that the circuit be self-exciting is satisfied when both the real and the imaginary components of the above impedance are individually equal to zero. Equating the imaginary component to zero, there is obtained

$$x_m r_s^2 + x_m(x_s - x_c)(x_m + x_s - x_c) + x_r r_s^2 + x_r(x_m + x_s - x_c)^2 = 0$$

from which

$$r_s^2 = -(x_m + x_s - x_c)\left(x_s + \frac{x_r x_m}{x_m + x_r} - x_c\right) \qquad (5)$$

Figure 2. Resonating characteristics of aparticular motor



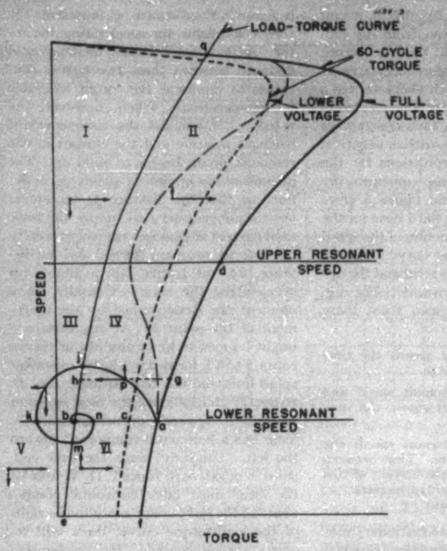


Figure 3. Speed-torque characteristic to show that the lower resonant speed is stable

and upon equating the real components to zero, there is obtained

$$\frac{s_1}{r_r} = -\frac{r_s^2+(x_m+x_s-x_c)^2}{x_m^2 r_s} \tag{6}$$

After squaring (6) and inserting r_s from equation 5, there results

$$\left(\frac{s_1}{r_r}\right)^2 = -\frac{x_m+x_s-x_c}{(x_m+x_r)^2\left(x_s+\dfrac{x_r x_m}{x_m+x_r}-x_c\right)} \tag{7}$$

Upon reinserting the f term, equations 5 and 7 become

$$r_s^2 = -\frac{1}{f^2}[f^2(x_m+x_s)-x_c] \times \left[f^2\left(x_s+\frac{x_r x_m}{x_m+x_r}\right)-x_c\right] \tag{8}$$

$$\left(\frac{s_1}{r_r}\right)^2 = -\frac{f^2(x_m+x_s)-x_c}{f^2(x_m+x_r)^2\left[f^2\left(x_s+\dfrac{x_r x_m}{x_m+x_r}\right)-x_c\right]} \tag{9}$$

The quantity (x_m+x_s) represents the exciting reactance of the motor and will be designated x_M; $x_s+(x_r x_m)/(x_m+x_r)$ is the blocked rotor reactance for r_r equal to zero and will be designated by x_B. Equations 8 and 9 then become

$$r_s^2 = -\frac{1}{f^2}[f^2 x_M-x_c][f^2 x_B-x_c] \tag{10}$$

$$\left(\frac{s_1}{r_r}\right)^2 = -\frac{[f^2 x_M-x_c]}{f^2(x_m+x_r)^2[f^2 x_B-x_c]} \tag{11}$$

Extraneous roots have been introduced in the manipulation of the equations, but consideration of equation 6 shows that s_1 will be negative. These two equations represent the two conditions which must be satisfied to produce self excitation. For a given r_s, the value of f which satisfies equation 10 determines the resonating frequency. Equation 11 determines the slip corresponding thereto and consequently the speed.

Figure 2 shows the general resonating characteristics of an induction motor with a series capacitor for a particular case. The upper curves represent the solutions of equations 10 and 11 plotted as a function of f. The lower curves were obtained from the upper ones and through the use of equation 2. They show how f and s vary with the stator and rotor resistors. For $r_s=0$ two resonant points occur, the lower one representing the frequency at which the capacitor resonates with the magnetizing reactance and the upper one the frequency at which the capacitor resonates with the magnetizing reactance and the upper one the frequency at which the capacitor resonates with the blocked rotor reactance. For other values of r_s two resonating points likewise exist, but, as will be shown presently, only the lower point is a stable operating point. The unusually low magnetizing impedance was chosen to take care of saturation.

Mechanism of Pull-in and Operating Points

As in any resonating circuit, the current increases until the actual losses in the circuit just equal the negative losses produced by the negative resistance. In the present case the losses are supplied through the shaft and thus the current is limited solely by the ability of the 60-cycle circuit to supply power to the resonant circuit at the speed corresponding to the resonant frequency.

In figure 3 are given the shaft torque characteristics of a motor with a series capacitor as determined from the conventional 60-cycle circuit. Likewise is given an assumed load-torque curve and two horizontal lines which indicate the speeds

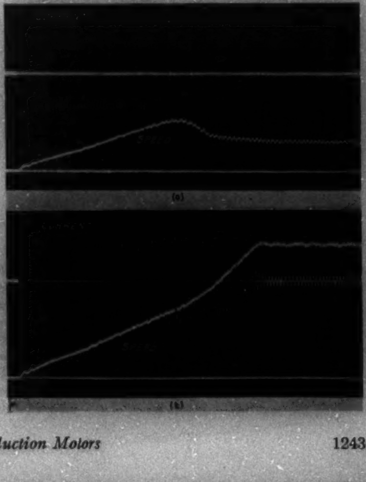

Figure 4. Oscillograms showing rotor speed and stator current as voltage is suddenly applied to a motor with series capacitor

(a) Low applied voltage—rotor stalling at resonant speed

(b) Higher applied voltage—rotor passing through resonant speed corresponding to the upper and lower resonant frequencies. On the lower resonant speed the distance *oa* is the total shaft torque. Of this torque *ob* is required to supply the load requirements. The excess *ab* is the torque which when converted to power at the particular speed represents the power input into the resonant circuit. If the applied voltage were lowered so that the 60-cycle torque curve were reduced to that shown by the dotted line, then the power into the resonant circuit would be reduced to that corresponding to the torque *bc*. Similarly, if the load torque characteristic were increased there would be less power available for circulation of current in the resonant circuit.

The right hand portion of the upper curve of figure 4*a* represents the steady-state stator current, which can be seen to consist of two components. One component has the same frequency as that of the 60-cycle applied voltage and the other a lower frequency corresponding to that of the natural frequency of oscillation.

The point *d* of figure 3, where the speed-torque curve intersects the upper resonant speed line, is the other solution from a curve, such as shown in figure 2. It is the purpose of this discussion to show that the point, *a*, represents a stable operating point and the point, *d*, an unstable point. For any particular speed, an induction motor with a series capacitor has three modes of oscillation. By this is meant that the transient resulting from any sudden change is composed of three terms. Two of these terms always have a negative time constant, which characterizes a condition wherein the components always tend to decrease. The time constant of the third term may be positive, negative, or infinitely large. Expressions for the calculation of these time constants are given in appendix I and figure 5 gives numerical values for the third term for the circuit of figure 2 as a function of the speed of the motor. The lower curve gives the natural frequency of this term and the upper curve the time constant. The significant facts to be drawn from these curves are that:

1. At the two resonant speeds the time constants are infinitely large.
2. Below the lower resonant speed and above the upper resonant speed, the time constants are negative.
3. Between the two resonant speeds the time constants are positive. Thus between the two resonant speeds the current of this term of the transient tends to increase; at all other speeds, to decrease.

If voltage is applied to a stationary motor for which the characteristics are given in figure 3, the distance, *ef*, represents the torque available for accelerating the rotor. As its speed increases, the horizontal distance between these two curves continues to represent the torque available for acceleration. When, however, the point, *a*, is reached the time constant becomes positive and the current in the resonant circuit begins to build up. The instantaneous operating point, *p*, is defined so that the distance *pg* represents the torque necessary to supply the resonant current at that instant (the power input into the resonant circuit) and the distance, *hp*, the torque still available for accelerating the rotor. Consider for a moment the locus formed by the movement of the point *p*. At any instant *p* might happen to lie in any one of the six zones, I to VI, formed by the two resonant speed lines and the load torque curve. In zones III and IV since the time constant is positive, *pg* tends to increase and the locus has a horizontal component toward the left. Similarly, since the time constant is negative in zones I, II, V, and VI the locus must have horizontal components to the right. For zones to the right of the load-torque curve, there still remains torque available for acceleration

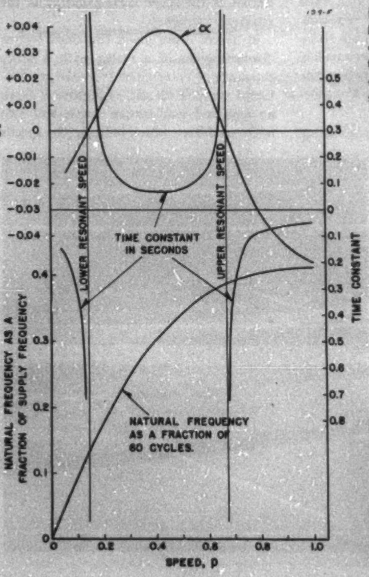

Figure 5. Natural frequency and time constants of induction motor having constants of those shown in figure 2

$r_r = 0.04$

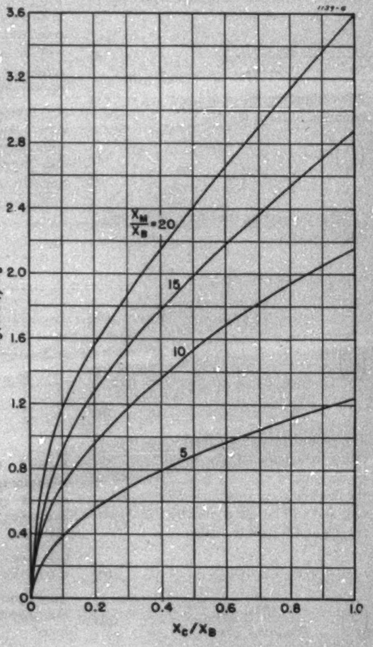

Figure 6. Maximum series resistance in stator, $r_{s(max.)}$, above which circuit will not resonate expressed as a function of locked rotor reactance, x_B, and no-load reactance, x_M

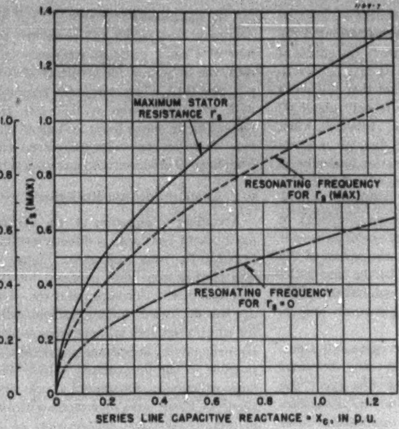

Figure 7. Effect of series capacitance for a specific case

$x_M=3.24$
$x_B=0.40$

of the rotor. Thus zones II, IV, and VI must have upward components of motion of *p*. Similarly, points to the left of the load-torque curve tend to decelerate and have downward vertical components. The point *p* moves from *a* with an upward and leftward motion, the upward component becoming smaller and smaller as the load-torque is approached. To the left of *j* (in zone III) the locus has a downward and leftward component, the leftward component decreasing with increasing time constant as the lower resonant speed line is approached at *k*. Following this reasoning it may be seen that the locus follows the spiral and reaches a stable point at *b*.

The foregoing assumed that the inertia of the rotating part was quite high or that the power available for acceleration was low, so that the current had sufficient time to build up. If on the other hand the above conditions are not fulfilled, the locus may take a path, such as indicated by the dashed line, finally attaining the stable operating point *q*.

Note that in neither case did the motor tend to operate at point *d*, the point for which the curves of figure 2 indicated a solution in the dotted portion of the graphs. If the upper resonant speed is greater than 1.0, the rotor must lock in at the lower speed for all cases.

Verification of the foregoing theory is presented in figure 4 which shows the rotor speed and stator current for the case (*a*) in which the rotor pulls in at the resonant speed and (*b*) in which it passes through this speed and finally attains a speed corresponding to normal operating conditions with a small slip. In both cases the motor was operating at no load, the only difference in the two cases being that the applied voltage for (*b*) was about 3 per cent higher than for (*a*). In the former case it can be seen that the speed overshoots the final value and finally settles down to the resonant speed. It differs from the story depicted in figure 3 in that the resonant current changes so rapidly that only the components in zones IV and III are of importance. The oscillogram also shows that the resonant frequency component of the stator current is a maximum a short time after the speed is a maximum, which conforms to the expectations of the foregoing theory. As the speed in figure 4*b* reaches the resonant speed, the resonant frequency component of the stator current begins to build up and then decreases again as the speed exceeds the upper resonant speed.

General Results

By slight transformation, equation 10 can be rewritten as

$$\frac{r_s}{x_c}=\frac{1}{f}\sqrt{\left[f^2\frac{x_M}{x_c}-1\right]\left[1-f^2\frac{x_B}{x_c}\right]} \qquad (12)$$

For specific values of x_M/x_c and x_B/x_c curves of r_s/x_c similar to that of r_s in figure 2 can be plotted as functions of r. It is impossible for the circuit to resonate for x_s/x_c in excess of the maxima of these curves. These maxima, $r_{s(\text{max.})}/x_B$, are plotted in figure 6 as a function of x_c/x_B and x_M/x_B. Both x_B and x_M include the external series reactance of the motor.

Figure 7 gives the maxima of r_s for typical values of x_M and x_B. In addition, the resonant frequency, f, corresponding to $r_{s(\text{max.})}$ is also given together with f for $r_s=0$. For intermediate values of r_s, f must lie between these two curves.

As pointed out by Butler and Concordia for other cases of instability, this particular type also can be alleviated by paralleling the capacitor with a resistor. The solution for this condition is given in the appendix for the special case in which there is no series resistance in the stator. The results of calculations employing this method are given in figure 8, which gives the minimum resistance necessary to suppress resonance. Of course, as series resistance is added to the circuit, the minimum parallel resistance increases. When the value of series resistance has reached the magnitude given in figure 6, no parallel resistance is necessary. This corrective method is particularly good because at system frequency so little of the current is by-passed but at the lower frequency of resonance sufficient current is by-passed to prevent resonance effects.

Utilizing the same general approach as that given for the development of equations 8 and 9 or that in appendix II, it is possible to calculate the parallel resistor required to suppress resonance for any particular value of series resistance. The same method can be extended further to cover any combination of resistors, reactors, and capacitors.

Test Results

In order to verify still further the correctness of the foregoing theory, tests were made upon a 220 volt, 7½ hp, three-

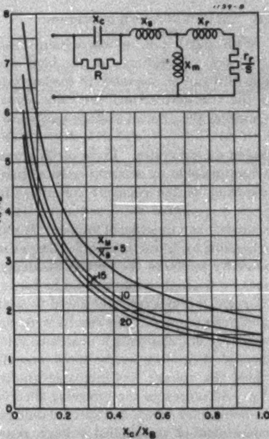

Figure 8. Minimum parallel resistor, $R_{\text{min.}}$, below which an induction motor with no series stator resistance will not resonate

phase, wound rotor induction motor. Power was supplied from a 100 kva, 2,200 volt generator. The generating voltage was stepped down from 2,200 to 220 volts by means of a 15 kw, three-phase transformer. Capacitors were connected in series in the 220 volt side. It was found that conditions of ferro-resonance were easily set up for this condition. Resistance representative of line resistance was then inserted in the 2,200 volt side of the circuit sufficient to suppress ferro-resonance. Additional resistance was at times placed in series in the low voltage side.

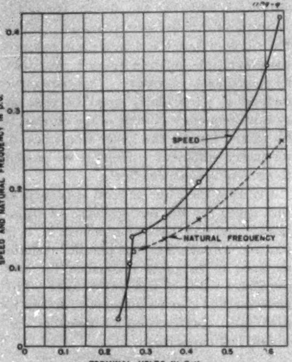

Figure 9. Variation of speed and natural frequency with terminal voltage

(a) Changing Applied Voltage

With 0.021 p.u. of capacitance and 0.071 p.u. of resistance in the high side and 0.16 p.u. of reactance in the low side of the transformer and the rotor short-circuited, the applied voltage was varied with no load on the shaft except an unloaded d-c generator. From oscillograms it was possible to determine the natural frequency of the resonant currents. In figure 9 is plotted the speed and natural frequency as a function of voltage. It was impossible to obtain the data for the entire range by applying the voltage suddenly, since for the higher voltages, the motor accelerated through resonant speed to near synchronous speed. The results were obtained by first applying a moderate voltage and then after steady speed was attained the voltage was increased gradually. According to the foregoing theory, the natural frequency and speed should be independent of the applied voltage, resonant current being limited only by the power input into the shaft for the particular speed and terminal voltage as determined by the system frequency characteristics of the motor. The variations in the curves of figure 9 are due to the effects of saturation. This may at first appear illogical in view of the fact that the maximum terminal voltage is only about 60 per cent of rated voltage. However, when it is recalled that the flux for a given amplitude of voltage varies inversely as the frequency, it may be seen that the influence of the resonant frequency voltage is very great. In addition, the effect of the resonant frequency voltage is not measured by the root-mean-square of the combined voltages but by the sum of the maximum values, the lower frequency being given greater weight inversely proportional to its frequency.

The break in the speed curve at 0.13 p.u. synchronous speed represents the lower resonant speed. Below this point the speed is determined purely by the nature of the shaft load; the oscillograms show no evidence of resonant frequency currents. The minimum frequency at which currents were discernible was 0.12 p.u.

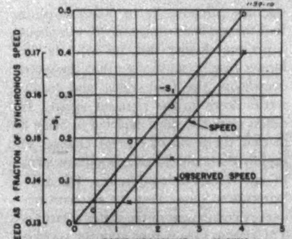

Figure 10. Effect of changing rotor resistance

In figure 9, as the applied voltage is increased the magnetizing impedance becomes lower. Likewise, the ratio x_m+x_B decreases quite rapidly but x_c/x_B increases but slightly. Thus, the limiting values of r_s, as determined from figure 6, decrease. Eventually, therefore, as the applied voltage continues to increase the resistance in the stator finally becomes greater than the limiting value corresponding to the changed constants. At this point the slope of the speed curve becomes infinitely large and the speed increases to the normal load speed near synchronous speed and the resonance current ceases to flow. This corresponds to the observed facts.

For a given terminal voltage, as the shaft load is increased, less power remains available to circulate resonant frequency currents. Thus to check the effect of saturation the circuit was left the same but the shaft load was increased. For the maximum load which still permitted the flow of a small resonant frequency current, the frequency for a voltage of 0.50 p.u. was 0.14. This compares favorably with the above value of 0.12 p.u. frequency at the much lower voltage of 0.34 p.u. Fifty per cent voltage under no load from figure 9 produces a frequency of 0.19.

(b) Changing Rotor Resistance

According to equation 11, the slip for fixed circuit constants is directly proportional to the rotor resistance. Figure 10 was plotted from data obtained for the $7^1/_2$ hp motor. For each point the voltage was decreased to the minimum value for which resonance still persisted so that the magnetizing impedance was as close as possible to the unsaturated value. The data indicates a substantial check with theory. These tests were made with capacitors of 29 ohms and resistors of 44 ohms in the high side of the transformer.

(c) Changing Capacitors

With a 44 ohm resistor in the high side of the transformer the capacitors were changed with the results upon the natural frequency shown in figure 11. Calculations indicated that the frequency should vary approximately as the square root of x_c. These tests verify this relation.

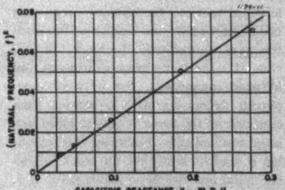

Figure 11. Effect of capacitive reactance upon natural frequency for a particular case

Appendix I. Generalized Angular Velocity of Induction Motor With Series Capacitor

The same general procedure will be followed as that used by Lyon[2] and Rüdenberg.[3] Figure 12 shows the schematic diagram of the induction motor. The symbols are self-explanatory. The instantaneous current, i_s, in the stator is

$$
\begin{aligned}
i_s &= \text{real part } [I_s\epsilon^{mt}] \\
&= \text{real part } [I_s\epsilon^{(\alpha+jf)t}] \qquad \text{(A1)}
\end{aligned}
$$

in which I_s is complex and m is the generalized angular velocity, a quantity whose real component determines the variation in amplitude with time and whose imaginary component determines the angular velocity. In the rotor the current will be designated by

$$i_r = \text{real part } [I_r \epsilon^{(m-jp)t}] \quad \text{(A2)}$$

For the stator the equation can be written

$$(r_s + ml_s)I_s + \frac{1}{mC}I_s + mM(I_s+I_r) = 0 \quad \text{(A3)}$$

and for the rotor

$$[r_r + (m-jp)l_r]I_r + (m-jp)\times M(I_s+I_r) = 0 \quad \text{(A4)}$$

Collecting terms

$$[mCr_s + m^2C(l_s+M)+1]I_s + m^2CMI_r = 0 \quad \text{(A5)}$$

$$(m-jp)MI_s + [r_r + (m-jp)\times(l_r+M)]I_r = 0 \quad \text{(A6)}$$

Solving equations $A3$ and $A4$ for m, there results

$$[(l_s+M)(l_r+M) - M^2]Cm^3 + [r_r(l_s+M) + r_s(l_r+M) - jp\{(l_s+M)(l_r+M) - M^2\}]Cm^2 + [r_r r_s C + (l_r+M) - jpr_sC(l_r+M)]m + [r_r - jp(l_r+M)] = 0 \quad \text{(A7)}$$

Now let ω be equal to 2π times system frequency and

$$l_s = \frac{x_s}{\omega} \quad \text{(A8)}$$

$$l_r = \frac{x_r}{\omega} \quad \text{(A9)}$$

$$M = \frac{x_m}{\omega} \quad \text{(A10)}$$

$$C = \frac{1}{\omega x_c} \quad \text{(A11)}$$

p will be expressed as a fraction of ω. Then Equation $A7$ becomes

$$[(x_s+x_m)(x_r+x_r) - x_m^2]\left(\frac{m}{\omega}\right)^3 + [r_r(x_s+x_m) + r_s(x_r+x_m) - jp\{(x_s+x_m)(x_r+x_m) - x_m^2\}]\times \left(\frac{m}{\omega}\right)^2 + [r_r r_s + (x_r+x_m)x_c - jpr_s(x_r+x_m)]\times \frac{m}{\omega} + [r_r - jp(x_r+x_m)]x_c = 0 \quad \text{(A12)}$$

Figure 5 gives the solution of the significant root of this equation for particular constants as a function of p. The other two roots of this equation are relatively unimportant because their real parts are negative. Letting

$$m = \alpha + jf = \frac{1}{T} + jf \quad \text{(A13)}$$

it can be seen from figure 4 that there are two rotor speeds for which α is zero ($T = \infty$). The natural frequencies, f, corresponding to these two points are the values of f found from a solution of equation 8, and the speeds, p, are the corresponding values calculated from the slip s_1 of equation 9.

Appendix II. Resistance Shunted Capacitor

If the resonant frequency, f, is unity, then considering the diagram from figure 8 the impedance of the resistor, R, and capacitance, x_c, in series with x_s is

$$\frac{Rx_c^2 - jR^2x_c}{R^2+x_c^2} + jx_s$$

Upon paralleling this impedance with jx_m and taking $r_r + jx_r$ in series, there is obtained

$$\frac{jx_m\left\{\frac{Rx_c^2}{R^2+x_c^2} + j\left[x_s - \frac{R^2x_c}{R^2+x_c^2}\right]\right\}}{\frac{Rx_c^2}{R^2+x_c^2} + j\left[x_s + x_m - \frac{R^2x_c}{R^2+x_c^2}\right]} + r_r + jx_r = 0$$

Equating the imaginary component to zero

$$x_m\left\{\left(\frac{Rx_c^2}{R^2+x_c^2}\right)^2 + \left[x_s - \frac{R^2x_c}{R^2+x_c^2}\right]\times\left[x_s + x_m - \frac{R^2x_c}{R^2+x_c^2}\right]\right\} + x_r\left\{\left(\frac{Rx_c^2}{R^2+x_c^2}\right)^2 + \left(x_s + x_m - \frac{R^2x_c}{R^2+x_c^2}\right)^2\right\} = 0 \quad \text{(B1)}$$

This equation reduces to

$$(x_c^2+R^2)\left(\frac{Rx_c}{R^2+x_c^2}\right)^2 - \left[(x_s+x_m) + \left(x_s + \frac{x_rx_m}{x_m+x_r}\right)\right]\frac{R^2x_c}{R^2+x_c^2} + (x_s+x_m)\times\left(x_s + \frac{x_rx_m}{x_m+x_r}\right) = 0 \quad \text{(B2)}$$

Letting

$$x_s + x_m = x_M \quad \text{(B3)}$$

$$x_s + \frac{x_rx_m}{x_m+x_r} = x_B \quad \text{(B4)}$$

then the above equation becomes

$$(x_c^2+R^2)\left[\frac{Rx_c}{R^2+x_c^2}\right]^2 - (x_M+x_B)\frac{R^2x_c}{R^2+x_c^2} + x_Mx_M = 0 \quad \text{(B5)}$$

This can be further reduced to the following

$$\left[1 - \frac{x_M+x_B}{x_c} + \frac{x_Mx_B}{x_c^2}\right]\left(\frac{R}{x_c}\right)^4 + \left[1 - \frac{x_M+x_B}{x_c} + \frac{2x_Mx_B}{x_c^2}\right]\left(\frac{R}{x_c}\right)^2 + \frac{x_Mx_B}{x_c^2} = 0$$

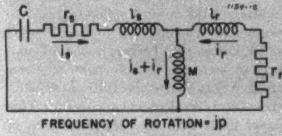

Figure 12. Schematic diagram of induction motor with series capacitor

Upon multiplying all inductive reactances by f and dividing x_c everywhere by f, there results

$$\left[1 - f^2\frac{x_M+x_B}{x_c} + f^4\frac{x_Mx_B}{x_cx_c}\right]\left(\frac{R}{x_c}\right)^4 + \frac{1}{f^2}\times\left[1 - f^2\frac{x_M+x_B}{x_c} + 2f^4\frac{x_M}{x_c}\frac{x_B}{x_c}\right]\left(\frac{R}{x_c}\right)^2 + \frac{x_M}{x_c}\frac{x_B}{x_c} = 0 \quad \text{(B6)}$$

This equation provides the relation from which the results of figure 8 were obtained.

LIGHTNING research is classified here for convenience into three main divisions. First, there are the meteorological and physical processes which give rise to the lightning stroke proper. Second, we have the characteristics of the lightning stroke as these appear at the point of incidence of the stroke to electric lines, to protective systems, and to earth. And third, comes that branch of the art connected with the development of these characteristics over electric circuits and their effects on electrical apparatus. This paper deals with the second division of lightning research. It is essentially a continuation of a previous report[1] and presents the results of investigations carried on particularly through 1937 to 1940.

The first part of the paper covers data and findings which pertain to the long-duration low-current components of lightning. The relative frequency of occurrence of these long-duration components is discussed. From these studies, we find that the electric charge of lightning discharges ranges from a few to 200 coulombs. Higher values are not entirely precluded but they would be rare. The second part of the paper refers to the type of component characteristics for lightning-stroke discharge prevalent to earth and to electric systems (figure 20).

The method of analysis in these investigations consists in comparing the physical effects on objects tested in the laboratory to the field data on similar objects that have been hit by lightning, such as lightning rods, ground wires, conductors of power and communication lines, coaxial cables, metal sheets, and other objects. The degree, nature, and amount of fusion on the metal is determined by ordinary measurements as well as by means of macrographs and micrographs of the objects affected.

Investigations on Long-Duration Lightning Currents

SIXTY-CYCLE FUSION TESTS

In some of the early laboratory investigations because of convenience in testing, sixty-cycle currents were used to correlate the fusion effects of the long-duration components in lightning discharges. The test arrangement and oscillograms typical of these tests are given in figures 1*A* and 2. Table I summarizes the more important data from these tests and figures 3 and 5 illustrate fusion effects obtained on electrode terminals. The amounts of fused metal in the tabulation correspond to a range which is representative of the fusion observed on similar objects that have been hit by lightning. Analysis of these data and of the physical processes involved will indicate that these fusion effects provide a practical and effective method to study lightning-stroke discharges.

Microscopic examinations of the wires and rods at the fused ends were made. As indicated by changes in the original grain structure of the metal, the depth of heat penetration is surprisingly small in every case. For instance, for the copper rod in figure 4, the portion which melted is shown by coarse columnar grains in contrast to the fine equiaxed original grains. The depth of heat penetration amounts to 0.075 inch (1.9 mm.). Micrographs of brass rods show an extremely small heat penetration due probably to the "boiling off" of the fused metal at the tip, the total depth measuring 0.0125 inch (0.33 mm). The wires and rods in this investigation had equiaxed grains, representative of annealed material. Differences in the original grain structure of wires may bring about different results. Even so, the visible depth of heat effects would probably not be much greater than observed here. For example, in a microscopic examination of cold-drawn copper conductors fused by lightning,[2] a depth of heat penetration less than one mm was found.

The physical factors that determine the amount of the metal fused become apparent from a consideration of the energy balance in the fusion process. Table IV presents data illustrating briefly the results of analyses that were made. In general, the energy absorbed from the arc is consumed largely in fusing the metal. This fact is also borne out by the limited penetration of the heat into the body of the metal. Where the conditions are such that the metal being fused does not progress at a rate sufficiently rapid to reabsorb the heat conducted away, then an appreciable proportion of the arc energy input goes simultaneously into conduction. For instance, in sample *K*, the bulk of the arc energy is absorbed in fusing the metal; whereas in sample *A*, a greater proportion is lost in conduction. Of interest, but of secondary importance here, are the radiation, thermal conduction through the gas, i^2R in metal, etc.

On the supply side, the energy developed from the arc is the factor of primary importance. Physicists have long studied the cathode and anode drop at the root of the arc,[3,4,5] but due to the complex phenomena these quantities are still largely a matter of experimental determination in each case and problem. For the practical purposes of this investigation, for a copper arc an energy input at the electrode of six to eight watt-seconds per coulomb appears reasonably substantiated from the good agreement indicated in the energy balance (table IV). About the same relative amount of energy input holds for other common metals as brass, aluminum, and iron. According to some investigators, the amount of fusion can vary with the electrode polarity, while others[6,7] have established by actual measurements about equal distribution for the two polarities. All considered, the results reported in this paper would indicate about equal energy input at the electrode for either polarity. It should be noted also that the shape of the electrode may influence the amount of melting. For instance, if there is an opportunity for the arc terminal to wander about an electrode, the melting may be reduced.

IMPULSE FUSION TESTS

These tests were made with the lightning-stroke generator[1] which is shown schematically in figure 1*B*. The generator can be operated to develop the component parts of the lightning-stroke discharge, either individually or combined.

Paper 41-141, recommended by the AIEE committees on power transmission and distribution and protective devices, and presented at the AIEE Pacific Coast convention, Yellowstone National Park, August 27–29, 1941. Manuscript submitted April 21, 1941; made available for preprinting July 7, 1941.

P. L. BELLASCHI is with Westinghouse Electric and Manufacturing Company, Sharon, Pa.

The author wishes to acknowledge particularly the assistance in securing the test data and material for the paper of the following: M. L. Manning, G. L. Candler, K. C. Kelley, and others of the Sharon high-voltage laboratory; Dr. R. C. Mason and Miss M. Ferguson of the research laboratories, Westinghouse Electric & Manufacturing Company. The author also appreciates the field data made available for these studies, from the following: A. H. Schirmer, Bell Telephone Laboratories, H. L. Hutchins, Electra Protection Company, and S. D. Kretzer, National Lightning Protection Company. Other field data are acknowledged in the references.

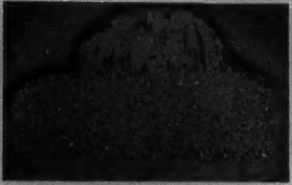

Figure 4. Micrograph of fusion on rod O (20 diameters)

First the results of the tests with the long-duration currents alone are presented. Typical oscillograms of these currents are given in figure 6. In figure 8, we have the discharge of a 2,000 ampere, 0.0023 second duration, unidirectional current between a copper rod and an aluminum plate. Table II summarizes some of the more important data obtained. In addition to the general scope of this investigation, individual samples were tested with the specific purpose of comparing and correlating the fusion effects with identically similar electrode objects hit by lightning.

The two sets of data in tables I and II substantiate each other quite well. It is apparent again that the conduction of heat to the body of the electrode assumes in certain cases some importance. For instance, for the same impulse discharge practically twice the volume of metal is fused from the wire of sample *S*9 than on the sheath of sample *S*7.

As to the probable error of the measurements, the electrical quantities are accurate within about four or five per cent. A greater error naturally is expected in determining the metal fused. This question was looked into from various angles. For example, the metal fused in the six samples, *S*10 to *S*17 in figure 9, was calculated by the usual caliper measurements. In addition to this, each sample was sectionalized and from the micrographs of the sections, the volume of metal fused was determined. The comparison between the two shows an agreement on the average within twenty per cent in spite of the fact that the volume of the metal fused in the last three samples is very small. In general, the probable error in determining the amount of the metal fused is not likely to exceed 20 to 25 per cent for the individual cases. When the data of a group are considered together, the mean error is even much less.

The "burning" effect produced on metals by the high current of lightning strokes is confined to a thin top layer at the surface of the metal. Table III presents typical results on samples that were

tested with currents as shown in figure 7. The duration of the initial high current in lightning discharges is relatively short, not more than 200 microseconds. For such currents, the average current density at the metal surface in contact with the arc is from 300 to 1,000 amperes depending somewhat on the metal and the polarity. Therefore the surface of metals is merely marked or blistered by the high current.[8] Thus for sample *H.S.*, the current density at the surface of the aluminum sheet is 650 amperes per square mm, so the corresponding discharge is 0.08 coulomb per square millimeter. For a drop of eight to ten volts at the root of the arc, the energy input at the surface of the metal then accounts for some 0.003 inch (0.1 mm) depth of metal fused, which is an amount in the order of the value observed. At these high currents, the ohmic losses would also add to the energy input.

Data and Test Results—Their Application

The fusion data in tables I and II for copper have been plotted in figure 13. An average of 2.0 to 2.2 coulombs per cubic mm of copper fused is representative, though for specific cases the amount may be from 2.5 to 1.8 depending on the electrode terminal, volume fused, and similar factors. Similar curves can be established for other metals, either by test or they may be estimated from the properties of the metal.[9] The physical properties would indicate that for the same discharge and identical electrodes, about three times the volume of fused metal is expected for aluminum (pure) than for copper, about the same amount for iron as for copper, and slightly more for brass than for copper. However, the experimental determination is preferred for dependable results. For instance, in sixty-cycle arcing tests on iron electrodes,[10] the amount of metal fused was found one cubic mm per coulomb.

For the best results, the specific value (coulombs per cubic mm of metal fused) to apply in evaluating field data naturally requires comparing the field specimen with a similar laboratory specimen, such as indicated in the tabulations and in the figures. From this correlation and the curves, the fusion method provides effective and practical means for determining the electric charge, the relative current, and the duration of long-duration compo-

(core of current discharge), to estimated depth 0.005 to 0.010". Metal fused approx. 25 to 50 cu. mm. Fused metal in 7/8" cusp form extending from core indicate molten metal was sucked up during discharge and deposited back on sheet. Sheath of discharge blasted out several inches from core

Comments—See footnote to table II. Typical oscillograms given in figure 7. Al sheet is grounded and rod at positive polarity on first half-cycle.

nents, as well as other important characteristics of the lightning-stroke discharge. It is estimated that in most cases the electric charges can be determined to within 20 to 25 per cent of their actual value. For the purpose of this study, where a mass of specific and statistical data are considered, the method enables establishing within a good degree of approximation, the minimum, the average, and the maximum values of the forementioned characteristics of lightning, their probable curve of distribution, and their frequency of occurrence.

Correlation of Field Data and Laboratory Tests

LIGHTNING RODS, WOOD-POLE GROUND WIRES, AND OTHER TERMINALS

The common lightning-rod terminal affords a fruitful source of field data on fusion, for thousands of lightning-rod systems are installed throughout the land and elsewhere. Figure 14 is a set of rod points that have been hit by lightning; these were obtained in Sweden.[11] The ends are of platinum, a metal which requires half the arc energy to fuse as copper.[9] To produce the fusion indicated, we estimate an electric charge in the stroke for each respectively in the order of 2.5, 33, and 100 coulombs.

Substantial field data and experience were kindly made available by the lightning-rod manufacturers for the purpose of this study. In one case, where in the course of time a group of 25 lightning-rod systems were examined, which according to the property owners had been hit, out of the 25 points hit, hardly half were fused. The fusing was about the same as on the samples in figure 15; the electric charge of fusion corresponding to these three samples is estimated at 10, 15, and 25 coulombs. From another source covering extensive field experience, we find that the solid points of copper-bronze terminals usually are not melted down more than approximately one-fourth of an inch. However, greater amounts of fusion have been found on hollow-shell points. As a rule, the hollow-shell point is installed upon the top of an air terminal. Apparently this type of terminal is exposed to the more severe as well as all other lightning discharges. An ample number of cases are on record where these points have been melted down for a distance of one to two inches from the tip. Also many cases are known where the entire point, including the hollow copper tube air terminal, has been crushed and fused into a solid mass. A case of the kind is shown in figure 16. In these instances, the copper fused reaches and even exceeds 100 cubic mm so the electric charge in these severe lightning discharges attains and may exceed 200 coulombs. The crushing effect is clear

evidence of the presence of a severe initial high current.[15]

The following illustrates the case of the more severe strokes encountered to wire terminals. On a 66 kv wood-pole line protected only with wood-pole ground wires, lightning struck the terminal of a ground wire (0.2 inch diameter copper) fusing the tip to the extent shown in figure 17. From it, 75 to 100 cubic mm of fused metal are estimated. The electric charge accounted by the long-duration component of this discharge is estimated in the order of 150 to 200 coulombs. The stroke was severe also from the standpoint of the high current, for it side-flashed from the wood-pole ground wire to the line conductors over six-foot cross arms and seven-unit suspension insulator strings affecting all three phases. From these data and the ground resistance (95 ohms meggered value), the high current is at least 50,000 amperes and possibly higher. The entire data point clearly to a severe lightning discharge.

The copper terminals in figure 18 are of particular interest, for here the current and the duration of the stroke for terminals 3 and 4 have actually been recorded.[12] For terminal 3, the metal fused is estimated at one cubic mm. The wave of the current is reported elsewhere.[13] The total charge is about four coulombs. A 20,000 ampere crest, short-duration initial current precedes the long-duration component, the entire discharge lasting 0.02 second. The charge associated with the low current, long-duration component is 2.5 to 3 coulombs. In the case of terminal 4, the current may be considered essentially a long-duration component for the entire duration of the discharge which is close to 0.10 second.[14] A total charge of 60 coulombs is associated with this stroke. The fusion of the rod tip is estimated at 25 to 30 cubic mm. In each case, the correlation is confirmation of the fusion method, of the sound principles on which the method is based. In the case of terminal 2, a 16,000 ampere crest was recorded on a magnetic link and a

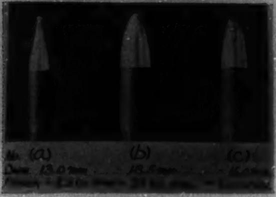

Figure 14. Lightning-rod terminals fused by lightning[11]

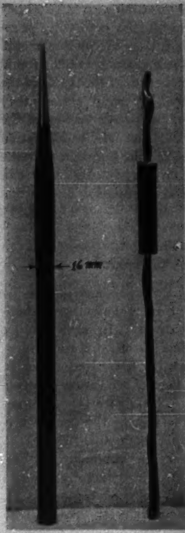

Figure 16. Lightning rod crushed and fused at tip by lightning[23]

Original rod shown

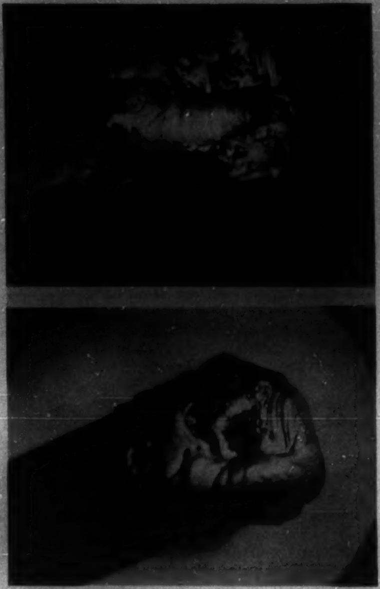

Figure 17. Fusion at end of wood-pole ground wire hit by lightning. Two macrograph views

0.032 inch (0.813 mm) diameter copper link carrying the discharge was fused. From these data the discharge apparently is of the same general form as that for terminal 3, except that judging from the amount of fusion of the rod tip, the long component would be substantially greater.

Conductors on Communication and Power Lines

The experience on open-wire telephone lines is another source of pertinent field data. For 1938, out of 1,435 cases of open-wire toll line troubles attributed to lightning, it is estimated that at least fifty per cent involved the burn-down of one or more conductors from direct strokes. In 1939, there were 1,210 wire troubles attributed to lightning—about half represents wire burn-downs from direct strokes. The average rate of wire troubles per 100 route miles for 1939 is three. The three common sizes of conductors used for toll lines are 0.104 inch (2.74 mm), 0.128 inch (3.38 mm), and 0.165 inch (4.36 mm) diameter copper. In any one instance, the number of conductors parted vary. For example during a storm in a given locality, eight 0.104 inch and two 0.165 inch diameter conductors were affected over a 1.7 mile section of the line; at places the conductors were fused in groups of two or more.

In general, the conductors are fused at a single point. From the fusion effect alone, the tests on samples $S13$ and $S14$ (figure 12) would indicate that a long-duration current of 40 coulombs is required to fuse the smaller conductor (0.104 inch). Actually it is less, for the high short-duration current in the lightning discharge, if sufficiently large, imparts an impact to the conductor over the span (about 50 kg for a 25,000 ampere current) which contributes to rupture the smaller conductors when the section of the wire is partly fused. An example is a three mm (0.12 inch) diameter conductor sundered apart with less than half the section affected by fusion (metal fused five cubic mm).[3] This example and calculations of the impact effect involved indicate that the lighter telephone line

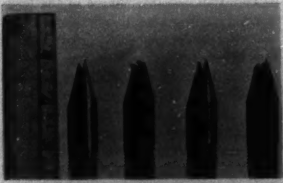

Figure 18. Rod terminals fused by lightning in lightning investigations[14]

Original rod shown

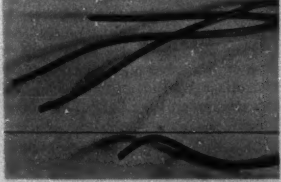

Figure 19. Fusion and sundering of distribution line conductors

conductors may be sundered by lightning discharges from a couple coulombs and up. The fusion of heavier conductors or of conductors in groups is evidence of higher charges. Thus, the field data on open-wire toll lines likewise establish a high frequency of occurrence of the long-duration components in strokes. Estimates of the electric charges from this source range from a few coulombs up into the higher figures.

The larger conductors on power lines rarely are affected; however, in the course of time, a medium-sized conductor would be found burned in two by lightning. In one case a copper conductor about 0.25 inch (0.64 mm) diameter was parted in the span—the evidence bearing the earmarks of fusion from the long-duration current. The charge in this stroke is estimated up in the 100 coulombs. Conductors on distribution lines occasionally are burned apart by lightning. For instance, two 0.128 inch (3.38 mm) diameter copper wires were parted at the point of incidence of the stroke and crushed solidly together over sections of the service span. This and other damage indicate both a severe initial current and a severe sustained current in the stroke discharge. Figure 19 shows a three-strand conductor (each strand 0.108 inch diameter) which was fused and sundered apart by a stroke. From this and other dependable evidence at adjacent electrical apparatus on this distribution line, the charge of the long-duration current of this stroke is estimated at 60 coulombs and greater. This case illustrates furthermore one of many characteristics which distinguishes the long-duration, low currents from the initial, short-duration, high current in the stroke. The latter usually is limited in its effects within a restricted area from the point of incidence of the stroke to the line. On the other hand, the long-duration currents appear to reach out over greater distances of the line—virtually miles in some instances. In the preceding case, the effects of the long-duration currents were clearly in evidence over a five mile section of the line. Similar cases of effects appearing over a large section of the line are on record. The evidence precludes as a general explanation the presence of multiple strokes from a single flash to points over a large section of the line, although simultaneous discharges of this character to the line may occur at times.

Globules and protrusions of fused metal, such as shown in *S*13 of figure 12, which we find on the conductors of communication lines,[16] on overhead ground wires, etc., are other effects associated with the long-duration currents. They are produced by the magnetic force or so-called pinch effect on the molten metal. A number of these globules may be found within a few inches or, as the result of the arc displacement by wind action, they may spread out over 30 to 40 feet of the conductor. They are definite indication of the presence of long-duration currents in the stroke discharge. Also they can give other useful information on the discharge.

Coaxial Cables, Tower Gaps, Metal Sheets, Miscellaneous

At various times coaxial cables at broadcasting stations have been damaged from lightning. In one instance where protection had not been provided, lightning struck the tower and the cable was fused. A view of the fusion effects is shown in item *F.S.* of figure 11. Approximately 30 cubic mm of the copper was melted from the conductor. From the fusion of either the conductor or the sheath, the electric charge estimates about the same—fully 60 coulombs. A separate but lighter fusion spot will be noted; which indicates a second discharge of about ten coulombs. The field and laboratory samples (figure 11) reveal close similarities to each other. However, there are visible indications from the relative blast action on each that the field current must have been of longer duration than the laboratory discharge.

Another group of field data is supplied from tower gaps. These are applied at the footing of transmission-line towers as described elsewhere.[17] Samples of these gaps tested in the laboratory with the long-duration currents appear in figures 5 and 10. The field survey reveals a variety of effects on the gaps, ranging from surface "blistering" to concentrated fusion and combinations of the two. The gaps affected by lightning discharges are located at some 500 towers. Out of the total number affected, five evidenced complete fusing to the extent that some of the metal fused bridged the air gap and has left a filament about 0.12 inch (3.05 mm) diameter frozen across the gap. Comparing the fusion on one of these five field gaps with the laboratory samples, an electric charge well up to 100 coulombs is estimated. Furthermore, from the development of the fusion, the relative blast-action, etc., which appear on the laboratory samples and on the field sample, convincing evidence is present to the effect that the long-duration currents of the lightning discharge in nature must have lasted well up to one second and possibly even longer.

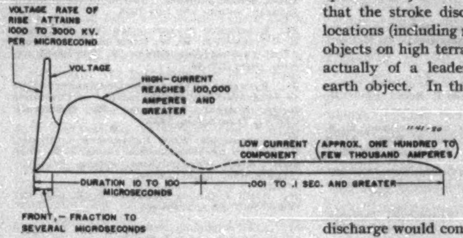
Other field data on metal objects may be mentioned briefly. For instance, from a report on atmospheric discharges to aircraft in flight,[18] evidence of fusion is presented. In a similar survey, out of sixteen cases in nearly half there is substantial evidence of the long-duration currents present in the discharge. In at least three, the charges which are required to account for the fusion are estimated well up in the order of 100 to 200 coulombs. All these discharges are likely to have been between clouds and may have been initiated by the moving plane itself.[19] There is also a mass of miscellaneous data, but much of this requires confirmation and should be used with considerable caution. One source[20] mentions the possibility of one to two thousand cubic mm of fused metal where the discharge enters the metal. While this amount of fusion is intended to relate only to the most severe strokes, even then it should be questioned and corroborated by specific instances before it can be accepted. Terminals on highly elevated objects[21] may indicate profuse fusion, but this would result because these objects frequently receive strokes, some of which must no doubt be quite severe. Other effects of interest associated with the long-duration currents in lightning discharges are the firing of combustible materials, fusion of sand into fulgurites, etc. These have been discussed in the previous report.[1]

Characteristics of Lightning-Stroke Discharge

At this point it is desirable to examine the type of lightning discharge prevalent to electric systems and to earth. Figure 20 shows in schematic form the pattern of the discharge. In this figure are presented the conclusions based on correlation studies of the lightning problem that have extended over a period of years.[1,23] From a recent survey in this same connection, other investigators[24] have come essentially to the same conclusions.

In the first place, the characteristics outlined schematically in the figure conform with the mechanism of the lightning-stroke discharge from cloud to earth.[25,26] The high-current component is associated with the main stroke which blazes its way up the channel upon the instant of contact of the tip of the leader stroke with the earth. The duration of the main stroke is from 10 to 100 microseconds. It determines in a large measure the duration of the high-current component. The low-current long-duration components are related to the discharge processes that follow the main stroke. The source of these components apparently resides largely in the cloud and they are due to a continuation of the lightning discharge in the cloud proper.[27,28] The lightning flash may well be a multiple stroke in which case there is a series of such component groups as indicated in the figure. It should not be construed from the schematic representation that the three components are necessarily uniform and of simple form. Under certain conditions, some may even be reduced and others intensified.

Likewise, the pattern of these characteristics conform with the data from the various field investigations as well as the mass of experience from electrical systems. In general, the high-current component is the one which is better established of the three. It is more or less exponential with possible variations from this form, rising to crest in some 2 to 10 microseconds and receding more slowly on the tail.[29,30] The time required for the current of the main stroke to flow from its source in the charge on the earth into the channel, precludes front durations of the high current component below a certain limit. These considerations and field data[31,32] indicate that the maximum current rate of rise on the front seldom, if ever, attains 50,000 amperes per microsecond, while the average is more in the order of 5,000 amperes per microsecond. The amplitudes of the current and the frequency of occurrence are quite well established.[33,34,35] They range from 5,000 to 200,000 amperes. Currents of 200,000 amperes or more are rare.[15] Actual direct measurements of the voltage component at or near the point of incidence of the stroke to the line likewise are few.[36,37] In this connection, the extensive experience on the performance of electrical apparatus to direct strokes affords a source of important information.[38,39] More data on the wave form of these two components are desirable to better establish the essential details on lightning-stroke discharges. However, it is apparent that the mass of the established data and experience available on lightning phenomena sustain the deductions presented in figure 20 as to the pattern of the characteristics of lightning discharges to objects near to the surface of the earth.



VOLTAGE RATE OF RISE ATTAINS 1000 TO 3000 KV. PER MICROSECOND

DURATION 10 TO 100 MICROSECONDS
.001 TO .1 SEC. AND GREATER
FRONT,— FRACTION TO SEVERAL MICROSECONDS

Figure 20. Schematic representation of lightning-stroke discharge

In regard to the long-duration components, it is only in the recent three or four years that this constituent part of the lightning discharge has received particular attention.[39,40,23,12] It should be pointed out that in this group of investigations, those in which the lightning-stroke phenomena are recorded at the terminal of very high structures, while they no doubt will contribute to the knowledge on lightning, yet the results from them need be interpreted carefully before these can be applied to electric systems and to protection systems located near the surface of the earth. For instance, in the greater part of the cases of strokes to the Empire State Building, the leader is from the structure up into the clouds, a process which is the reverse of the lightning-stroke process from cloud to ground in open country. There is the possibility that the stroke discharge from elevated locations (including mountain tops, ridges, objects on high terrain, etc.) may consist actually of a leader initiated from the earth object. In these special cases, the discharge would consist initially of a low-current, long-duration component possibly followed later by high current spurts as the leader reaches into and taps the cloud.

The following are examples drawn from the paper which illustrate the characteristic components in the lightning discharge. In the case of the stroke to the wood-pole ground wire discussed in connection with figure 17, the high-voltage, the high-current, and the low-current components are clearly in evidence. The crushing of the lightning-rod tubes and the fusion at the terminals, such as in figure 16, present evidence of severe multiple strokes consisting of high currents accompanied by long-duration components. The case of two service conductors crushed solidly together over sections of the span and parted at the point where the stroke entered the conductors is another similar example. As discussed in the paper, the fusion and the sundering of conductors on communication lines result from the combined effect of the two components of the current. The shattering of line and station apparatus as well as other objects in which the concurrence of fusion of metallic parts can only be ascribed to the low-current component is further indication of the presence of the two components in the lightning discharge. The crash of thunder followed by a sustained arc combined with a flicker of the flash are evidence of a multiple stroke with all the components shown in figure 20.

The presence in the lightning discharge of the two components simultaneously can be distinguished quite readily from a number of distinguishing features inherent with one which are absent in the other, with overlapping in part for some of the effects. As discussed at length previously, the earmarks indicating the presence of long-duration currents is found principally in the fusion effect produced at the surface of the conductor where the metal is in contact with the arc of the stroke. In the case of the high-current components, their presence is evidenced by shattering, crushing, bursting, and similar effects as well as "blistering" at the surface of metal, the fusion of conductors through ohmic loss, the development of high voltages, etc. For instance, a thin-wall, hollow tube was set up for test. A moderate high-current discharge would readily crumble the tube, whereas even a heavy long-duration discharge would leave the tube completely intact.

In regard to the electric charge associated with long-duration currents, the fusion data in this investigation are of particular interest and significance. If to this component charge the generally smaller amount associated with the high current is added, we have the total charge of the stroke. In summary, from the combined fusion data, the total charge for strokes to ground is found to range from a few coulombs and possibly less up to 200 coulombs. There is evidence from the high volume of fusion in limited cases that the electric charge of unusually severe and rare strokes may reach 200 to 300 coulombs. A few isolated and unconfirmed cases would suggest even higher values, but in the opinion of the writer, these must be dismissed until future confirmation becomes available. The statistical data in the paper indicate that practically all strokes to earth have long-duration currents of greater or lesser amounts associated with each. From the mass of the data, the mean value of the charge is estimated between 15 to 30 coulombs. That is 50 per cent of the strokes exceed this amount. In a previous estimate determined from a limited amount of data, a somewhat higher average was suggested between 25 to 50 coulombs.

Close similarity is generally found between the fusion of the test samples and that on the specimens from the field. However, in one respect the nature of the fusion on field specimens would point to longer sustained duration and correspondingly lower currents in the field than for the currents used in the laboratory tests. In some of the field specimens, the smooth appearance of the fusion and other evidence connected thereto are indicative of a relatively gradual development of the fusion which in turn suggests current discharges in the field estimated in effect well up to one second. In general, the effective currents and corresponding durations of the long-duration components cover a range as shown in figure 20.

For purpose of general comparison, the following investigations may be cited. In a recent investigation in New Mexico[41,42] the electric charge from cloud to ground was determined from electric field recorders located at the surface of the earth at widely separated stations. Out of more than 200 discharges occurring during thunderstorms, all of the cloud ground strokes measured have transferred negative charge from cloud to ground the quantity of charge ranging from 5 to 200 coulombs with an average of 30. In the Empire State Building investigation,[40] out of 27 strokes the charge of the stroke discharges ranges from a fraction to 164 coulombs, the data indicating an expectancy of 35 coulombs or more on 50 per cent of the cases. Amounts of charge within these limits are found from the field investigation at the Cathedral of Learning and elsewhere.[13,14] We should note again that on account of the inverted mechanism of the lightning discharge on highly elevated structures, the data from these sources may not be altogether comparable to the data for strokes from cloud to earth which normally represent more nearly the conditions encountered in practice. In spite of all considerations on the methods of measurement, the source of the four groups of data, etc., similarity in the results can hardly be considered coincidental.

An Analysis of Transient and Sustained Voltages in Ground-Fault Neutralizer Systems

Introduction

THE first ground-fault neutralizer (Petersen coil) in the United States was installed on the Alabama Power Company system in 1921. The technical press at that time devoted considerable attention to the substantial improvement in service continuity which was obtained with the neutralizer, and also described the overvoltages which occurred on the system during switching operations.[1] Since this first application, more than fifty ground-fault neutralizers have been installed on systems in the United States in all voltage classes from 22 kv to 230 kv. Considering the total number of neutralizer-years of successful operating experience that have now been accumulated, it can therefore be stated that the ground-fault neutralizer has definitely proved its value as a service protective device, and that practical means have been found to eliminate the overvoltage troubles encountered in the first application. The very favorable operating record obtained to date indicates that ground-fault neutralizers may be expected to find increasingly widespread application in the future.[2,3,4,5]

The question of overvoltages, however, is still raised from time to time with reference to prospective applications of ground-fault neutralizers, presumably because of the attention which the overvoltage problem has received in the past,[6,7,8,9,10] and it is felt that an analysis of the possible causes of and the means used to control overvoltages is in order. It is the specific purpose of this paper, therefore, to present data to indicate possible sources of overvoltages in ground-fault neutralizer systems, to point out the factors affecting the voltage magnitudes, and to show how the overvoltages are limited by present design and application practices.

It is to be noted that a major change in ground-fault neutralizer design occurred after the first application. The first neutralizer was a non-saturable air core reactor. Its reactance remained substantially constant, regardless of the voltage existing between its terminals. All subsequent neutralizers, however, have iron cores, carefully designed to saturate on the occurrence of voltages exceeding normal line-to-neutral voltage of the systems to which they are applied. This characteristic plays an essential part in limiting voltages of the series resonant type to harmless values. Furthermore, all ground-fault neutralizers, except the first one, include Thyrite by-pass arresters connected between their high voltage terminal and ground to limit the magnitude of any abnormal voltages that might appear at the system neutral.

In this analysis particular emphasis is placed on the condition of "series resonance." This condition was long considered to be, although erroneously, a dangerous source of overvoltage. In modern installations, however, it is realized that voltages of the series resonant type, if system conditions permit them to occur at all, are limited by the saturation of the neutralizer iron cores and by the lightning arresters mounted integral with the neutralizers. The quantitative effects of neutralizer saturation and the part played by lightning arresters in limiting overvoltages are illustrated. Out-of-phase switching conditions are also analyzed; and the advantages of short interrupting time in circuit breakers are pointed out.

In most of the previous work of analyzing system performance, the effects of saturation and of lightning arresters have been omitted, since to include them with their non-linear characteristics would be practically impossible by means of longhand calculation. It has been found that the miniature system representation method of attack used in this analysis is eminently suited for including these factors, and thereby readily facilitates the acquisition of much new knowledge concerning power system performance and the part played by protective equipment.

What Produces Series Resonant Overvoltages

In a three-phase system the method of grounding (whether grounded solidly, through resistance or reactance, including the ground-fault neutralizer, or not grounded) has no effect on the normal steady-state flow of balanced three-phase power. Under unbalanced or transient conditions, however, the method of grounding is an important factor in determining the behavior of the system. The condition which permits series resonant overvoltages in a ground-fault neutralizer system occurs only when one or two conductors of a three-phase system become open circuited; when all three phases are intact no series resonant overvoltages can occur.

With an opening in either one or two of the phases in a ground-fault neutralizer system, a flow of current tends to persist between the two parts of the system located on either side of the break, by taking a path from the system to ground through the neutralizer, in parallel with the line-to-ground capacitance on one side of the break, and from ground back into the system by way of the line-to-ground capacitance on the other side of the break. The opening in the circuit, in effect, places the ground-fault neutralizer inductive reactance in series with the system capacitive reactance, and since this constitutes a tuned circuit, the net impedance to the flow of current is very small. If the tuned condition is allowed to exist for all values of load and fault current, overvoltages may occur. With respect to this possibility several practical factors may be evident:

1. The larger the current previously flowing in the one or two opened conductors, the higher will be the resulting voltages. A line-to-line short circuit on the load side of the open point would be an extreme example of this condition.
2. Opening one or two conductors on a line carrying only charging current is not expected to cause serious overstress of the system insulation, particularly if the line is short relative to the extent of the system. However, the unbalance produced by such an opening will cause a sustained current to flow through the neutralizer. This must be taken into consideration in the neutralizer design and application.

Figures 1 and 2 are presented for the benefit of those who are familiar with the

use of symmetrical components. It has been shown previously[11] that the case of one open conductor may be represented diagrammatically by inserting the negative and zero sequence network diagrams, in parallel, into the open point of the positive sequence network, as shown in figure 1. The effect of the negative sequence network is negligible, since it is effectively "short circuited" by the low impedance series resonant circuit of the zero sequence network. The case of two open conductors has likewise previously been shown[11] to be represented as shown in figure 2. Here the negative and zero sequence networks, in series, are inserted in the opening in the positive sequence network. The presence of the negative sequence network, in this case being in series between the load and the zero sequence network, tends to reduce the magnitude of current that can flow, and to this extent tends to reduce the overvoltages that may occur. However, if saturation in the ground-fault neutralizer has occurred, its beneficial role in destroying resonance may be partially offset by the presence of the additional unsaturated negative sequence reactance in series with it. From figures 1 and 2 it will be apparent that in a single neutralizer system the mechanism which may give rise to overvoltages is independent of the location of the open point except in case the opening is at the terminals of a load transformer.

How Series Resonant Overvoltages Are Limited

Fortunately, series resonant overvoltages can readily be limited. Since they result from a tuned circuit, it follows that any means which are effective in detuning the circuit will necessarily reduce the magnitudes of the overvoltages. This detuning is successfully accomplished by building the ground-fault neutralizer with iron cores which are carefully designed to saturate when the voltage across them exceeds the normal system line-to-neutral voltage. The effect of the neutralizer saturation is, of course, to reduce the neutralizer inductive reactance, and the change in reactance effectively detunes the circuit.

During all the time that ground-fault neutralizers have been applied, it has in general been recognized that an open conductor in either one or two phases of the system could create the condition of series resonance. One of the application rules, therefore, has been that no ground-fault neutralizer system may include line sectionalizing fuses or sectionalizing switches which are not gang-operated.

A broken conductor may, of course, set up the condition for series resonance. However, if a conductor breaks, it will usually fall to earth, thus grounding one side of the opening and destroying the condition of resonance. Broken conductors have occurred on ground-fault neutralizer systems without producing dangerously high voltages. This condition almost invariably increases the neutralizer current sufficiently to cause the by-pass switch[13] to close, thereby solidly grounding the system neutral. Up to this point, the performance is the same as if a sustained line-to-ground fault had occurred on the system. However, when the by-pass switch closes, but no circuit breaker operation follows, the experienced system operator recognizes that an open conductor has occurred, and efforts are made to locate and repair it.

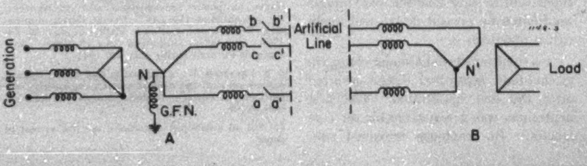
Results of the Miniature System Study of Series Resonance

As a typical illustration of a series resonant condition, the system shown in figure 3 was studied by means of the miniature system method of analysis. In this figure, the ohmic values of source reactances are purposely omitted because the results are essentially unaltered by these values as long as the ohmic impedance of the neutralizer is large by comparison. Therefore, the results of this study apply not only to one specific system operating at a given voltage, but apply in general to all ground-fault neutralizer systems conforming to the circuit arrangement shown in figure 3.

Since the description of the basic equipment and general procedure used in investigations of this type have been disclosed elsewhere in the literature,[7,8,10,12] it will not be repeated here. The miniature representation of ground-fault neutralizers and by-pass or conventional lightning arresters, however, is believed to be unique to this study, and a few words concerning these devices appear desirable.

The miniature ground-fault neutralizers were built for operation at 110 volts rms. They were constructed so as to have saturation characteristics and losses closely approximating those of a large neutralizer as shown in figure 4. For flexibility in tuning and adjusting to a

Figure 3. System used as a basis for study



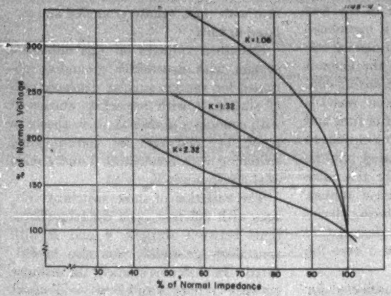


Figure 4. Typical ground-fault-neutralizer saturation curves

K is the ratio of impedance at 100 per cent of normal voltage to the impedance at 200 per cent voltage. Values of *K* in most modern neutralizers lie between 1.06 and 2.32, depending upon the type of neutralizer and the tap setting

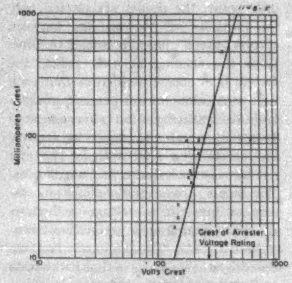

Figure 5. Comparison of miniature system and full size arrester volt-ampere characteristics

——— 240-kv (20-unit) arrester reduced to 190-volt base which was the normal line-to-line voltage in the miniature system

× Test points from oscillograms of instantaneous voltage across the miniature arrester and current passing through the arrester

Note: For representing arresters of different voltage ratings in the miniature system, it was necessary to reduce their volt-ampere characteristic to the 190-volt base and then put in the number of miniature discs to duplicate this characteristic in the miniature system

variety of system sizes, the miniature models were equipped with a total of 25 taps. At 110 volts, the effective impedance of these units covers a range of values of from 1,750 ohms on tap 25 to 460 ohms on tap 1, all at 60 cycles.

The miniature lightning arresters were Thyrite discs or wafers, about one inch in diameter and $^1/_8$" thick. Several of these could be stacked together as desired to obtain a voltampere characteristic duplicating to scale that of a full size arrester as shown in figure 5. The homogeneity and electrically stable characteristics of Thyrite material even in such relatively small pieces permitted this miniature representation.

A means for duplicating the spark-over of an arrester gap is illustrated in figure 6. Use of this device was helpful in determining the effect of an arrester sparking over during transient conditions. By adjusting the grid bias voltage, the spark-over voltage could be controlled as desired. The energy dissipated in an arrester following spark-over could be determined from the oscillograms of voltage and current during the transient period. This energy might be considered a measure of the severity of overvoltage disturbances from the standpoint of duty imposed upon protective equipment.

The first study was to show the effect of the degree of saturation in the neutralizer core. To distinguish between degrees of saturation, a factor *K* was introduced. It is defined as the ratio of the neutralizer effective impedance at normal voltage to impedance at two times normal voltage. The larger the value of *K*, the higher the degree of saturation in the neutralizer.

A curve showing the relationship between overvoltages and the factor *K* for phase *A* opened at the generating end of the system described in figure 3 is shown in figure 7. Similar data are given for phases *B* and *C* open on figure 8. In these and subsequent figures and tables the subscripts indicate the points between which the voltages were measured. In case only one subscript appears, the voltage was measured to ground. These two curve sheets show that neutralizer saturation is an important factor in limiting the magnitude of voltages caused by series resonance.

The second study was to show how the overvoltages vary with the physical location of the break in the system, and was made with a saturable core neutralizer having a *K* factor of 2.2. Crest values of voltage as a function of the location of open phase *A* in the system for no load conditions is shown on figure 9. Similar data for phases *B* and *C* open are given on figure 10. This study was repeated with the system loaded, and the results are given on figures 11 and 12.

These results indicate that in a given typical system, the highest overvoltages are obtained when all of the capacitance is on the load side of the open conductor or conductors. The overvoltages decrease in magnitude as the break position occurs nearer the load. In a typical network system consisting of many lines, only a small percentage of the total system capacitance could be on the load side of an open conductor, and therefore the overvoltages would be limited.

It is to be pointed out that the series resonant overvoltages shown in these studies are hardly high enough in magnitude to spark over a lightning arrester. Furthermore, the voltages build up gradually requiring 4 to 5 cycles to reach their maximum values, so that they are very unlikely to occur while switching off a line by means of an oil circuit breaker.

After this general study was made, an attempt was made to reproduce the overvoltage conditions obtained in the first neutralizer application. As mentioned before, this neutralizer was a non-saturable core reactor. To reduce the amount of current flowing through it during conditions of normal operation, it was adjusted so as to be slightly out of tune and on a tap such that the charging current in the fault was undercompensated, that is, the neutralizer had a greater reactance than that required for precise tuning. Overvoltages were obtained during oil circuit breaker operations on this installation of sufficient magnitude to flash over the bus insulators.

For the miniature system selected for this study, the non-saturable core neutralizer was in tune with the system at 818 ohms. The voltage across the neutralizer, which is a direct measure of the voltage on the system, for phase *A* open at the source end of the system with a neutralizer in tune, is shown in figure 13, oscillogram 80-2. The voltage across the neutralizer for the same conditions but with a reactance of 854 ohms is shown in oscillogram 80-5, and for 935 ohms is shown in oscillogram 80-6. It is seen from these oscillograms that detuning the non-saturable core reactor in this manner gave rise to very high series resonant overvoltages. The same conditions were set up using a miniature system saturable core neutralizer (set on tap #9) and the voltage across the neutralizer is shown in oscillogram 80-7. The effectiveness of saturation in limiting series resonant overvoltages is at once apparent.

Out-of-Phase Switching

In the miniature system investigation of out-of-phase switching, the system of figure 3 was used with the load at *B* replaced by a source of generation which could be varied in phase position with respect to the source of generation at *A*. The overvoltages were recorded with the system neutrals at *A* and *B* grounded through ground-fault neutralizers, and also with them solidly grounded and isolated in turn.

Sustained voltages on this miniature system with neutralizer grounding obtained for various angular displacements of station *A* with respect to station *B* with conductor *a* open at *A* are shown in figure 14. Voltages for corresponding switching with conductors *b* and *c* open at *A* are shown in figure 15.

The variation of these switching voltages with different open conductor locations between stations *A* and *B* with neutralizer grounding was also investigated. In the cases studied, the distance between stations *A* and *B* was equivalent to 100 miles, although because of the symmetry existing on both sides of the 50 mile point, the results are plotted only for locations of the opening between station *A* and the midpoint of the line. With the opening at this point, the system is of course divided so that each part constitutes an independent ground-fault neutralizer system. For one conductor open refer to figure 16, for two conductors open refer to figure 17.

These curves indicate that angular displacements between two portions of a system can give rise to voltages as high as 3.5 times normal on a ground-fault neutralizer system. The significant fact disclosed by these curves is that if the open conductor location is such that on either side of the break there is a tuned system, no overvoltages of any consequence are obtained for even the worst condition of 180 degrees out-of-phase switching, except across the contacts of the breaker itself, which is to be expected regardless of the method of system grounding.

The significance of this portion of the study has no background of definite field

experience, since there have been no clear indications that out-of-phase switching on ground-fault neutralizer systems has given rise to troublesome overvoltages. In order to make comparisons of the severity of these overvoltages on ground-fault neutralizer systems with systems using other methods of neutral grounding, the miniature system study was extended to include data for the same system with neutrals grounded solidly and later, ungrounded. The relative severity of out-of-phase switching in solidly grounded, isolated, and ground-fault neutralizer systems is shown in table I.

The results of this miniature system study show that out-of-phase switching in any system regardless of the method of connecting the neutral to ground may present severe breaker interrupting duty requirements. It is probable, however, that the worst conditions of out-of-phase switching as outlined here are seldom realized in practice.

IDEALIZED BREAKER OPERATION

The effect of arcing time in clearing a circuit under out-of-phase switching conditions is illustrated by the results in table II. In obtaining these results, a three-phase synchronous switch was used which interrupted all three phases of the circuit at adjacent current zeros without restriking—an ideal circuit interruption. Arcing time may be of importance since it determines the maximum possible interval of time between the opening of the first phase and the opening of the last phase. In particular, it is believed to be important when recovery voltages differ in severity for the first and last phases to clear. While short arcing time offers a distinct advantage in any system, this advantage is most apparent in the ground-fault neutralizer system, because it prevents occurrence of any voltages of the series resonant type which otherwise might arise from this cause. This follows from the previously mentioned fact that such voltages take several cycles to build up to their full magnitude.

Effect of Lightning Arresters

The lightning arrester consists of two component parts, a gap element and a valve element. For surge voltages below the gap breakdown voltage, the system response to these voltages is as though the arresters were not connected to the system. For surge voltages of sufficient magnitude to cause the gap to become conducting, the transient overvoltages are limited to the *IR* drop through the arrester valve element. It is through this valve element that the energy of the surge is dissipated.

Arresters of the ungrounded neutral class are used on the isolated neutral, and the ground-fault neutralizer system. The minimum gap breakdown of this arrester is approximately 2.6 times the normal line-to-neutral crest voltage for the relatively slow transient switching voltages studied. The frequency of these voltages is for the most part less than ten times normal frequency. Arresters placed in the system neutrals to by-pass the neutralizers have a maximum permissible line-to-ground voltage rating equal to at least the system line-to-neutral voltage, and have a minimum gap breakdown voltage equal to approximately 1.5 times the line-to-neutral crest voltage.

The ability of neutralizer by-pass arresters to limit overvoltages is indicated in table III. This table lists three cases of overvoltages caused by 180° out-of-phase switching in ground-fault neutralizer systems. Case I lists the overvoltages obtained without any arresters on the system. The next case shows how these voltages were reduced at station *B* by a single arrester connected from the system neutral to ground by-passing the neutralizer. The third case shows how the overvoltages at both stations were reduced when each neutralizer was equipped with a by-pass arrester.

From this table it is clear that such by-

pass arresters are very effective in reducing series resonant overvoltages even under the worst out-of-phase switching conditions.

An inspection of the results in table IV reveals some significant facts regarding the same phenomena in isolated neutral systems. These cases serve to illustrate the fact that while voltages of the series resonant type are not present in isolated neutral systems (note that voltages are lower for case V than for case I), the reduction of voltage obtained in case V when a conventional line type arrester sparks over (case VI) is relatively slight (from 2.0 to 1.5 at the arrester location). A comparison of the voltages shown for cases I and IV shows that the voltage at the arrester location was reduced from 3.2 to 1.3. In other words, after spark-over, the voltage across the arrester tends to be greater in the isolated neutral system than in the same system equipped with neutralizers. This emphasizes one important characteristic of series resonant voltages, namely, that they are inherently of very poor regulation. That is, as soon as any resistance path for current to flow to ground is introduced at the point of highest voltage (e.g., an arrester), the voltage collapses quickly at this point to a value below the arrester rating. It possibly also explains in part the fact that arrester troubles on some ground-fault neutralizer systems have been observed to be greatly reduced over what they were when the system was operated with neutrals isolated.

These results indicate also that in systems operating with only partial arrester protection, e.g., arresters at only one end of the line, there is a tendency to "shift" the overvoltages from the protected area to the unprotected area. That is, after an arrester gap has sparked over, voltages are reduced in the vicinity of that arrester, but may become higher in remote portions of the system than they were before the arrester gap broke down. This is another good reason for applying arresters to all apparatus on a system. From an inspection of the results in table V, it is apparent that arresters are more effective in lower voltage systems than in higher voltage systems as far as reducing overvoltages of the type described here is concerned. (Compare values of V_a at B, the voltage across the arrester, for the three cases in table V.) This is explained by the fact that an arrester will pass approximately the same follow current at rated voltage regardless of the arrester rating. Series resonant overvoltages are intimately associated with transmission line constants which are relatively independ-

ent of voltage. Therefore, the effective impedance of an arrester is lower in a low voltage system, and the arrester is thus more effective in reducing such overvoltages. It is important to note that voltages across the valve element are always low after an arrester has sparked over, and therefore regardless of system voltage, the arrester gap spark-over voltage is the factor limiting instantaneous overvoltage magnitude.

In interpreting the results of tables III, IV, and V, it is important to bear in mind the fact that the extremely severe condition of 180° out-of-phase switching has been considered. Furthermore, a relatively low neutralizer saturation factor ($K=1.08$) was used. As a general conclusion following these and numerous other similar tests, it may be said that in most practical open-conductor cases an arrester will not be required to function. If, in extreme cases, such as these under discussion, it should be required to function as a result of overvoltages reaching the gap spark-over value, it is apparent that such overvoltages are immediately and effectively reduced to harmless values.

Since it is evident that series resonant voltages of the type under discussion, if produced at all, must be in evidence at the system neutral (i.e., across a neutralizer) an arrester selected on the basis of system normal line-to-neutral voltage plus whatever factor is deemed necessary to avoid the possibility of overstressing the arresters during a single line-to-ground fault condition, should afford excellent protection against the most severe overvoltages of this type. Such an arrangement in no way affects the normal operation of the neutralizer. Every ground-fault neutralizer in this country, except the first one, has been equipped with a shunting by-pass arrester mounted on the neutralizer tank and it undoubtedly has been a contributing factor to the absence of any series resonant overvoltages in subsequent neutralizer installations.

Switching Off Neutralizers

When a system is to be equipped with more than one neutralizer, it is desirable that the neutralizers be located in the system so that they, and the system sections to which they are tuned, can be switched as units. It is recognized that some switching operations will inevitably detune the neutralizers. Staged tests on ground-fault neutralizer equipped systems have demonstrated that successful arc extinction may be obtained even if the system capacitance is as much as 25% overcompensated and 10% undercompensated.

The undercompensated condition, that is, when the neutralizer impedance is greater than that required for exact tuning, results in making the system line-to-ground impedance capacitive rather than inductive. This is an approach to the condition of isolated neutral operation. If a ground fault should occur under these

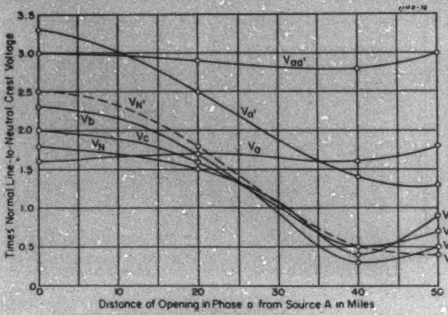

Figure 16. Effect of open conductor location on sustained overvoltages under out-of-phase conditions

conditions, overvoltages approaching in magnitude those which would be encountered if the system neutral were isolated may occur. These overvoltages can be abnormally high, particularly if the system is large in extent and a large share of the generation is lost during such switching operation.[10] Furthermore, in the event of an open conductor, saturation of the excessive neutralizer reactance, instead of detuning the system would actually tend to bring the system closer to a resonant condition.

It has long been recognized by operating companies using neutralizers that to obtain the full benefit of the neutralizer protection, continued operation in the detuned condition is to be avoided, because in addition to the overvoltages encountered in the above-mentioned undercompensated condition, the arc may not be extinguished. Diligence in always keeping the neutralizers correctly tuned to the connected system capacitance reduces the chances to the minimum that dangerous overvoltages will be encountered, and insures that the maximum benefits in service continuity will be realized. The latest design of neutralizers has a motor mechanism for changing the taps remotely which is an aid in keeping the neutralizers in tune.

Effect of Bus Capacitance

On typical systems there would usually be several lines radiating from a bus. Switching off any one of these lines would not be expected to cause overvoltages of any consequence on the system side of switch. This is because the system capacitance to which a neutralizer is tuned is generally large relative to that of a single line.

Under some conditions, however, a system may have only one line radiating from a bus which is at the main source of generation and is, furthermore, the location of the neutralizer. The system of figure 3 represents this condition. In the case of the fault being cleared on such a line, the circuit would look like that in figure 18 for the last phase to clear, assuming the faulted phase clears last. Under such conditions certain values of circuit constants may give rise to overvoltages provided the interrupting device has characteristics which permit restriking and reclearing of the arc to occur in a certain sequence. Such phenomena have been investigated and reported for a wide range of circuit constants, and criteria have been presented for eliminating these overvoltages.[8,9]

A curve of overvoltages which may be obtained under such conditions is shown in figure 19. In this case the ground-fault neutralizer was tuned to approximately 90 miles of line. Generation was such that the ratio of zero sequence to positive sequence reactance in the source was 30. The capacitance connected to the bus was varied. It is of particular interest to note that for the last line being switched off a bus, the transformer winding capacitance to ground is of the right order of magnitude to give rise to this phenomenon.

While it is not necessarily true that all circuit interrupters will give rise to a restriking sequence, the fact that the constants may be such as to render this circuit susceptible to these phenomena suggest that in switching the last line from a bus, protective equipment may be called into operation.

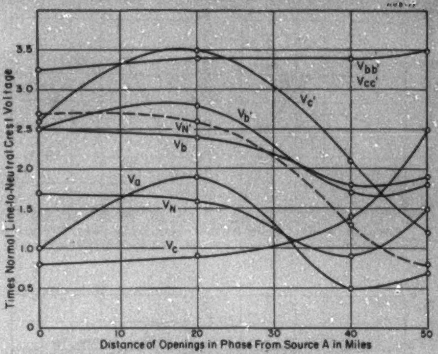

Figure 17. Effect of open conductor location on sustained overvoltages under out-of-phase conditions

System as in figure 3, but neutralizers at both *A* and *B* and load at *B* replaced by a source of generation. No load on system
Phases *b* and *c* open
$K=1.08$ at both *A* and *B*
Sources *A* and *B* 180° out of phase

An illustration of this phenomenon giving rise to arrester spark-over is shown in figure 20. For this case, the bus capacitance was equivalent to that of approximately one mile of overhead line. The arrester gap in phase *A* was set to spark over at about 1.5 times the crest arrester rating. The oscillograms in figure 20 show the gap spark-over and subsequent discharge to ground and arrester discharge voltage.

A detailed analysis of these oscillograms and others of a similar nature indicate that a conventional arrester is very effective in limiting the magnitude of the overvoltages of this type as well as others previously mentioned. Either the conventional line-type arrester or an arrester with a line-to-ground voltage rating connected across each neutralizer should give good protection and experience is substantiating this contention.

It is to be noted that the energy to be dissipated in this type of overvoltage is relatively small for circuit constants likely to give rise to this phenomenon in ground-fault neutralizer systems. Furthermore, the overvoltages are relatively short in time duration with the result that the arrester duty is comparatively light.

Other Factors

The size of system (length of line) is relatively unimportant from the standpoint of possible overvoltages. Line losses, at least up to the point where the

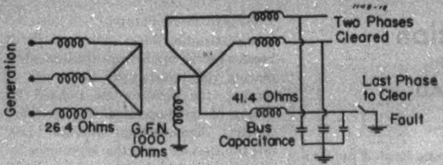

Figure 18. Equivalent circuit for last phase to clear a fault near a bus when no other lines are connected to that bus

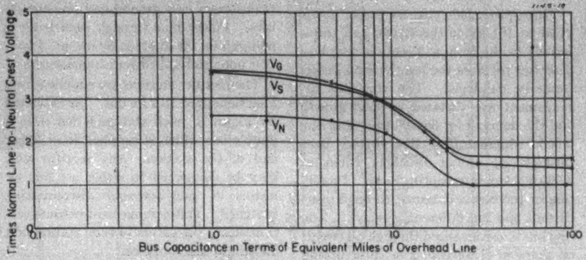

Figure 19. Maximum transient voltages which may be obtained as a result of restriking in the switch for the system shown in figure 18

V_S—Maximum voltage across switch
V_G—Maximum voltage from phase to ground
V_N—Maximum voltage at the neutral

line resistance is equal to the line reactance are also only of minor importance.

Source reactances (positive and negative sequence) have only minor effects on the general phenomenon. This is to be expected because it is mainly the zero sequence circuit that is affected, and practically all of the zero sequence reactance is in the neutral or neutrals.

Waterwheel overspeeding increases the frequency and in ground-fault neutralizer systems tends to make the system zero sequence reactance capacitive viewed from any fault location. If a line-to-ground fault were accompanied by a considerable amount of generator overspeeding, dynamic voltages to ground would be increased and might reach magnitudes sufficiently great to damage protective equipment.

Conclusions and Summary

As a result of this investigation, a number of conclusions have been drawn. In evaluating these, however, it is important to bear in mind that while these and other investigations have shown that it is possible for overvoltages to exist in various types of power systems, it was necessary in many instances to study extreme cases in order to obtain any that were dangerously high. In an actual system, therefore, the probability of the occurrence of dangerous overvoltages is very small. The best evidence of this with respect to the ground-fault neutralizer system is the excellent trouble-free operation to date of more than 50 neutralizers in service in the United States alone to say nothing of the great number operating satisfactorily elsewhere.

1. Saturation in ground-fault neutralizers is generally very effective in preventing the occurrence of dangerously high overvoltages.

2. With a given neutralizer saturation characteristic, the smaller the current interrupted by an opening in one or two conductors of a line, the lower will be the voltages obtained.

3. While tests and operating experience show that successful arc extinction is obtained even when neutralizers are somewhat out of tune, care should be taken to avoid having the neutralizer reactance higher than the "tuned" value.

4. The number and location of ground-fault neutralizers on a system is relatively unimportant as far as resonant overvoltages are concerned. Operating experience indicates, however, that in an extensive system better service continuity may be obtained if more than one neutralizer is used.

5. When one or two conductors are open on a given line, loads on the remainder of the system do not appreciably affect the overvoltages resulting. However, the more lines there are radiating from the source (that is, the more extensive the system) the lower will be the series resonant voltages, because the ratio of current interrupted to rated neutralizer current will, in general, be smaller.

6. Source reactance, which includes the reactance of the grounding transformer or of the power transformer bank in the neutral of which the ground-fault neutralizer is connected usually has only a slight effect on series resonant overvoltages. This reactance normally constitutes only a small part of the total reactance required for neutralization, but since in general, it does not saturate, its tendency is to produce slightly higher overvoltages than would occur if all the neutralizing reactance were concentrated in the saturable ground-fault neutralizer.

7. Line resistance has practically no effect on the magnitude of resonant overvoltages.

8. A fault-to-ground on either side of an open conductor will reduce resonant overvoltages to harmless values. In practice this is the condition which would most probably occur in event of a broken line conductor, since it is improbable that a broken conductor could avoid contact, either directly or indirectly with ground.

9. Unequal pole openings of circuit breakers is undesirable if the interruption in the different phases is more than 3 or 4 cycles apart. Short arcing time and a minimum tendency to restrike are desirable.

10. Fuses or other single pole interrupting devices should not be used on the lines of a ground-fault neutralizer system. Such devices may, however, be used in the terminals of load transformers.

11. Lightning arresters, connected in the system neutral or to the lines, are effective in limiting transient or resonant overvoltages to the gap spark-over levels of the arresters.

A survey of these conclusions, together with the steadily growing number of successful ground-fault neutralizer installations, establishes the fact that practical and effective means have been found to eliminate difficulties with overvoltages. With the modern designs of ground-fault neutralizers, and with proper attention to their application, the record of trouble-free operation and effectiveness in service protection should continue to be excellent. On a ground-fault neutralizer system having only one radial line, the voltages occurring across a breaker may be appreciably higher than if the system

Alcoa Rectifier Installation

J. ELMER HOUSLEY
MEMBER AIEE

H. WINOGRAD
MEMBER AIEE

IN 1938, 15 mercury arc rectifier units, with a total capacity of 82,500 kw, were placed in service by the Aluminum Company of America to supply d-c power for the electrolytic production of aluminum.[1] In the plant at Alcoa, Tenn., ten of these units were installed to supply two 45,000 ampere, 600 volt, d-c circuits. In the plant at Massena, N. Y., five units were installed to supply one such circuit.

These installations are noteworthy as they marked the first application of power rectifiers in this country for the electrolytic production of metal. At that time the Alcoa installation was the largest concentration of rectifiers in the country, with the highest kilowatt capacity, installed in a single station and operating on a common bus. Since 1938, one unit was added to each station in space reserved for it. At Alcoa twelve additional units were installed in a second station; six of these were placed in service in May 1940, and six in January 1941.

This paper will describe the Alcoa rectifier installations. The Massena station is practically identical with the first Alcoa installation except for the number of units.

Power Circuits

A single-line diagram of the power circuits for the Alcoa rectifier installations is shown in Figure 1. The stations are designated as number 3 and number 4. The buildings are indicated by dotted lines.

The 13.2 kv, 3-phase, 60-cycle, a-c power is supplied to the station busses over four lines from a number of 42,000 kva transformer banks located approximately 100 feet away.

Three-phase, 60-cycle, a-c power is supplied at 161 kv to the 42,000 kva transformer banks from a 4-section ring bus. This bus replaces the longitudinal busses formerly employed. The ring bus arrangement was dictated by load growth and the demand for flexibility. The ring bus is supplied from five 161 kv lines through oil circuit breakers rated at 2,500,000 kva interrupting duty. Protection of the bus is obtained through overcurrent and bus differential relays. The ring bus is sectionalized through oil circuit breakers of 2,500,000 kva interrupting duty and 8-cycle timing. Transformer and 13.2 kv bus protection is provided by bus differential, overcurrent, transformer case ground and pressure relays.

The 42,000 kva wye-delta transformer banks are connected to the ring bus in groups of two to four banks per section. The high-tension sides of the transformers are disconnected from the bus by means of gang-operated, horizontal double-break disconnecting switches. The disconnecting switches are provided with arcing tips to break the magnetizing current. Some of these transformers are fan-cooled for emergency overload operation. The 13.2 kv sides of the transformer banks are provided with oil circuit breakers of 1,500,000 kva interrupting duty. These oil circuit breakers serve to interrupt the load when placing the transformers in or out of service; the breakers are isolated by means of gang-operated, high-pressure contact, disconnecting switches. Low side transformer protection is provided by instantaneous and time overcurrent, transformer case ground and pressure relays. Power flow through each bank is metered on the low side by means of suitable potential and current transformers.

The rectifier stations are supplied from a sectionalized 13.2 kv bus. As indicated by Figure 1, each station is fed from a double bus which is supplied from either end of the station. Any rectifier unit may be connected to either a-c bus by means of gang-operated disconnecting switches. This arrangement permits sectionalizing the halves of each station and facilitates maintenance.

Inasmuch as the rectifiers feed a continuous electro-chemical load, continuity of supply is essential. Consideration of this factor has influenced the arrangement of busses and equipment as described above. Under the existing arrangement, individual items of equipment, and in certain instances complete bus sections, may be isolated as necessary for maintenance or repairs without interruption to the station supply. At the stations a spare transformer is available and each station has sufficient capacity to permit the isolation of any one complete unit. A constant source of d-c power for operation of controls is insured by making the storage battery at each station available to another station or stations.

A comprehensive program of preventive maintenance has proved an important factor in minimizing power interruptions resulting from equipment failures. One feature of this program is the regular testing of the power factor of insulation.

Paper 41-167, recommended by the AIEE committee on electrical machinery, and presented at the AIEE Southern District meeting, New Orleans, La., December 3–5, 1941. Manuscript submitted August 29, 1941; made available for preprinting October 1, 1941.

J. ELMER HOUSLEY is superintendent of power for the Aluminum Company of America at Alcoa, Tenn. H. WINOGRAD is engineer-in-charge of rectifier design for the Allis-Chalmers Manufacturing Company, Milwaukee, Wis.

---

neutral were solidly grounded, but no more severe than if the system neutral were completely isolated. However, for the network or multi-circuit type of ground-fault neutralizer system, the breaker voltages are correspondingly less severe than for a single radial line.

Figure 1. Single-line diagram of the rectifier stations and the power-supply system

Each major item of equipment, including transformers, oil circuit breakers and bushings, is tested when installed, or overhauled, and annually thereafter. Any indication of faulty insulation is investigated immediately and corrected. Failures have been averted by correcting faulty conditions in the initial stage. The problem of transformer maintenance has been simplified by close attention given to the oil.[3] Activated alumina bypass treaters are used for the treatment of oil; similarly activated alumina is used for treating bushing oil. Activated alumina breathers have been successful in excluding air-borne moisture from transformers, thereby maintaining a high dielectric property of the oil.

The a-c switching equipment, phase-shifting auto-transformers, rectifier transformers, anode disconnecting switches, negative disconnecting switches, and d-c busses are located outdoors. Stranded all-aluminum cables are used for the connecting lines between the a-c station busses and the main 13.2 kv bus. The a-c busses are made of aluminum channels. The d-c busses are constructed of aluminum bars. Aluminum tubing, bars and channels are used for the power circuit connections between the component parts of the equipment.

The d-c busses are suspended from brackets on one wall of the station building. The d-c load circuits are connected solidly to the positive and negative busses. The negative bus runs the full length of each station with a solid tie between the busses of the two stations. The positive bus is sectionalized in the middle of each station through a bus-tie breaker. The positive busses of the two stations are connected through a tie breaker to permit transfer of power between the stations if desired.

Rectifier Station 3

Equipment and Layout

A view of the outdoor equipment of station 3 is shown in Figure 2. A view of the station interior is shown in Figure 3. All equipment is located on one floor.

The station is divided into two sections, each containing five units, with a spare unit (unit 6) in the center which may be operated on either section. Near the center of the station, outdoors, are located two sets of potential transformers and two 200 kva, 3-phase transformers for supplying 230 volt power to the rectifier auxiliaries and station lights. One auxiliary power transformer and one set of potential transformers are connected to each a-c bus.

Figure 2. View of a-c switching equipment and transformers, rectifier station 3

Figure 3. Interior view of rectifier station 3

At the center of the station inside the building are located the control benchboard, a switching cubicle for the 230 volt auxiliary power supply, and a 600 volt d-c bus-tie switch. On the benchboard are mounted the circuit breaker control switches and meters for the incoming lines, the rectifier units, and the load circuits. Control switches are also provided for regulating the load current of individual rectifiers by grid control.

The connections between the neutral bushings of the rectifier transformers and the negative bus are run through the building below the ceiling. The connections between the cathodes and the d-c breakers are located in floor trenches.

A diagram of connections of one rectifier unit is shown in Figure 4. Each rectifier unit consists of the following equipment: two 3-pole, a-c disconnecting switches; a 3-pole solenoid-operated oil circuit breaker; three current transformers; a phase-shifting auto-transformer, if required; a 3-phase rectifier transformer; two steel-tank, 12-anode, grid-controlled rectifiers; two sets of cooling equipment for the rectifiers; a twin cubicle containing the rectifier excitation and grid-control equipment; a 2-panel switchboard on which are mounted the vacuum meters, the a-c overload relays and the control equipment for the rectifier auxiliaries; two solenoid-operated, 6,000 ampere, high-speed d-c breakers which will clear in approximately 0.75 cycle on a 60-cycle basis; two 6,000 ampere negative disconnecting switches located outdoors and operated by means of a lever inside the station building; and 12 anode disconnecting switches. The cubicles and cooling equipment are located at the rear of the rectifiers. The switchboards are located along the aisle in front of the rectifiers.

The rectifier units are so designed that between the transformer and d-c bus each rectifier may be operated as a self-contained unit. Each tank is provided with a complete set of auxiliary and control equipment, and it is possible to shut down and isolate a rectifier and its auxiliaries by opening the d-c breaker and the anode disconnecting switches, without shutting down or affecting the operation of the companion rectifier.

The rectifier transformer has a delta or wye high-voltage and two groups of low-voltage windings. Each low-voltage group has a double 6-phase connection with interphase transformers, and supplies power to one rectifier. The rectifier transformers in the station have alternately delta and wye high-voltage windings.

Phase shifting auto-transformers are connected ahead of the rectifier transformers. For units 1 to 5, these phase shifters produce a phase displacement of 12 degrees among corresponding transformer low-voltage phases, resulting in a 30-phase system. For units 6 to 11, the phase shifters produce a displacement of 10 degrees among the corresponding low-voltage phases of the transformers, resulting in a 36-phase system.

Each rectifier tank is rated at 4,580 amperes, 600 volts. It has 12 main anodes provided with control grids, two auxiliary excitation anodes, and an ignition rod. On the tank is mounted a vacuum pump set consisting of a water-cooled mercury condensation pump and a motor-driven rotary pump, also an expansion tank for the water circulating system, and a panel with grid resistors.

Cooling System

Each rectifier is cooled by a closed cooling system using a water-to-water heat exchanger. A diagram of the cooling system is shown in Figure 5. The water is circulated between the water jackets of the rectifier and the shell of the heat exchanger by means of a motor-driven pump. The flow of raw water through the tubes of the heat exchanger is regulated automatically by means of an electrically-operated valve which is actuated by a thermostat located in the recirculating system.[3]

All the cooling equipment, including the rubber hose between the heat exchanger and the cold water supply, is assembled on a frame which is insulated from ground. The heat exchanger and all the equipment and piping connected with it are at approximately the same potential as the rectifier. In Figure 6 is shown a photograph of the cooling unit.

The station has two water supply lines, a city water line and a mill supply line. Normally the mill water is used to cool the rectifiers and the city water to cool the mercury vacuum pumps. However, in case of need, either line may be used to supply all the cooling water.

Excitation and Grid Control

A diagram of connections of the excitation and grid control circuits of each rectifier is shown in Figure 7. The excitation equipment, shown at the left of the diagram, is used to start and maintain an auxiliary arc in the rectifier between the cathode and two excitation anodes, which are connected in a single-phase full-wave rectifying circuit of about 10 amperes d-c. When the excitation transformer is connected to the 230 volt auxiliary supply, the ignition solenoid pulls the ignition rod into the cathode mercury against the action of a spring. The current flowing through the rod causes operation of relay 31*X* which de-energizes the ignition coil. The rod is pulled out of the mercury, starting an arc at the cathode which is maintained by the fixing of the excitation anodes. Relay 53 then operates to open the circuit to the ignition rod.

When voltage is applied to the main anodes from the rectifier transformer and the rectifier is connected to the load circuit, the main anodes can fire during those parts of the voltage cycle when they are

positive with respect to the cathode. The start of the firing of each anode is controlled by its grid. An anode can start firing only when the grid is at a positive potential to the cathode. During the firing period of the anode the grid has no controlling effect. It is at the potential of the arc, and carries a small current as determined by the voltage and impedance of its external circuit. It can regain control at the conclusion of the anode firing period. This property of the grid is used for controlling the output voltage of each rectifier. The rectifier voltage may be reduced by retarding the start of the anode firing during each cycle. The anodes may be blocked from firing altogether by applying to the grids a negative potential.

In the grid control circuit of Figure 7, provision is made for regulating the rectifier d-c voltage and for applying to the grids a high negative potential to block the anodes upon occurrence of a backfire in the rectifier. The grids are connected through resistors to the 6-phase secondary winding of a grid transformer, the primary winding of which is connected to a 3-phase circuit. The neutral point of the grid transformer secondary is connected to the cathode over a grid bias circuit which is supplied by a 3-phase full-wave selenium-type rectifier. The voltage between each grid and the cathode thus consists of an a-c component and a variable d-c component. The point of the cycle at which the grid-to-cathode voltage changes from negative to positive, to permit the pick-up of its associated main anode, is determined by the relative values of the a-c and d-c components. This point can be retarded by increasing the negative d-c bias voltage, which can be adjusted by means of a motor-operated grid control rheostat.[4]

For the units provided with a phase shifter on the high-voltage side of the rectifier transformer, a small auto-transformer type phase shifter is connected in series with the primary winding of the grid transformer, with the same angle of shift as the main phase shifter, in order to maintain the same phase relation between the grid and anode voltages for all the units. A fixed resistor, *Rm*, connected between the end of the grid control rheostat and the cathode, provides a small negative bias to keep the anodes blocked when the supply to the grid transformer is open.

Relays 77*T* and 77*G* are used for grid blocking of the anodes. Each relay has two coils which are connected to current transformers in two phases of the a-c supply line to the rectifier transformer. Upon occurrence of a backfire, the increase of current in the a-c line causes operation of these relays. Relay 77*T* short-circuits the primary winding of the grid transformer, thus removing the a-c components of the grid voltage. Relay 77*G* connects the neutral of the grid transformer to the negative terminal of the bias supply circuit, increasing the negative bias on the grids. One contact of this relay inserts additional resistance in the grid bias circuit to prevent overloading of the auxiliary rectifier. Short-circuiting of the grid transformer increases the current through the sealing current transformer, which holds the relays in the operated position. It also increases the voltage on the coil of the auxiliary relay 78, causing it to operate. The contacts of this relay take over the function of relays 77*T* and 77*G* and permit them to reset by short-circuiting the sealing current transformer. Relay 78 also trips the oil circuit breaker of the unit. Tripping of the circuit breaker resets relay 78 by short-circuiting its coil through an auxiliary switch.

PROTECTION

The individual rectifier units are protected against overload by induction type overcurrent relays, connected to current transformers on the high-voltage side of the rectifier transformer. These relays are connected to trip the oil circuit breaker of the unit. The rectifiers are protected against backfire by the high-speed cathode breakers which are provided with reverse current trips, and by the grid-blocking relays. Upon occurrence of a backfire, current flows to the faulty anode from the transformer low-voltage winding through other anodes of the rectifier, and from the d-c bus through the cathode. The grid-blocking equipment stops the flow of current from the other anodes, and the tripping of the cathode breaker interrupts the flow of current from the d-c bus.

Operation of the grid-blocking relays or automatic tripping of the cathode breaker also trips the unit oil circuit breaker, in order to insure complete interruption of current flow from the other anodes of the rectifier to the faulty anode. The unit is returned to service immediately after tripping of the breakers. A reverse current relay is connected to the ammeter shunt of each rectifier. These relays are

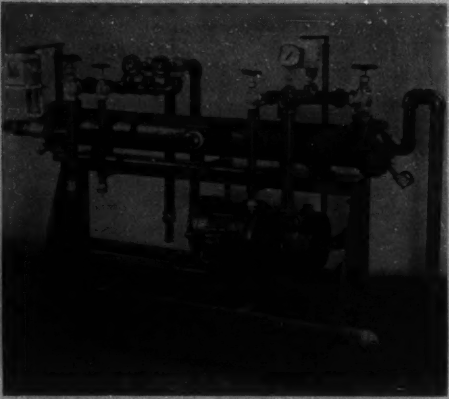

Figure 6 (left). Cooling unit for rectifier in station 3

Figure 8. View of a-c structure and transformers, rectifier station 4

connected to trip the cathode breakers of all the rectifiers operating in parallel on the d-c bus, and are set to operate only in the event that the reverse current flowing from the d-c bus to the backfiring rectifier is not cleared successfully by its cathode breaker. This back-up protection was considered essential in view of the number of rectifiers connected in parallel to the d-c bus.

Rectifier Station 4

Rectifier station 4 differs from station 3 in several respects, particularly in regard to the switching and control equipment and the cooling system of the rectifiers. The changes involved important innovations in the engineering practice relating to the application of rectifiers for electrochemical service.

Equipment and Layout

As may be seen in Figure 1, the electrical arrangement of the a-c and d-c busses and their connections to the supply and load circuits are similar to those in station 3. The width of the station building and the longitudinal space per unit are also the same as in station 3. A view of the outdoor a-c equipment is shown in Figure 8. A view of the station interior is shown in Figure 9. The station building is windowless. Illumination is provided by three rows of fluorescent lighting fixtures.

The rectifier units are divided into two groups, each supplying a load circuit, with a d-c bus tie breaker between them. Each group of six units constitutes a 36-phase system.

Auxiliary power, at 460 volts, is supplied by two 650 kva, 3-phase transformers. This power is distributed through a switching cubicle and an auxiliary bus provided with outlets through thermal-release switches. More auxiliary power is required than in station 3 because of the additional load for the fan motors of the rectifier cooling and station ventilating equipment. This made it advisable to use 460 volt distribution. These motors and the vacuum pump and water pump motors are rated at 460 volts. The other auxiliaries of each rectifier are supplied with 230 volts through a $7^1/_2$ kva, 460/230 volt transformer.

The station building is provided with a basement in which are located the control cables, the cathode bus-bars and reactors, the $7^1/_2$ kva auxiliary power transformers, and the station ventilating units. These units consist of fans and self-cleaning air

filters. Air from the outside is drawn through the filters and discharged into the basement. From there it passes through floor gratings into the rectifier room, and is discharged through roof ventilators.

RECTIFIER UNITS

A diagram of connections of the power circuits of one rectifier unit is shown in Figure 10. Each unit is connected to the a-c busses through gang-operated air-break disconnecting switches which are mounted on top of the bus structure. They are capable of interrupting the magnetizing current of the rectifier transformers. There is no circuit breaker on the high-voltage side of the rectifier transformer, as in station 3. Its function is performed by a 6-pole, high-speed, anode breaker between each rectifier and the low-voltage side of the rectifier transformer.

The high-voltage windings of the rectifier transformers are connected in delta or wye. Four units of each group of six are provided with phase-shifting auto-transformers for phase multiplication. Three through-type current transformers are connected on the high-voltage side of each unit. For units having phase shifters, the current transformers are located inside the phase shifter tanks.

Each rectifier transformer has two groups of 6-phase low-voltage windings, with interphase transformers. Each phase winding is connected to two of the rectifier anodes through a paralleling anode reactor.

The cathode of each rectifier is connected to the positive d-c bus through a reactor of approximately 0.1 millihenry, and a semi-high-speed breaker. The purpose of the reactor is to reduce the rate of rise of the current from the d-c bus to the rectifier during a backfire. This was considered desirable in view of the lower impedance of each low voltage phase winding of the rectifier transformer as compared to the transformers of station 3, which have a separate winding for each anode.

PROTECTION

The anode breakers are pneumatically operated. The six poles may be opened and closed simultaneously by means of an electrically operated air valve. Each pole is independently latched, is trip-free, and is provided with a reverse-current trip attachment. The interrupting time is approximately 0.75 cycle. A view of the anode breakers is shown in Figure 11. The anode reactors are located below the breakers. The anode reactors are connected to the anode terminals of the rectifier by means of cables passing underneath the station floor.

The use of anode breakers, instead of a circuit breaker on the high-voltage side of the rectifier transformer, has several advantages. Upon occurrence of a backfire, the circuit of the faulty anode is opened at high speed, thus cutting off the flow of current from the other anodes of the same rectifier as well as the current from the d-c bus. Only the backfiring rectifier is removed from service, without affecting the second rectifier of the same unit. A circuit breaker on the high voltage side of the rectifier transformer would have to be of relatively high interrupting capacity in view of the large power concentration, and would require a more elaborate outdoor installation.

The individual rectifier transformers are protected by induction-type over-

GRID BIAS CIRCUIT

Figure 12 (right). Diagram of connections of grid control and protection circuits or rectifier in station 4 current relays connected to the current transformers on the high-voltage side of the unit. These relays are connected to trip the oil circuit breakers supplying the a-c busses.

The semi-high-speed cathode breaker of each rectifier is equipped with reverse-current and overload trip attachments. These breakers provide overload protection for the individual rectifiers and back-up protection for the anode breakers. They are also used for isolating the rectifiers from the positive bus and for switching the load circuit.

Each rectifier is provided with high-speed grid-blocking protection, the purpose of which is to limit to a minimum the number of anodes in a backfiring rectifier participating in the flow of current to the faulty anode.

GRID CONTROL

A diagram of connections of the grid control and blocking circuit is shown in Figure 12. This circuit is similar to that of Figure 7 except that thyratron tubes, 77*T* and 77*G*, are used in place of mechanical relays. The grids of these tubes are actuated by a rectified impulse from differentially-connected anode current transformers. In normal operation, when the currents of parallel anodes are balanced, there is no residual current through resistor *K*. Upon occurrence of a backfire, the resulting unbalance current flows through resistor *K*. The voltage-drop across this resistor is applied to the grids of the tubes through auxiliary rectifier *S*3, overcoming the negative bias of the grids and releasing the tubes.

The firing of tube 77*T* short-circuits the tertiary winding of the grid transformer through the auxiliary rectifier *S*2, thus reducing to a relatively small value the a-c component of the rectifier grid voltage. Operation of tube 77*G* connects the neutral point of the grid transformer to the negative side of the grid bias circuit, thus applying a blocking negative voltage to the grids of the rectifier. Operation of tube 77*T* also causes operation of reset relay 78. The contacts of this relay short-circuit the primary winding of the grid transformer and tube 77*G*, taking over the function of the tubes and permitting their grids to regain control. Opening of the anode breaker resets relay *RR* by short-circuiting its coil through auxiliary switch 52.

Figure 14. View of rectifier cooling equipment on roof of station 4

The grid-blocking circuit of Figure 12 has greater selectivity and higher speed than the circuit of Figure 7. The anode current transformers are clamped over the ends of the anode bus bars of the rectifier (see Figure 11).

The operation of the grid voltage control of the rectifiers in station 4 is similar to that in station 3.

COOLING SYSTEM

A diagram of the rectifier cooling system is shown in Figure 13. Due to the limited supply of raw water at this installation, it was decided to use water-to-air instead of water-to-water heat exchangers.

The cooling system of each rectifier is self-contained. Water is circulated between the rectifier and the radiator of the cooling unit. The radiator is cooled by a fan driven by a two-speed motor, with a rating of 10 and $2^{1}/_{3}$ horsepower at the high and low speeds, respectively. The water temperature is regulated by means of a 3-way valve combination which controls the relative rate of water flow through the radiator and the by-pass circuit at the rectifier.

The water pump, with the temperature control equipment and hand valves, is mounted on the side of the rectifier tank. The cooling unit, consisting of the radiator, fan, and motor, is installed on the roof of the station building (see Figure 14). The radiator is insulated from ground and the fan housing. It is connected to the rectifier by means of copper pipes running along the ceiling and down the wall of the station, as may be seen in Figure 9. The pipes terminate several feet above the station floor and are connected to the rectifier tank by rubber hoses passing underneath the floor.

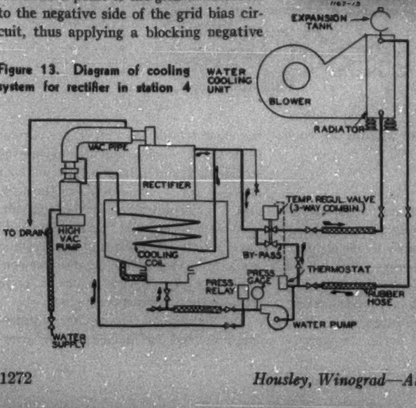

Figure 13. Diagram of cooling system for rectifier in station 4

Figure 15 (left). Control cubicle for a rectifier unit in station 4

Figure 16. Control switchboard in rectifier station 4

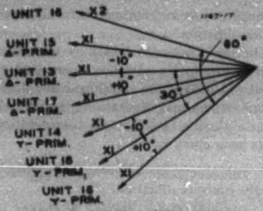

Figure 17. Vector diagram of 36-phase system for units 13 to 18 in rectifier station 4

The cooling units are designed to dissipate the full-load losses in the rectifier at an air temperature of 105 degrees Fahrenheit. During the greater part of the year the fans operate at low speed. An antifreeze solution is added to the cooling system for the winter months.

The high-vacuum pumps are cooled by water from the city supply, as in station 3.

SWITCHBOARDS

The excitation and grid-control equipment and motor starters of the vacuum and water pumps, for the two rectifiers of each unit, are assembled in a cubicle shown in Figure 15. The grid control rheostats are mounted on the swinging doors. The cubicle is located in front of the rectifiers, facing the cathode breakers.

The control switchboard in the center of the station is of the totally-enclosed duplex-type construction. It is provided with a passage-way between the front and rear panels and a door at each end. A front view of the switchboard is shown in Figure 16.

On the front panels are mounted the control switches and indicating instruments of the rectifier units, incoming a-c lines, and load circuits. On the control panels of the rectifier units are mounted the instruments and control switches required for complete supervision and control of each rectifier, including the vacuum meters, drop annunciators, grid control switches, position indicators of the temperature regulating valves, and control switches for the fan motors. On the rear panels of the switchboard are mounted relays, battery switches, and the incoming line watthour meters.

The terminal blocks of the switchboard and cubicles project through the floor into the basement. This arrangement facilitates the connections of the control cables and conserves switchboard space.

LOAD SWITCHING

The cathode breakers and the control grids of the rectifiers are utilized for switching the load circuits. To drop the load on one of the load circuits, the positive bus section to which it is connected is isolated by opening the adjoining bus tie breakers. The cathode breakers of the rectifiers feeding the load circuits are then tripped simultaneously through a multicontact relay by turning the control switch of the load circuit to the "trip" position. This operation also opens a grid contactor which supplies 3-phase voltage to the grid transformers of these rectifiers. With the a-c components of the grid voltage removed, the rectifier anodes are "blocked" by the fixed negative bias applied to the grids.

To pick up the load, the anode and cathode breakers of the rectifiers are closed. The load circuit is then "closed" by turning the control switch to the "close" position. This energizes the grid contactor and applies voltage to the grid transformers, permitting the rectifier anodes to fire in their regular sequence.

The load circuits of station 3 are controlled similarly. Originally, the load circuits in that station were connected to the positive bus through 50,000-ampere breakers, which have since been removed. The omission of these breakers simplified the installation by making it unnecessary to bring the heavy connections between the load circuits and the positive bus into the station building.

PHASE MULTIPLICATION

As was mentioned previously, each group of six rectifier units operates as a 36-phase system which cancels or reduces to a negligible value the harmonic components of the current in the a-c supply line, below the 35th harmonic. This is accomplished by displacing the phases of the units by equal angles from each other, as indicated in Figure 17. This diagram shows the voltage vectors of low-voltage phase $X1$ of the rectifier transformers for units 13 to 18. The phase displacement is effected by delta and wye high-voltage windings of the rectifier transformers and ten-degree phase shifters, as indicated in Figure 1. Units 13 and 18 have no phase shifters. Their phases are displaced by 30 degrees due to the delta and wye connections. Units 14 and 15 are shifted by ten degrees in the lagging direction, and units 16 and 17 by ten degrees in the leading direction.

The a-c line current of each 6-phase unit contains all the odd, nontriple harmonics: 5th, 7th, 11th, 13th, 17th, 19th, etc. In Figure 18 are given the vector diagrams of some of the harmonic components for the six units, showing their relative phase positions in harmonic degrees. It may be seen readily that the sum of the vectors in each of the diagrams shown is equal to zero. They are therefore cancelled from the line current.[5] This applies to all the harmonics below the 35th. The vectors of the 35th and

Operation of Load-Ratio Control Transformers Connected in Parallel and in Networks

F. M. STARR
MEMBER AIEE

SUBSTATIONS equipped with automatic load-ratio control equipment are frequently operated with their secondaries in parallel. The units may be physically together, the secondary tie being a bus; or they may be some distance apart connected together by a tie line or group of tie lines as in a primary network. At the present time large numbers of factory-built distribution substations are being sold, and well over half of them are equipped for some form of network operation.

As with most voltage regulators, automatic load-ratio control equipment is usually controlled by means of a line-drop compensator and a contact-making voltmeter.* This automatic control equipment has two principal functions:

1. It serves to maintain some specified voltage regulation at some point on the distribution system.
2. It serves to maintain regulator stability and to keep circulating currents at a minimum.

To be stable a regulator must not "pump" (that is, successively buck and boost unchecked) under any operating condition, and it must be so compensated that there will be no tendency to run away (that is, go to full boost or full buck) under any operating condition except as dictated by regulation requirements. Pumping is prevented by adjustment of the voltmeter band width, and the units operating in parallel are held together by proper adjustment of the reactance compensation as will be explained below. This same compensator adjustment, of course, serves to correct for circulating currents resulting from any cause, such as changes in high-side supply voltages or unbalanced loads.

When a single compensator is used for the dual purpose of providing voltage regulation as well as regulator stability in a network, it naturally will not be adjusted in the conventional manner of adjusting the compensator on a radial feeder regulator. Instead of adjusting the resistance and reactance elements to some value of line impedance, the reactance compensation is greatly reduced (sometimes made negative) to insure stability, and the resistance compensation is substantially increased to obtain the prescribed voltage regulation at peak load. Generally, the compensator and voltmeter can always be adjusted as will be shown, to

1. Insure stability,
2. Correct for circulating currents,
3. Provide the desired voltage at a specified location at peak load.

This may mean some compromise in desired voltage levels at light load periods but, because of changing power factors during light load periods, this is usually not the case.

The purpose of this analysis is to establish quantitative criteria for adjusting compensators and voltmeters for this type of application.

In the discussion which is to follow, three criteria for adjusting compensators and voltmeters are developed and their applications and limitations are stated. In developing these criteria consideration has been given to:

1. Different assumed degrees of accuracy in the control calibration.
2. Different assumed rates of change in voltage.
3. Large and small groups of units.

The case of two similar units operating in parallel has been examined in great detail because this case occurs most frequently in practice, and also, because of its simplicity it is an excellent one from which to develop principles.

Definition of Stability Criteria and Statement of Conditions to Be Studied

CRITERIA FOR STABILITY

Assume a load-ratio-control transformer, operating in parallel with several other units, makes a tap change, $\overline{\Delta E}$ in magnitude. This change will initiate a circulating current which, by virtue of the voltage drop it produces in the transformer and compensator impedances, contributes a voltage change at the voltmeter of $\overline{\Delta V}$. Obviously, to avoid a succession of tap changes in the same direction $\overline{\Delta V}$ must be less than $\overline{\Delta E}$, for otherwise the voltmeter would never receive any indication that the correction it had called for had been consummated.

Thus, one criterion for insuring stability would be:

$\overline{\Delta V}<\overline{\Delta E}$ (criterion A)

This criterion is frequently used in adjusting compensators on induction voltage regulators operating in parallel. However, as will be disclosed in the more detailed analysis to follow below, this criterion for stability may be inadequate under certain conditions. One of the reasons for this is that the circulating current produced by $\overline{\Delta E}$ may induce opposing tap

changes in other units resulting in increased circulating currents, and a total change in voltage contributed by circulating currents which is greater than $\overline{\Delta E}$. As will be shown below, to avoid this possibility, further restrictions must be placed on the magnitude of $\overline{\Delta V}$ such that:

$\overline{\Delta V} < \frac{\overline{\Delta E}}{2}$ (criterion *B*)

This criterion will insure that parallel units will never get more than two tap changes apart (except when correcting for circulating currents due to other causes). It is practically impossible to keep all parallel units on the same tap by compensator adjustments, but positive insurance against more than one step apart (again except when correcting for circulating currents due to other causes) can be obtained by further restricting $\overline{\Delta V}$ to a value:

$\overline{\Delta V} < 0$ (criterion *C*)

This criterion states that $\overline{\Delta V}$ is always negative which, of course, is obtained by a relatively large amount of negative reactance compensation.

The three basic criteria defined above have to do with keeping the units in step and correcting circulating currents, and are established by compensator adjustments. The stability criterion to avoid pumping, on the other hand, is determined principally by voltmeter band-width adjustment. Pumping will be avoided if the net change in voltage at the voltmeter, following a tap-change of $\overline{\Delta E}$, is always less than the voltmeter band-width. In combination with criteria *A* or *B* above, this condition is always satisfied if:

$\overline{\Delta E} < \overline{B.W.}$

In combination with criterion *C* above, however, since $\overline{\Delta V}$ is always negative, this condition is satisfied only if:

$\overline{\Delta E} - \overline{\Delta V} < \overline{B.W.}$

Therefore, in the following more detailed examinations which will be made, the following three general criteria will be applied:

Criterion *A* $\overline{\Delta E} < \overline{B.W.}$
$\overline{\Delta V} < \overline{\Delta E}$

Criterion *B* $\overline{\Delta E} < \overline{B.W.}$
$\overline{\Delta V} < \frac{\overline{\Delta E}}{2}$

Criterion *C* $\overline{\Delta E} - \overline{\Delta V} < \overline{B.W.}$
$\overline{\Delta V} < 0$

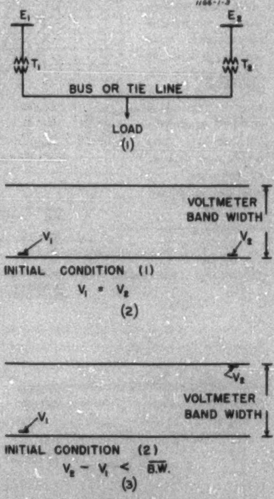
Control-Equipment Calibration

A considerable amount of study on the problem of stability has shown that the adequacy of any particular criterion is greatly influenced by the degree to which the actual calibration of the compensators and voltmeters deviates from the intended values. To establish quantitatively the magnitude of such influences, this analysis has been made on each of two different assumed conditions.

Condition 1.—All voltmeters and compensators have zero errors in their calibration and always function as intended.

Condition 2.—Compensator and voltmeter calibrations are in error to the extent that any two units which should normally respond together for a given set of conditions actually respond as if the delivered voltages to the two voltmeters differed by a value approaching band width in magnitude.

These two assumptions represent two extremes, the actual operating condition probably lying somewhere between them.



Figures 1, 2, and 3. Study of the case of two similar units operating in parallel was based upon two different assumed conditions of instrument calibration

Condition 1. All voltmeters and compensators have zero errors in their calibration and always function as intended. This is illustrated in figure 2 where the voltages V_1 and V_2 as seen by the voltmeters of T_1 and T_2 are equal as intended

Condition 2. Compensator and voltmeter calibrations are in error to the extent that any two units which should normally respond together for a given set of conditions actually respond as if the delivered voltages to the two voltmeters differed by a value approaching band width in magnitude

Sudden Voltage Dips

This analysis has further indicated that the adequacy of any particular stability criterion is influenced by the rate at which the voltage changes. All cases studied were analyzed for two different assumed conditions of rate of voltage change:

1. Voltage rate of change is sufficiently slow that the actual change occurring during the time required to make a tap change is small.
2. Sudden voltage dips occur. The actual magnitudes of voltage dips considered were the critical ones pertinent to each particular case.

Compensator Adjustment for Voltage Regulation

The key to the stability criterion is the value selected for $\overline{\Delta V}$. A large part of this quantity consists of the voltage drop in the compensator produced by circulating currents. As noted above, stability assurance increases as $\overline{\Delta V}$ decreases, and $\overline{\Delta V}$ is reduced by reducing the reactance compensation. The compensator must also provide the desired voltage boost and regulation required at peak load. Since the reactance compensation has been reduced below normal, regulation can be obtained only by increasing the resistance compensation. As might be expected, the more that reactance compensation is reduced to reduce $\overline{\Delta V}$, the more resistance compensation is required to give a specified voltage boost at peak load.

Thus, an appropriate balance between resistance and reactance compensation adjustments is necessary to best meet the stability and regulation requirements.

All three of the stability criteria defined above have been studied from this point of view.

The Case of Two Transformers Operating in Parallel

The case of two load-ratio-control transformers operating in parallel is the simplest one. It is also one of the most common. Many radial substations consist of two three-phase transformers serving a distribution bus. Also, many primary networks consist of only two units or at least start with only two. Thus, the case of two units in parallel is a good one from which to develop principles.

It will be assumed in this analysis that two similar units with the same impedance characteristics and having the same compensator settings are operating in parallel, either on the same bus or over a tie-line.

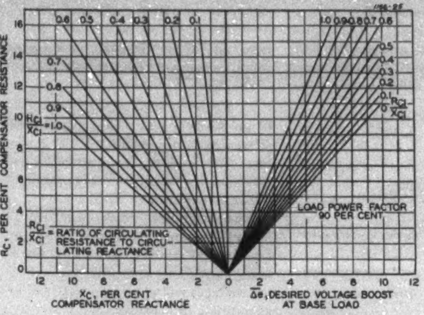
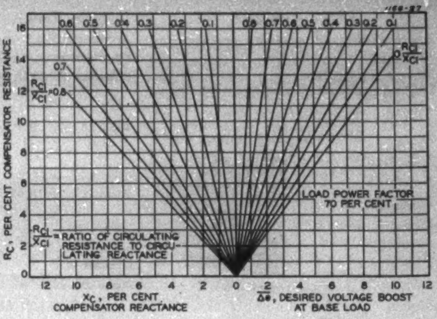
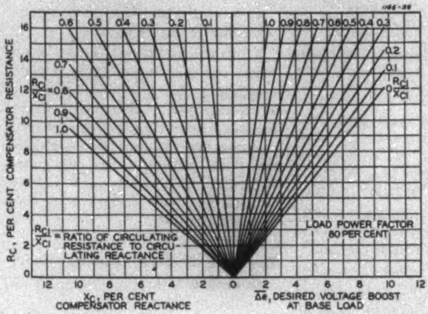
Figures 18–24. Regulator operation with compensator and voltmeter adjusted according to criterion C for the same respective initial values of V_1 and V_2 assumed in Figures 4–10 and 11–17

Refer to Table III







Figures 25, 26, and 27. These curves give the values of reactance and resistance compensation (R_c and X_c) necessary to insure stability and also to give a specified amount of voltage boost at peak load for the case of two similar units operating in parallel on the same bus

All values of X_c are negative and have a ten per cent marginal factor of safety to insure stability

transformers operating in parallel will be examined:

1. For each of the three stability criteria defined above—that is, *A*, *B*, and *C*.
2. For two assumed conditions of voltmeter and compensator calibration as defined above and illustrated in Figures 2 and 3.
3. For both gradual changes in voltage and sudden voltage dips of critical magnitudes.

CRITERION A

To repeat, this criterion states that when T_1 makes a tap change of a magnitude $\overline{\Delta E_1}$, the voltage drop in the transformer (and system back of it) plus that in the line-drop compensator due to the resulting circulating current must be less than $\overline{\Delta E_1}$. That is:

$$\overline{\Delta V_1} < \overline{\Delta E_1}^{*} \qquad (1)$$

Now consider this criterion for condition 1 above (Figure 2) where both V_1 and V_2 are on the verge of calling for a tap change in the same direction. Assume V_1 and V_2 are dropping slowly and V_1 calls for a tap change. The resulting condition, shown in Figure 4, is stable with the two units one step apart. V_1 has increased by an amount $\overline{\Delta E_1} - \overline{\Delta V_1}$ and $\overline{V_2}$ has increased by an amount $\overline{\Delta V_2}$ which is equal and opposite to $\overline{\Delta V_1}$.

A second case to consider is that when V_1 and V_2 are not changing slowly as above, but drop suddenly to a value $(V-d)$. This case must be studied for two values of *d:*

$$\overline{\Delta V} < d < \overline{\Delta E} \qquad (2)$$

$$d < \overline{\Delta V} < \overline{\Delta E} \qquad (3)$$

A larger value of *d* need not be considered since any larger value would revert to one of the above two values after the necessary changes in voltage.

Consider first the case of $\overline{\Delta V} < d$ and assume that T_1 makes the first tap change. This will be followed immediately by another tap change by T_2, since $\overline{\Delta V_2}$ is not sufficient to put V_2 back in the voltmeter band. This is illustrated in Figure 5. Following the second tap change both V_1 and V_2 are inside the voltmeter band and the two units become stable and are in step.

Now consider the case where $\overline{\Delta V} > d$. If T_1 makes the first tap change, since this puts V_2 back in the voltmeter band, T_1 will make a succession of tap changes until

$$n(\overline{\Delta E} - \overline{\Delta V}) > d \qquad (4)$$

where n = number of tap changes.

Following this T_2 will likewise call for tap changes in the reverse direction resulting in instability unless

$$n\overline{\Delta V} - d < \overline{B.W.} \qquad (5)$$

This is illustrated in Figure 6 where three tap changes of T_1 were necessary to obtain stability and then it was obtained only with large value of $\overline{B.W.}$, a much larger value than is considered desirable for good voltage regulation.

Three cases have been considered for condition 1, that is, when V_1 and V_2 are substantially together initially. Now consider condition 2 with V_1 and V_2 substantially apart by some value approaching $\overline{B.W.}$ Thus, assume the condition in Figure 3 exists initially and that V_1 drops gradually until a tap change is called for. As soon as T_1 makes a tap change, an opposite one is called for in T_2. Both V_1 and V_2 are now outside the band, which calls for two further opposing tap changes, and so on until the regulators are in full opposition. This case, illustrated in Figure 7, is unstable and obviously not satisfactory.

Again, with the initial condition of Figure 3, assume that, instead of a gradual change in V_1 and V_2, they drop suddenly by an amount *d*. Consider first the case where $d < \overline{B.W.}$ and leaves V_2 barely inside the voltmeter band. T_1 will then make a succession of tap changes until—

$$n(\overline{\Delta E_1} - \overline{\Delta V_1}) > d \qquad (6)$$

and stability will result only if

$$n\overline{\Delta V_2} < \overline{B.W.} \qquad (7)$$

This is illustrated in Figure 8. Here again, as in Figure 6 several tap changes and a wide $\overline{B.W.}$ were necessary to secure stability if it can be obtained at all.

---

* See appendix for definition of symbols.

Table I. Criterion A

Condition 1.		
Figure 4	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\overline{\Delta E}$	Stable—one step apart
Figure 5	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\overline{\Delta E}$ $\overline{\Delta V}<d<\overline{\Delta E}$	Stable—no steps apart
Figure 6	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\overline{\Delta E}$	$d<n(\overline{\Delta E}-\overline{\Delta V})$ $n\overline{\Delta V}<\overline{B.W.}+d$ Stable—two steps apart
Condition 2.		
Figure 7	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\overline{\Delta E}$	Unstable
Figure 8	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\overline{\Delta E}$ $d<\overline{B.W.}$	$n(\overline{\Delta E}-\overline{\Delta V})>d$ $n\overline{\Delta V}<\overline{B.W.}$ Unstable
Figure 9	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\overline{\Delta E}$ $d>\overline{B.W.}$	$n(\overline{\Delta E}-\overline{\Delta V})>d$ $n\overline{\Delta V}<\overline{B.W.}$ T_1 changes first Unstable
Figure 10	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\overline{\Delta E}$ $d>\overline{B.W.}$	$n(\overline{\Delta E}-\overline{\Delta V})+\overline{\Delta V}>d$ $n\overline{\Delta V}+\overline{\Delta E}-\overline{\Delta V}<\overline{B.W}$ T_2 changes first Unstable

Again, starting with the initial condition of Figure 3, assume $d>B.W.$ leaving V_2 slightly outside the voltmeter band. The resulting criterion for stability now depends on whether T_1 or T_2 changes taps first. If T_1 changes taps first, V_2 is restored inside the band and relations 6 and 7 above still hold (see Figure 9). If T_2 changes taps first, T_1 will have to follow with n changes until—

$$n(\overline{\Delta E_1}-\overline{\Delta V_1})+\overline{\Delta V_1}>d \qquad (8)$$

and stability will result only if

$$n\overline{\Delta V}<\overline{B.W.} \qquad (9)$$

This case is illustrated in Figure 10. Here again stability is obtained only with the two units several taps apart and using a large value of $\overline{B.W.}$

A summary of conditions for the seven cases studied under criterion A and illustrated in Figures 4 through 10 is tabulated in Table I.

CRITERION B

The second criterion as defined above is:

$$\overline{\Delta V_1}<\frac{\overline{\Delta E_1}}{2}$$

This criterion will be examined for the two initial conditions illustrated in Figures 2 and 3 and for each of the cases analyzed under criterion A. The results of this examination are shown diagrammatically in Figures 11 through 17 which may be compared directly with Figures 7 through 10, respectively, for the corresponding cases under criterion A.

The conditions and results of criterion B for these seven cases are tabulated in Table II.

Table II. Criterion B

Condition 1.		
Figure 11	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\frac{\overline{\Delta E}}{2}$	Stable—one step apart
Figure 12	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\frac{\overline{\Delta E}}{2}$ $\overline{\Delta V}<d<\overline{\Delta E}$	Stable—no steps apart
Figure 13	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\frac{\overline{\Delta E}}{2}$ $d<\overline{\Delta V}$	Stable—one step apart
Condition 2.		
Figure 14	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\frac{\overline{\Delta E}}{2}$	Stable—two steps apart
Figure 15	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\frac{\overline{\Delta E}}{2}$ $d<\overline{B.W.}$	$n(\overline{\Delta E}-\overline{\Delta V})>d$ $n\overline{\Delta V}<\overline{B.W.}$ Stable—two steps apart
Figure 16	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\frac{\overline{\Delta E}}{2}$ $d>\overline{B.W.}$	$n(\overline{\Delta E}-\overline{\Delta V})>d$ $n\overline{\Delta V}<\overline{B.W.}$ T_1 changes first Stable—three steps apart
Figure 17	$\overline{\Delta E}<\overline{B.W.}$ $\overline{\Delta V}<\frac{\overline{\Delta E}}{2}$ $d>\overline{B.W.}$	$n(\overline{\Delta E}-\overline{\Delta V})+\overline{\Delta V}>d$ $n\overline{\Delta V}+\overline{\Delta E}-\overline{\Delta V}<\overline{B.W.}$ T_2 changes first Stable—one step apart

Since any operating condition will revert into one of the above seven assumed possible conditions, and since each of the above seven conditions results in stable operation, criterion B may be considered satisfactory so far as stability is concerned.

CRITERION C

The third criterion has been examined for these same seven cases analyzed under criteria A and B above.

Criterion C states:

$$\overline{\Delta V}<0$$

This criterion states that $\overline{\Delta V}$ must always be negative, requiring a large amount of negative compensation—more than may be obtainable in some compensators.

Figures 18 through 24 show graphically the regulator operation for the seven cases. The conditions for these cases correspond respectively to those in Figures 3 through 10 for criterion A, and to those in Figures 11 through 17 for criterion B.

The conditions and results of criterion C are tabulated in Table III.

CONCLUSIONS FROM TWO-UNIT ANALYSIS

1. Criterion A, $\overline{\Delta V}<\overline{\Delta E}$, should never be used. If the voltmeters and compensators are not closely calibrated, instability of the regulators may result. In any case, an excessively high band width would be required to insure stability most of the time.

2. Criterion B, $\overline{\Delta V}<\overline{\Delta E}/2$, appears to be an excellent one. This criterion will always guarantee stability of the regulators. When the input voltages are equal and when the compensators are set alike, the units will usually remain within one step of each other. Under conditions of bad calibration they may stabilize two taps or possibly three taps apart. Circulating currents set up by differences in input voltages will always be corrected by appropriate tap changes.

Criterion B is not too severe to interfere with effective voltage regulation.

3. Criterion C, $\overline{\Delta V}<0$, is also an excellent one since it will insure stability usually at no steps apart and occasionally at one step apart. Criterion C, however, requires so much negative reactance compensation that voltage regulating requirements will probably be seriously interfered with. It does not appear to have sufficient merit over criterion B to warrant its preference.

The Case of More Than Two Units in Parallel

Again, in the case of more than two units operating in parallel, the problem may be treated generally, whether the units are paralleled on the same bus or whether they are connected through tie lines.

The case of two units was a simple one to the extent that a change in voltage on one unit, $\overline{\Delta E}$, produced a circulating current which flowed through each unit and which produced equal and opposite voltage changes at each voltmeter, that is, $\pm\overline{\Delta V}$.

In the case of more than two units, if there is a change in voltage in T_1, the resulting circulating current divides in the remaining units in inverse proportion to the transfer impedances between unit 1 and the other units. Thus, the stimulus of a change in T_1 to cause secondary changes in the other units becomes increasingly less as the number of units increases, and conversely the influence on T_1 of these secondary effects becomes less as the number of units increases. Thus, the operation of T_1 in a large network or in parallel with a large number of units approaches the operation of T_1 in parallel with an infinite bus. On the other hand, the operation of T_1 in a small network or in parallel with a small number of units

Table III. Criterion C

Condition 1.		
Figure 18	$\overline{\Delta E}-\overline{\Delta V}<\overline{B.W.}$ $\overline{\Delta V}<0$	Stable—no steps apart
Figure 19	$\overline{\Delta E}-\overline{\Delta V}<\overline{B.W.}$ $\overline{\Delta V}<0$ $\overline{\Delta V}<-d$	Stable—no steps apart
Figure 20	$\overline{\Delta E}-\overline{\Delta V}<\overline{B.W.}$ $\overline{\Delta V}<0$ $-d<\overline{\Delta V}$	Stable—no steps apart
Condition 2.		
Figure 21	$\overline{\Delta E}-\overline{\Delta V}<\overline{B.W.}$ $\overline{\Delta V}<0$	Stable—one step apart
Figure 22	$\overline{\Delta E}-\overline{\Delta V}<\overline{B.W.}$ $\overline{\Delta V}<0$ $\overline{\Delta E}-\overline{\Delta V}>d$ $d<\overline{B.W.}$	Stable—one step apart
Figure 22(a)	$\overline{\Delta E}-\overline{\Delta V}<\overline{B.W.}$ $\overline{\Delta V}<0$ $\overline{\Delta E}-\overline{\Delta V}<d$ $d<\overline{B.W.}$	Stable—one step apart
Figure 23	$\overline{\Delta E}-\overline{\Delta V}<\overline{B.W.}$ $\overline{\Delta V}<0$ $d>\overline{B.W.}$	T_1 changes first Stable—one step apart
Figure 24	$\overline{\Delta E}<\overline{\Delta V}<\overline{B.W.}$ $\overline{\Delta V}<0$ $d>\overline{B.W.}$	T_2 changes first Stable—one step apart

approaches the operation of the two-unit network analyzed in detail above.

If T_1 were operating in parallel with an infinite bus, all secondary effects would be zero, and it is obvious that the necessary and sufficient conditions for stability of T_1 are:

$$\overline{\Delta V_1}<\overline{\Delta E_1}<\overline{B.W.}$$

In the two unit analysis it was shown that the minimum criterion for stability was:

$$\overline{\Delta V_1}<\frac{\overline{\Delta E_1}}{2}$$

$$\overline{\Delta E}<\overline{B.W.}$$

Thus, with several units operating in parallel, it appears that the proper criterion for a value of $\overline{\Delta V}$ varies between something less than $\overline{\Delta E}$ and something less than $\overline{\Delta E}/2$. Since most networks are small, the criterion, $\overline{\Delta V}<\overline{\Delta E}/2$ probably should always be used in preference to the less conservative one. The author uses criterion *B* for all networks or groups having less than six units in parallel.

General Conclusions

Load ratio control transformers operating in parallel on the same bus or in a network can be made to operate in a stable manner, be made to correct for circulating currents, and be made to give a specified amount of voltage boost at peak load by proper adjustment of their compensators and voltmeters. Three different criteria may be used in making these adjustments:

Criterion *A*—$\overline{\Delta E}<\overline{B.W.}$
$\overline{\Delta V}<\overline{\Delta E}$

Criterion *B*—$\overline{\Delta E}<\overline{B.W.}$
$\overline{\Delta V}<\dfrac{\overline{\Delta E}}{2}$

Criterion *C*—$\overline{\Delta E}-\overline{\Delta V}<\overline{B.W.}$
$\overline{\Delta V}<0$

The criterion used will depend on:

1. The amount of circulating current permissible.
2. The amount of voltage regulation required at peak load.
3. Whether the number of units in parallel is small or large.

Criteria *A*, *B*, and *C*, in this order, give increasingly more positive assurance of stable operation and increasingly greater limitation on circulating currents. Criteria *A*, *B*, and *C*, in this order, give an increasingly smaller amount of voltage boost possible at peak loads for a specific compensator.

Criterion *A* should preferably not be used for less than six units operating in parallel. It is well suited to large networks. Criterion *B* is the preferred one since it represents the best compromise for stability control and voltage regulation. Criterion *C* would only be used where it is desired to keep all units within one tap of each other (except when correcting for circulating currents), and to insure maximum stability.

Appendix. Compensator Adjustments

Case of Two Units in Parallel

The foregoing analysis has indicated criterion *A* to be unsatisfactory, the choice being between *B* and *C*.

First consider criterion *B* which states that:

$$\overline{\Delta E}<\overline{B.W.} \text{ (to prevent pumping)} \tag{10}$$

$$\overline{\Delta V}<\frac{\overline{\Delta E}}{2} \text{ (for stability)} \tag{11}$$

By definition:

$$\overline{\Delta V}=\frac{\overline{\Delta E}}{Z_{ct}}\left[(R_t+R_c)\cos\theta_{ct}+(X_t+X_c)\sin\theta_{ct}\right]$$

$$\cos\theta_{ct}=\frac{R_{ct}}{Z_c}$$

$$\sin\theta_{ct}=\frac{X_{ct}}{Z_{ct}}$$

$$Z_{ct}=\sqrt{X_{ct}^2+R_{ct}^2} \tag{12}$$

This is simply the value of the voltage consumed in the transformer impedance (and the system back of it) and the compensator impedance by the circulating current due to one tap change.

Combining (11) and (12) we get:

$$R_c\cos\theta_{ct}+X_c\sin\theta_{ct}<\frac{Z_{ct}}{2}-R_t\cos\theta_{ct}-X_t\sin\theta_{ct}<\frac{R_L\cos\theta_{ct}+X_L\sin\theta_{ct}}{2} \tag{13}$$

Since

$$Z_{ct}=(2R_t+R_L)\cos\theta_{ct}+(2X_t+X_L)\sin\theta_{ct} \tag{14}$$

From relation 13

$$X_c<\left(\frac{R_L}{2}-R_c\right)\left(\frac{R_{ct}}{X_{ct}}\right)+\frac{X_L}{2} \tag{15}$$

If the two units are bussed, R_L and X_L become zero and equation 8 becomes:

$$X_c<-R_c\left(\frac{R_{ct}}{X_{ct}}\right) \tag{16}$$

Thus X_c is limited by the value of R_c and R_c is determined by the value of regulation required at normal load. This is:

$$e=(R_t+R_c)\cos\theta_L+(X_c+X_t)\sin\theta_L \tag{17}$$

Substituting the value of X_c (equation 15 in 17) we get:

$$R_c>\frac{e-(R_t\cos\theta_L+X_t\sin\theta_L)}{\sin\theta_L\left(\dfrac{\cos\theta_L}{\sin\theta_L}-\dfrac{R_{ct}}{X_{ct}}\right)}-\frac{\left(\dfrac{X_L}{2}+\dfrac{R_LR_{ct}}{2X_{ct}}\right)}{\left(\dfrac{\cos\theta_L}{\sin\theta_L}-\dfrac{R_{ct}}{X_{ct}}\right)} \tag{18}$$

If the compensator is not required to compensate for transformer regulation at peak load, the term in the numerator, $(R_t\cos\theta_L+X_t\sin\theta_L)$ drops out.

If the two units are bussed and there is no tie line, R_L and X_L are zero and the last term in equation 18 drops out.

If both of these conditions prevail, that is, the units are bussed and transformer compensation is not required, equation 18 becomes:

$$R_c>\frac{e}{\cos\theta_L-\dfrac{R_{ct}}{X_{ct}}\sin\theta_L} \tag{19}$$

Allowing a 10 per cent factor of safety for X_c, relations 16 and 19 become:

$$X_c=1.1R_c\frac{R_{ct}}{X_{ct}} \tag{20}$$

$$R_c=\frac{e}{\cos\theta_L-1.1\dfrac{R_{ct}}{X_{ct}}\sin\theta_L} \tag{21}$$

These have been plotted for several load power factors, values of e and R_{ct}/X_{ct}, in Figures 25, 26, and 27.

Now consider criterion C which states that:

$$\overline{\Delta E}-\overline{\Delta V}<\overline{B.W.}\text{ (to prevent pumping)} \quad \textbf{(22)}$$

$$\overline{\Delta V}<0 \quad \text{(for stability)} \quad \textbf{(23)}$$

Relation 22 states that not only must X_e be always negative, but sufficiently so that $\overline{\Delta V}$ is also always negative. This is a rigid criterion, but will insure the two units against ever getting more than one step apart in any case and it will insure against even one step apart if the two units are on the same bus. This criterion also means that the change in voltage at the voltmeter following a tap change will always exceed the magnitude of the tap change.

Expanding relation 23, we have:

$$\overline{\Delta V}=\frac{\overline{\Delta E}}{Z_{ct}}[(R_t+R_c)\cos\theta_{ct}+(X_t+X_c)\times \sin\theta_{ct}]<0 \quad \textbf{(24)}$$

$$[(R_t+R_c)\cos\theta_{ct}+(X_t+X_c)\sin\theta_{ct}]<0 \quad \textbf{(25)}$$

$$X_c<-\left[(R_t+R_c)\frac{R_{ct}}{X_{ct}}+X_t\right] \quad \textbf{(26)}$$

Combining equations 17 and 26, we obtain a value of R_c to give the desired voltage regulation e at normal load.

$$R_c<\frac{e-(R_t\cos\theta_L+X_t\sin\theta_L)}{\sin\theta_L\left(\frac{\cos\theta_L}{\sin\theta_L}-\frac{R_{ct}}{X_{ct}}\right)}+\frac{\left(\frac{R_tR_{ct}}{X_{ct}}+X_t\right)}{\left(\frac{\cos\theta_L}{\sin\theta_L}+\frac{R_{ct}}{X_{ct}}\right)} \quad \textbf{(27)}$$

If 10 per cent factor is applied in adjusting X_c, relations 26 and 27 become:

$$X_c=1.1\left[(R_t+R_c)\frac{R_{ct}}{X_{ct}}+X_t\right] \quad \textbf{(28)}$$

$$R_c=\frac{e-(R_t\cos\theta_L+X_t\sin\theta_L)}{\sin\theta_L\left(\frac{\cos\theta_L}{\sin\theta_L}-1.1\frac{R_{ct}}{X_{ct}}\right)}+\frac{\left(\frac{R_tR_{ct}}{X_{ct}}+X_t\right)}{\left(\frac{\cos\theta_L}{\sin\theta_L}-\frac{1.1R_{ct}}{X_{ct}}\right)} \quad \textbf{(29)}$$

The term $(R_t\cos\theta_L+X_t\sin\theta_L)$ may be dropped from equations 20 and 22 for the value of R_c if regulation to compensate for transformer impedance is not necessary.

Having determined X_c and R_c, $\overline{\Delta V}$ should be computed from (24) and the value of $\overline{B.W.}$ determined from (22).

In using criterion B, it might be found that R_c is too great to be obtained on standard compensators. If so, it can be reevaluated from (26), and it can be set at its maximum value. In this case, of course, e will have a value less than desired. Its actual magnitude may be determined from (29).

Example

Assume two similar transformers are networked over a tie line. Assume five per cent voltage boost is required at peak load (compensation for transformer regulation not required), and that the units are never to get more than two steps apart except to correct for circulating currents arising from outside influences. Assume the system constants as follows:

$\overline{\Delta E}=1.25\%$ $\quad X_L=6\%$ $\quad e=5\%$

$X_t=8\%$ $\quad R_L=3\%$ $\quad \cos\theta_L=0.80$

$R_t=2\%$ $\quad \sin\theta_L=0.60$

From these we obtain:

$X_{ct}=(2\times8+6)=22$

$R_{ct}=(2\times2+3)=7$

Criterion B will be applied in this case and from (15) and (18) above we get:

$$R_c>\frac{5}{0.6\left(\frac{0.8}{0.6}-\frac{7}{22}\right)}-\frac{\left(\frac{6}{2}+\frac{3\times7}{2\times22}\right)}{\left(\frac{0.8}{0.6}-\frac{7}{22}\right)}>4.7\%=5.3\%\text{ (allowing 10\% margin)}$$

$$X_c<\left(\frac{3}{2}-5.3\right)\frac{7}{22}+\frac{6}{2}<1.792=1.6\text{ (allowing 10\% margin)}$$

In this case,

$$\overline{\Delta V}=\frac{\overline{\Delta E}}{Z_{ct}}[(R_t+R_c)\cos\theta_{ct}+(X_t+X_c)\sin\theta_{ct}]$$

$$=\frac{1.25}{23.0}\left[(2+5.3)\frac{7}{23}+(8+1.6)\frac{22}{23}\right]$$

$$=0.61$$

The band width in this case would probably be set at about two per cent.

Suppose, now, that these two units had been bussed in which case R_L and X_L would be zero. From (16) and (19) above

$$R_c>\frac{5}{0.8+\frac{7}{22}\times0.6}>5.61=6.2\%\text{ (allowing 10\% margin)}$$

$$X_c<-6.2\frac{7}{22}<-1.97=-2.3\%\text{ (allowing 10\% margin)}$$

$$\overline{\Delta V}=\frac{1.25}{23.0}\left[(2+6.2)\frac{7}{23}+(8-2.3)\frac{22}{23}\right]=0.43$$

$$\overline{B.W.}>1.25+0.43>1.68=2\%\text{ or more}$$

Compensator-Adjustment Case of More Than Two Units in Parallel

As was pointed out above, criterion A would be adequate in a large network with a large number of units, but probably would not insure stability in a network of from two to five units. Consider the case where criterion A is adequate.

$$\overline{\Delta E}<\overline{B.W.} \quad \textbf{(30)}$$

$$\overline{\Delta V}<\overline{\Delta E} \quad \textbf{(31)}$$

Combining relations 31 and 12 we get—

$$X_c<\frac{Z_{ct}-(R_t+R_c)\cos\theta_{ct}-X_t\sin\theta_{ct}}{\sin\theta_{ct}} \quad \textbf{(32)}$$

Substituting this value of X_c in equation 17 we get for R_c:

$$R_c>\frac{e-(R_t\cos\theta_L+X_t\sin\theta_L)}{\sin\theta_L(\cot\theta_L-\cot\theta_{ct})}-\frac{Z_{ct}-(R_t\cos\theta_{ct}+X_t\sin\theta_{ct})}{\sin\theta_{ct}(\cot\theta_L-\cot\theta_{ct})} \quad \textbf{(33)}$$

Relations 32 and 33 cannot be further simplified, as in the case of two similar units, because Z_{ct} cannot be expressed in terms of the other quantities. The value of Z_{ct} for any particular unit will be the driving point impedance from the source through that unit and into the network.

The term $(R_t\cos\theta_{ct}+X_t\sin\theta_{ct})$ may be dropped from equation 33 if regulation to compensate for transformer impedance is not necessary.

If the network is small and it is decided to use criterion B instead of A, the proper expressions for R_c and X_c may be determined by replacing the term, Z_{ct}, in equations 32 and 33 with $Z_{ct}/2$.

Definition of Symbols

E_1, E_2—System voltages back of network on T_1 and T_2

V_1, V_2—Voltages impressed on contact-making voltmeter of T_1 and T_2

$\overline{\Delta E_1}$, $\overline{\Delta E_2}$—Change in E_1 and E_2 due to one tap change or regulator step

$\overline{\Delta V_1}$, $\overline{\Delta V_2}$—Change in V_1 and V_2 due to circulating current in transformer and compensator impedances following a tap change

R_{t1}, R_{t2}—Transformer resistances for T_1 and T_2

X_{t1}, X_{t2}—Transformer reactances for T_1 and T_2

R_{c1}, R_{c2}—Compensator resistances for T_1 and T_2

X_{c1}, X_{c2}—Compensator reactances for T_1 and T_2

X_L—Line reactances

R_L—Line resistances

R_{ct}—Circulating resistances

X_{ct}—Circulating reactance

Z_{ct}—Circulating impedance

$\overline{B.W.}$—Band width of voltmeter

e—Voltage boost required by compensator at normal load

θ_{ct}—Power-factor angle of circulating current

θ_L—Power-factor angle of load

d—Critical magnitude of sudden voltage dips

n—Number of tap changes required to reach a stable condition

All of the above voltage and impedance quantities are in per cent on base kilovolt-amperes and voltage. R_t and X_t include system resistance and reactance back of the transformer.

Tennessee Valley Authority Hydroelectric Stations—Electrical Design

RAYMOND A. HOPKINS
MEMBER AIEE

THE Tennessee Valley Authority, since its establishment in 1933, has, among its many other activities, developed an electric generating and transmission system which now has a generating capacity of 1,050,200 kilowatts in 69 generating units, a one-hour peak load of about 907,200 kilowatts, and a monthly output of 520,000,000 kilowatt hours. The original generating facilities taken over by the Authority in the fall of 1933 consisted of the Wilson Hydro and Steam Plants both built at Muscle Shoals, Alabama, by the United States Government during the years 1918 to 1925 and totaling 244,000 kilowatts in generating capacity. During subsequent years the Authority has acquired and leased from private utilities previously operating in the Tennessee Valley area 5 hydro plants and 4 steam plants, totaling 292,300 kw in generating capacity, with transmission lines. Up to the present time the Authority has built and put into operation 6 new hydro plants and extensions to existing hydro plants, totaling 513,900 kilowatts in 15 generating units, with transmission lines. The Authority now has under construction 6 new hydro plants, 1 new steam plant and extensions to 2 existing hydro plants, totaling 969,200 kilowatts in 29 generating units, with transmission lines. The system as now operating and under construction, including the future generating units definitely provided for, will have a total capacity of 2,584,700 kilowatts in 115 generating units.

This paper discusses the principal electrical design features of the ten hydroelectric stations designed and constructed or under construction by the Tennessee Valley Authority. Ocoee No. 3 and Apalachia, authorized in July 1941, are now in the early stages of design and are not described herein.

The Transmission System

Figure 1 presents a map of the Tennessee Valley area showing, as of August 1941, locations of the principal generating stations, transmission lines, substations, and points of interconnection with adjacent systems. Table I lists the principal generating stations as of August 1941, giving the number of units and capacities at each station.

The voltage of the main transmission system, nominally 154-kv, was chosen because study indicated that this voltage would be adequate for transmission purposes within the Tennessee River Basin, and also because 154-kv was already established at Muscle Shoals. The 500-mile transmission line connecting Norris, Watts Bar, Wheeler, Wilson, and Pickwick dams and the Memphis substations has, however, been designed for 220-kv operation to provide the higher transmission voltage if it is required in the future, but is now operated at 154,000 volts. All new generating stations have been connected to the 154-kv transmission system.

The lower voltages, 110-, 66-, and 44-kv, were also existing in the Valley. At Norris, Pickwick, and Guntersville, auto transformers are installed to supply 110-kv transmission. At Chickamauga 3-winding step-up transformers are provided to serve the 44-kv transmission system of the city of Chattanooga, both from the generators and from the 154-kv system. As a rule, step-down points have been located near load centers and not at generating stations, but in every case where the most economical step-down location is in the vicinity of a generating station, the economies of centralized station attendance have been secured by combining the step-down and generating stations.

The Generating Stations

Two general designs of generating station arrangement have been developed to suit the two general classes of sites: (1) the tributary developments, and (2) the main river developments. While these two patterns do not represent all the variations of design employed to meet various specific requirements of each site, they do give a general picture of the two fundamental classes of developments.

The tributary development, illustrated by Figures 2, 3, and 4 is in many respects typical of Norris, Hiwassee, and Cherokee. There is no navigation lock. The dam is high, and the spillway is short. The concrete dam abuts rock on both sides of the river. The water wheels are Francis type, of relatively large capacity and small number. Being usually away from load centers, the plant requires only a minimum number of transmission lines. Sloping, rocky, and often steep terrain usually requires a high, stepped switchyard structure.

The main river development, illustrated by Figures 5, 6, and 7 is in many respects typical of Wheeler, Pickwick, Guntersville, Chickamauga, Watts Bar, Kentucky, and Fort Loudoun. This type of development usually requires a navigation lock, a long adjustable spillway, long earth embankments, propeller-type water wheels of relatively small capacity in large number, and a number of transmission lines. Sufficient level natural terrain or fill is usually available for a low, flat, economical switchyard arrangement.

The electrical bay is generally located downstream from the generator room and extends the full length of the generator room in space available over the draft tubes without adding to the total width of the structure. Within the electrical bay are located the generator-voltage switchgear and connections, the station service transformers and switchgear, the control cable tunnel for serving the generating units, and the generator fire protective equipment.

The service bay is at the shore end of the station. It contains facilities for the handling of incoming equipment, space for assembly of water wheel and generator parts, and auxiliary equipment common to the entire station such as machine shop oil purifying and storage facilities and sump pumps. The control room is located in the upper part of the service bay where it is somewhat central between the generators and switchgear in the station and the transformers and switchgear in the yard. Office space and public facilities are also located in the service bay.

The transformers and switchyard are usually located on shore slightly downstream from the centerline of generating units, although the exact location is largely determined by the topography. At all plants except Pickwick, local topography permits the alternating of generators and lines along the bus.

Main Electrical Connections

The single line wiring diagram of Figure 8 is in many respects typical for the new

hydro stations designed and built by the Authority.

All generation for the new plants is at 13,800 volts, with step-up transformers connecting the generators to the 154-kv transmission system. At Norris, Pickwick, Guntersville, Watts Bar, and Hiwassee, one transformer bank is provided for each generator, with no circuit breakers between the generator and transformer, so that they are operated as a unit with all switching on the high voltage side of the transformers. At Wheeler, Kentucky, Cherokee, and Fort Loudoun, one transformer bank is provided for each pair of generators, and generator circuit breakers are provided in addition to the breakers on the high voltage side of the transformers. At Chickamauga, one bank is provided for each generator, but since three-winding transformers are required to serve the 154-kv and 44-kv systems, generator breakers are provided for switching the generators without interrupting the 154-kv–44-kv connections.

The scheme of bussing and switching of the 154-kv circuits has proved to be simple, economical, adaptable to all system operating requirements, and susceptible to a number of modifications to meet specific requirements. Fundamentally it is the main-and-transfer-bus scheme with each circuit connected to the main bus by one breaker and to the transfer bus by a motor-operated disconnecting switch. The conventional bus tie bay with bus tie oil circuit breaker is not provided but two oil circuit breakers are provided for at least one and usually for each main step-up transformer for connecting to both the main and transfer busses. The saving in eliminating the bus tie bay largely offsets the cost of the additional breakers which are considered as spare breakers and which can be substituted for any of the normal transformer or line breakers for use in case of breaker trouble, for maintenance and inspection of breakers, and for special system operating setups. Each spare breaker is equipped with a set of overcurrent and directional ground relays for emergency use in the event of failure of normal transmission line relays.

The main-and-transfer bus arrangement is also used for the 110-kv switchyards and for some of the lower voltages which are fed from the 154-kv busses through auto-transformers. Following the 154-kv practice, bus tie bays are not provided for the spare breakers but instead the auto-transformer circuits are provided with double low-voltage circuit breakers to connect the auto-transformers to both the main and transfer busses. At Chickamauga, the double-bus double-breaker arrangement for 44-kv circuits is used to provide the most reliable service possible for the important load of the city of Chattanooga.

Modifications of the main-and-transfer-bus scheme can be readily made without any major changes to structures or moving of equipment. During the early stages of development of a station, when not more than two circuits are installed, for instance a transformer with one outgoing line, a single high voltage breaker with bypass disconnect can be used. Later, with three or four circuits, the ring-bus scheme with one breaker per circuit can be used by extending the original structure. With this scheme, each circuit is connected to two breakers and the busses are included in the relay protection of the circuits. With more than four circuits the ring-bus scheme is readily developed into the main-and-transfer-bus scheme by again extending the same structures. At stations where lines and generators can be paired, the adding of sectionalizing disconnects in the transfer bus permits the breaker-and-a-half scheme of operation with one and a half breakers per circuit. Under this method of operation, each circuit is connected to two breakers, the busses are provided with differential relay protection, all breakers are operated closed and all bus sections energized. Considerable operating flexibility is secured to meet emergency or special loading conditions or for operating with the system split. The conventional double-bus double-breaker scheme with two breakers per circuit can be secured, if needed, by merely removing a disconnect motor mechanism and adding a breaker and isolating switch for each line circuit.

Generators

Ratings of turbines at all plants are based on normal heads. Greater capacities, averaging in the neighborhood of 16 percent greater, are inherently available at maximum heads. A normal generator rated at 60-degree rise, allowable with class *A* insulation, has a capacity about 15 percent greater if operated at 80-degree rise, allowable with class *B* insulation. To match the variable turbine outputs due to head variations, the generator is provided with class *B* insulation but is given a normal rating at 60-degree rise about equal to the turbine rating at normal head. It, therefore, operates at conservative temperatures ranging from 60-degree rise to 80-degree rise with full gate, at heads ranging from normal to maximum. It is expected that the total time of operation at the higher temperature under high heads will not be sufficient to reduce materially the normal life of the insulation. Table II illustrates the above coordination of ratings by actual data from four typical installations.

Power factor ratings are all 0.9. Actual power factor under full load generation is usually above 0.95 lagging. At some plants, particularly those near heavy load centers, generators are often floated at zero load, leading power factor to assist power transmission and to stand by as spinning reserve generating capacity. Voltage rating is uniformly the AIEE standard, 3-phase, 60-cycle, 13,800-volt with performance tolerance of 5 percent plus or minus.

The general type of generator at all plants is vertical shaft with bearings below the rotor. The shaft is coupled to the water wheel; the rotor is overhung above the thrust and guide bearings; the ventilating air is re-circulated by means of fans on the rotor within a closed housing and is cooled by water from the scroll case; the main and pilot exciters are on the shaft above the rotor and uniquely telescoped one within the other. Table III presents principal turbine-generator data from four typical installations.

The shaft is a solid forging with a flange at the lower end for coupling to the turbine shaft, and in most cases it is also flanged at the upper end to receive the rotor which is centered by a male-female fit, keyed by a diametrical torque key and secured by bolts.

The rotor is of conventional design with a fabricated or forged hub, fabricated arms, laminated rim, and field poles. It is assembled and stacked on a center pedestal on the erection floor of the powerhouse.

The thrust bearing and the guide bearing are located immediately below the rotor in the same lubricating oil reservoir, and both bearings are self-lubricating without the assistance of oil pumps. The oil is cooled by water coils. Temperatures of the oil and of the stationary shoes are measured by thermometers which indicate and record on the turbine gauge board.

The stator is shop-fabricated in four or more sections, and in most cases completely assembled and wound at the factory with the exception of the joint coils and their connections, which must be assembled and connected at the site. At Chickamauga, all the stator coils were installed at the site after the stator was completely assembled. All stator windings are arranged in two parallel paths per phase, and both ends of each path are brought out to terminals for protective relaying. The neutral ends are bussed within the generator housing and one lead is carried out for grounding.

The neutral is grounded through an individual reactor for each generator. The value of reactance is chosen to limit the phase-to-ground fault current to a value about equal to the phase-to-phase fault current. This amount of neutral reactance is low enough to assure dependable generator relay action and to avoid danger of resonant voltages and is high enough to avoid excessive fault currents.

The excitation system consists of a main exciter and a pilot exciter directly connected to each generator main shaft above the rotor, together with rheostats, switching, and regulation. Spare exciters are not provided since experience records of low-speed, direct-connected exciters indicate generally better reliability than other essential parts of the entire turbine-gener-

ator unit. All exciters are rated 250 volts and the main exciters have a ceiling voltage of 325 volts. The main exciter is connected directly to the generator field without rheostat or breaker. Voltage control is by electrically operated rheostat and breaker in the main exciter field circuit. The pilot exciter field circuit has no circuit breaker but is provided with a manually operated rheostat which is given a permanent setting during preliminary operation and adjustment of the unit. The rheostats and breaker, together with the voltage regulator contactors, are located in a steel cubicle on the operating floor close to each generator with the result that the entire excitation circuit is short and compact.

Voltage regulation acts upon the field rheostat of the main exciter. The regulator measures voltage through a three-phase torque motor connected to potential transformers on the generator main leads. Cross-current compensation is used where two generators are connected to one transformer bank to assure proper division of wattless current between the two generators. The regulator is the standard face-plate, rheostatic type with high and low contactors for quick response. The nominal exciter response ratio is 1.0, and the speed of response is 3 cycles or less.

A voltage-limiting device is provided for limiting automatically the pilot exciter voltage in case of overspeed. It consists of a fixed resistance in series with the pilot exciter field rheostat, and normally shunted by a contactor which opens on excessive pilot exciter voltage and re-closes on restoration of normal voltage. The contactor is controlled by a d-c overvoltage relay connected to the pilot exciter main leads. An a-c overvoltage relay is also provided and connected to potential transformers on the main generator leads. The relay actuates the quick-lowering contactor on the main exciter field rheostat and is set to operate at about 16,000 volts.

Carbon dioxide fire extinguishing equipment is provided at each station for the protection of the generators. The enclosed generator housing, which is made especially tight for this purpose, renders this type of protection particularly effective. A centralized assembly of standard 50-pound, 850-pounds-per-square-inch, carbon dioxide cylinders is provided for a group of one to five generators. The liquid is automatically discharged and routed through valves and permanent piping to the particular generator indicated, where it is discharged through nozzles into the generator. The initial discharge provides a concentration of not less than 50 percent within the generator, which is sufficient to extinguish a fire and is effective in cooling any hot metal. This is followed by delayed discharges automatically timed to maintain for 30 minutes a concentration of not less than 25 percent, which is sufficient to prevent reignition. The initiation of the discharge is actuated either by thermostats within the generator housing, by the operation of the generator differential relays, by a break-glass push-button station located on the turbine gauge board, or by a manual release at the centralized assembly of carbon dioxide cylinders

Generator-Voltage Switchgear and Connections

Indoor switching apparatus, including breakers, switches, instrument transformers, arresters, and condensers for the generator-voltage circuits, is assembled in factory-built metal cubicles. Each generator circuit is isolated in a separate room in the electrical bay. Enclosing cubicles are of steel or aluminum, as best adapted to each application. Breaker enclosures requiring considerable structural strength are of steel plate reinforced with structural steel frames and protected by Parkerizing and painting. Barriers between phases are of non-magnetic steel or aluminum. In locations where re-painting is difficult, copper-bearing steel is used. Enclosures for disconnecting switches, instrument transformers and other light equipment and for the busses are generally of aluminum sheet with aluminum barriers. The principal advantages of aluminum for enclosures are ease of fabrication, light weight, and permanence without paint or other protection. Recently, due to greater need of aluminum elsewhere, steel cubicles with copper or transite barriers are being substituted. Hinged doors and glazed windows are provided as required for access and vision to the interiors. Ventilation is provided usually by gravity circulation through screened louvers. All enclosures are assembled and riveted in the shop in as large units as can be conveniently handled, and these units are bolted together in the field.

Cables from the generators to the switching cubicles are insulated with corona-resisting rubber compound, shielded with copper tape, and covered with tape and braid. At each end the braid and copper shield are removed for a sufficient distance back from the lug to provide adequate creepage distance. The shielding tape is belled out at each end to form a stress cone and is grounded. Such circuits are designed for conductor tempera-

Capacity with fans, kva	36,000	40,000	48,000	75,000

tures not exceeding 70 degrees centigrade.

Cables from the switching cubicles to the main transformers in the switchyard are generally paper-insulated, lead-covered, and installed in transite ducts surrounded by concrete envelopes. To protect the lead against alkaline corrosion, the sheaths are protected by waterproof tapes or rubber jackets. To prevent excessive sheath currents and voltages, the sheaths are grounded at each end and insulated by porcelain sleeves at about midpoint. Such circuits are designed for conductor temperatures up to 82 degrees centigrade. Where a vertical rise of over approximately 30 feet is required, varnished cambric insulation with non-migrating impregnating compound and shielding tape is used. The covering is braid if conditions are dry, and rubber jacket if conditions are likely to be wet. Such cables are designed for conductor temperature not exceeding 78 degrees centigrade. Configuration of the cables in all these long runs is chosen to give the most uniform division of current consistent with a practical physical arrangement.

Bare structural shapes used within the switching cubicles and in some cases for heavy circuits between the cubicles and the transformers consist of flat bars, tubes, or channels. Joints are silvered and bolted where many connections and taps are required and are welded where long uninterrupted runs are involved. At Hiwassee the leads from the generators to the transformers, having a capacity of 3,200 amperes per phase and a length of about 180 feet, consist of two aluminum 6-inch channels per phase, forming a hollow square with ventilation top and bottom and with welded joints. With the absence of low voltage busses, the short circuit stresses at all plants are within the limits of conventional bus supports. Enclosures for these heavy circuits are of non-magnetic material, usually aluminum plate. Such circuits with silvered and bolted joints or with welded joints are designed to operate at conductor temperatures not exceeding 85 degrees centigrade. At Hiwassee forced ventilation of the housing is provided.

Transformers

Transformers for stepping up the generation voltage to the transmission voltage are self-cooled with blowers on the radiators. This type of cooling provides a range of capacity somewhat corresponding to the range of generator 60-degree to 80-degree capacity, as described under "Generators." The generator capacity, however, at 80-degree rise is 115 percent of its capacity at 60-degree rise, while the transformer capacity when blown is 133 percent of its capacity self-cooled. Hence, for a generator having for example a capacity range from 100 to 115, the transformer might be assigned a capacity range from 86 to 115, or from 100 to 133, or any $33^{1}/_{3}$-percent range intermediate between these two extremes. Since experience indicates that the transformer is usually designed on a little closer margin than the generator, and since the blower capacity is secured by forced cooling which results in a greater spread between hot-spot temperature and indicated temperature, the transformer rating is chosen somewhat above the middle of the permissible range, say, 96 to 128. This coordination of transformer and generator ratings is illustrated in Table II by actual data from four typical installations.

Auto-transformers for power transfer between two system voltages at the same generating station are also self-cooled with blowers, but their ratings are determined entirely by power system requirements. In some cases the blowers are omitted in the initial installation and added as power-transfer requirements increase.

The three-phase transformer is preferred to a bank of single-phase transformers because of its lower cost, smaller size, simpler wiring, and less maintenance. It, of course, has a cost disadvantage when a spare unit is required, and it becomes difficult to ship and handle in the large sizes, particularly in cases where more than two windings are required, or where load-ratio control is required. The policy of the Authority is to use three-phase transformers generally for the smaller banks, particularly in multi-unit stations, and single-phase transformers for the larger banks and for those having three windings or load-ratio control.

The transformers are built generally to conventional standards. Oil is maintained by inert gas in the tank above the

oil level. Standard no-load ratio changers are provided in the neutral ends of the high-voltage windings. For the three-winding step-up transformers at Chickamauga and for most of the auto-transformers used for system power transfer, load-ratio changers are provided with remote control and indication at the main switchboard. The autotransformers at Norris and Pickwick and the three-winding transformers at Chickamauga are provided with automatic voltage control equipment to maintain predetermined voltages on the 110-kv and 44-kv busses.

The neutrals of the wye-connected high-voltage windings are grounded through a single neutral reactor for each transformer bank. The value of neutral impedance is chosen between two criteria: high enough to limit phase-to-ground fault currents to values not greater than three-phase fault currents, and low enough to limit the ratio of zero to positive sequence impedance to not greater than two.

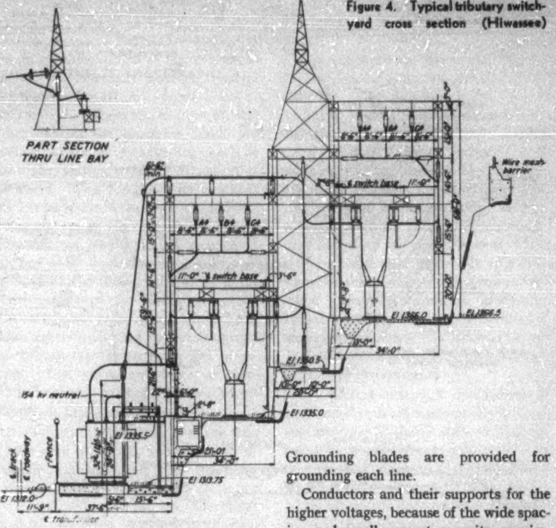

Figure 4. Typical tributary switchyard cross section (Hiwassee)

Transmission-Voltage Switchgear and Connections

Two general designs of switchyard arrangements have been developed to suit the two general classes of plants described under "The Generating Stations." The tributary plants where the terrain is steep are illustrated in Figure 4, and the main river plants where ample level ground area is available are illustrated in Figure 7. Both of these general types are designed to be developed into the ring-bus scheme, the main-and-transfer-bus scheme, the breaker-and-a-half scheme, or the double-bus double-breaker scheme of connections as described under "Main Electrical Connections."

Oil circuit breakers, disconnecting switches, and other equipment are all of conventional outdoor design. The 161-kv breakers are 2,500,000-kva 8-cycle tripping class except Guntersville and Norris which are 1,500,000-kva, 8-cycle tripping class. The 115-kv breakers are 1,500,000-kva, 8-cycle tripping class. Except for the original installations at Norris and Wheeler all line breakers are of the 35-cycle reclosing type. At the present time, however, the breakers are not operated as 35-cycle reclosing breakers but instead the breakers are arranged to reclose only on a de-energized line or bus or on an energized line which is in synchronism with the bus as determined by a synchronism check relay. In the future, after additional tie lines have been installed to give greater assurance that synchronism will be maintained between the two ends of a line which has tripped out, it is expected that the high-voltage line breakers will be provided with relays to reclose the breakers in 35 cycles without checking synchronism or voltage. Higher speed closing and reclosing breakers are now being considered for critical locations on the system. Breakers of each rating are interchangeable with respect to locations of current transformers, mechanisms, oil connections, and other accessories. Oil supply and return lines are installed under the surface of the yard near the breakers with outlets for temporary hose connections for filling, draining, and filtering from an oil storage and treating plant located either in the yard or in the powerhouse.

Disconnecting switches have two fixed insulator stacks and one rotating insulator stack, and are mounted either upright or underhung. Those used for isolating circuit breakers and other devices are 3-pole manually operated. Those used for connecting circuits to the transfer bus and for sectionalizing the busses are 3-pole electrically operated. Interlocking of the electrically operated disconnects with breakers to prevent operating them under load is not found necessary, but as an operating aid, two control switches for each disconnect are used on the control board, and are so wired that both must be turned simultaneously to operate the disconnect. This scheme has proved to be simpler and just as reliable as interlocking the disconnect with the breaker. Grounding blades are provided for grounding each line.

Conductors and their supports for the higher voltages, because of the wide spacing and small current capacity requirements, constitute a design problem which is principally a structural one. Busses are of four-inch galvanized steel pipe with welded connections. The welds are zinc-sprayed outside and asphaltum-painted inside. The busses are supported on pedestal insulator stacks. At the terminals of equipment such as transformers, arresters, and disconnects, flexible connections are provided to prevent unnecessary stresses on the porcelains. Connections from breakers to lines are of stranded copper cables supported on strain insulators.

Structures are of conventional latticed truss, galvanized steel construction, standing on concrete foundations. Trusses and columns are shop-riveted in maximum allowable shipping lengths and field-bolted as erected.

The surface of the switchyard is drained and finished with from 6 to 12 inches of crushed stone which is intended, among other things, to dissipate heat in case of an oil fire. Walkways are provided for the most traveled routes.

Relaying

Each generator is protected against grounds, open circuits, and turn-to-turn faults by induction differential relays connected to give both over-all-differential and split-winding protection. The differential relays are connected in the full winding at the line end and half the wind-

Figure 5. Typical main river development (Chickamauga)

ing at the neutral end. An overcurrent ground back-up relay with a low current long-time setting is also provided in the generator neutral ground lead to protect against ground faults near the neutral end of the stator windings which would not ordinarily trip the main differential relays and also to serve as a back-up for the main differential relays. The relays are arranged to clear the generator, remove the excitation, shut down the turbine, and initiate the discharge of CO_2 into the generator housing. Where a generator is connected to its step-up transformer or to its auxiliary power transformer without breakers, the transformer is cleared along with the generator.

Each step-up transformer, auto-transformer, and main auxiliary power transformer is protected against internal faults by induction differential relays arranged to clear the transformer. Where a transformer is connected to a generator without breakers, the generator is also shut down but CO_2 is not released.

Main busses are protected by high-speed overcurrent relays which are differentially connected to isolate the bus section at fault. Auxiliary power busses are protected by overcurrent relays on incoming circuits.

The 154-kv transmission lines are provided with carrier current pilot relays, using the center conductor, *B*, of the transmission line flat configuration, and with directional overcurrent ground back-up. The 110-kv lines generally have distance phase relays and directional overcurrent ground relays with provision for future carrier current operation. The 66-kv lines are generally provided with distance relays. The 44-kv and 12-kv lines generally have 3-shot automatically reclosing breakers with induction overcurrent relays and both high-speed and standard-speed overcurrent directional ground relays, the high-speed ground relays being locked out after the first ground fault tripping. The high-speed and standard-speed ground relays are so coordinated with the 44-kv and 12-kv transformer and branch circuit fuses that for momentary ground faults the high-speed relay causes the breaker to clear the fault and reclose without blowing the fuse, and for permanent ground faults the standard-speed relay allows the fuse to clear the fault on reclosure of the breaker. A number of the shorter lines of various voltages are provided with pilot wire relays.

Annunciation

Audible and visual annunciation is provided for excessive temperatures of bearings, windings, air, oil, and water, abnormal liquid levels and flows, and faulty operation of equipment throughout the station. Those deserving the attention of the control room operator are located in the main control room, and those requiring the attention of the turbine room operator are located on the governor actuator boards. The audible signal can be silenced by a push button, but the visible signal persists until normal conditions are restored.

In connection with the annunciator, in the more recent installations, an operation recorder located on the operator's desk in the control room automatically records all annunciations and all normal operations such as starting, stopping, and switching. Each record on the strip chart of the recorder identifies the source of the signal and records the date and time when the signal is received. The time required by the recorder to set up the type wheels and print a signal is about $2^1/_2$ seconds. When signals are received at intervals shorter than $2^1/_2$ seconds, they are stored and subsequently recorded at $2^1/_2$-second intervals.

Lightning Protection

The overhead ground conductors coming in from the transmission lines are carried across the top of the switchyard in the form of a network supported by and grounded to steel peaks rising from the tops of the steel structures. The network is sufficiently extensive to include all equipment and conductors within a protective cone having a base radius equal to its height. The multiple points of support for the overhead network are thoroughly grounded to a ground network below the station which is also connected by underground cables to the footings of the nearest transmission line towers. Low resistance earth connections are secured by connecting the ground network to buried ground mats of copper cable or copper strap, driven ground rods and pipes, abandoned steel sheet piling, buried pipes, and penstocks. Arresters are provided at transformer high-voltage terminals, and in shunt with the transformer neutral grounding reactors. Each arrester is chosen with as little spread as possible between the break-down voltage and the reseal voltage and the latter is chosen with a safe margin above the maximum voltage expected at generator run-away speed. Spill gaps are provided at line entrances wherever a higher level of insulation is used on the line than in the switchyard, and in some cases as back-ups to the arresters. Arresters and condensers are provided at the terminals of generators.

Switchboards and Controls

The main electrical controls, instruments, and relays are centralized in the control room in the service bay at the end of the powerhouse while the turbine controls and instruments are located on the governor actuator cabinets on the operating floor near the turbines. The control room is partially soundproofed by the use of linoleum floor, acoustical tile ceiling, and double-glassed doors and windows. A specially designed asymmetrical indirect lighting system is provided, utilizing an arched ceiling and a deep gutter at the front of the room behind the operator. By this arrangement the front part of the ceiling is brightly and uniformly lighted, thus lighting the fronts of the boards without causing glare in instrument faces, and the rear part of the ceiling is lighted to a much lower intensity, thus avoiding any high lights within the vision of the operator facing the board. The room is air-conditioned, summer and winter. Files, supplies, toilet facilities, and lunching accessories are provided in small rooms adjoining the control room.

Within the control room, the controls and mimic busses are located on a free-standing benchboard. Instruments and relays are on two back-to-back vertical boards at the rear of the benchboard. Recorders and load-frequency controllers are on a vertical board at the left, while battery and standard frequency control and distribution are on a vertical board at the right. On the bench, instrument, and relays boards the generator panels are grouped at the left and the line panels at the right, leaving room for expansion at each end. With the generator panels at the left end toward the recorder and load-frequency board, the controls and indications for the generators are grouped at one end of the control room, and the controls and indications for the lines at the other end thus facilitating operation. The mimic bus presents a single-line diagram substantially like the actual switchyard, both diagrammatically and physically. The operators' desks are centrally located in front of the benchboard.

All switchboards are of steel cubicle construction with black finish. At the later stations all indicating and recording instruments are semi-flush type. Relays are generally of the conventional projection type although some of the later relay boards are being equipped with flush draw-out relays. Control handles are of distinctive shapes and colors for the various functions, uniform at all plants. Mimic busses are of chromium-plated brass, polished brass, and polished copper, representing various voltages.

Wiring of the switchboard panels is usually performed by the Authority's construction forces. It is carried in steel wiring gutters extending from top to bottom behind panel joints. At most of the generating stations the gutters extend down through the floor to terminal cabinets in a terminal room below. At some of the installations now under construction it is planned to locate the terminal blocks on wing panels behind the switchboards. From the terminal blocks, in each case, rubber-insulated, rubber-jacketed, multiconductor control cables are carried away on transite cable trays through a control cable tunnel extending the full length of the powerhouse and in the larger stations extending also out into the switchyard. From the cable trays in the tunnel, the control cables are carried in individual steel conduits to their destinations at equipment. Color coding of wires is not used but all conduits, cables, individual wires and terminal studs are tagged or marked with a uniform designation which is carried consistently throughout all conduit drawings and wiring diagrams. The multiple conductor control cables range in size from 2 conductors to 19 conductors. Each conductor is insulated with 35-percent performance rubber and the cable is covered with a 60-percent tough rubber jacket.

The control storage battery and the two duplicate motor generator sets operate at 250 volts. They are generally located immediately below the battery control and distribution board in the main control room. Smaller 48-volt batteries and charging rectifiers are provided for the annunciators and for the telephones.

A standard frequency source is provided in some of the stations for automatic time control of the power system. The source consists of an accurately adjusted, 60-cycle tuning fork, operating in a shock-proof, constant-temperature enclosure. Its accuracy is within three-fourths of a second in 24 hours. It is checked by Arlington radio time signals every day and corrected when necessary.

A 6-element automatic oscillograph is provided at each of the generating stations and arranged so that it may be plugged into the current and potential circuits of the transmission lines so that a record may be obtained of the current and voltage conditions in the lines under fault conditions. The oscillographs are of the switchboard type and are mounted on the main control switchboards. Darkroom facilities are provided close to the control room.

The governor cabinets on the turbine operating floor contain all essential auxiliary controls and instruments for operation of the turbines. These controls consist principally of bearing oil and cooling water pump controls, thermometers and pressure gauges, air brake controls and gauges, manual CO_2 release for generators and emergency shut-down switches. The generating units are started and brought up to speed by the turbine operator. Synchronizing and loading of the units is done by the main control room operator. The governor drive for most of the plants consists of a permanent magnet generator direct-connected to the generator shaft and a synchronous motor direct-connected to the governor head. At several of the plants, potential transformers connected to the generator main leads are used to drive the governors. Both methods of governor drive have proved satisfactory.

Auxiliary Power

The amount of auxiliary power load varies so greatly with the type of development that the demand can be estimated only by careful analysis of the connected load after the major features of the development and the expected operating procedures have been determined. At

Guntersville, with about 100 motors, 30 heaters, and the lighting system, the connected load amounts to 3,750-kva, and the demand is under 1,000-kva. At Hiwassee, with 66 motors, 35 heaters, and the lighting, the connected load is 1,895-kva, and the demand is under 600-kva. It is generally found that the demand amounts to from 25 to 30 percent of the connected load.

Figure 9 shows a single-line diagram of a typical auxiliary power supply and distribution system, simplified with respect to the distribution circuits for convenience of presentation. Two duplicate auxiliary power transformers constitute the normal supply. Each is connected to the low-voltage leads of a main step-up transformer and hence each has two sources of supply, one from the power system, the other from the generator. Each has a capacity sufficient for the entire auxiliary power demand of the station so that each may be considered a 100-percent spare for the other, although they may be operated separately at about half load. A third source consists of an auxiliary power transformer usually of much smaller capacity, stepping down from an outside source coming eventually from the transmission system. It may be used in case of emergency and for necessary lighting, heating, and pumping during any period when all generators are shut down and the main step-up transformers are de-energized. At Chickamauga, where the three-winding step-up transformers are connected to two high-voltage transmission systems, each of the two duplicate normal auxiliary power sources is always expected to be available and in this particular case the auxiliary power transformer from another outside source is not considered necessary. At some of the dams where it is of vital importance that spillway gates be operable in the extreme emergency of all electric power sources being lost, a small gasoline-engine-driven generator is provided for this purpose.

Voltage of motors and large heaters is 440-volt, 3-phase, 3-wire, ungrounded, and that for lighting and smaller heating units is 220/110-volt, single-phase, 3-wire, grounded. At a few of the larger plants such as Wheeler, a 2,300-volt, 3-phase, 3-wire, ungrounded system is also provided for the larger motors and for longer feeders.

Main feeders are provided with interlocked breakers at source and double-throw switches at destination so that sources of supply cannot be paralleled. Every bus and bus section is provided with a normal and an emergency source of supply. Transfer from normal to emergency is by manual switching. Automatic switching to the emergency source in case of loss of the normal source is not considered warranted, because of the complex relaying required, because such automatic switching always involves risk of spreading the fault, and because momentary interruptions to the auxiliaries do not affect power production. The manual transfer is accomplished by a momentary interruption of voltage which is considered more acceptable than the possibility of a surge resulting from momentary paralleling of sources of supply.

Inspection and maintenance of all parts of the auxiliary power distribution system may be done without seriously curtailing generation. The main auxiliary power bus is in two essentially duplicate sections, either of which, together with its supply and feeder breakers, can be retired leaving the other section and all essential auxiliaries in full operation. The bus sectionalizing breaker can be withdrawn for

maintenance, leaving both bus sections in operation. Each unit bus may be retired whenever its generator is shut down. Either section of the common bus may be retired without shutting down essential auxiliaries. Each circuit from the various distribution centers may be isolated individually by its own disconnecting switch.

Transformers are generally located indoors in order to secure short, well-protected primary and secondary connections, and are therefore of the noninflammable liquid-filled type. They are self-cooled and their rooms are adequately ventilated. Primary and secondary terminals and circuits are totally enclosed.

Protection of auxiliary power transformers is by differential relays and of the main auxiliary power busses by overcurrent relays. Motor and heater circuits are protected against overload by thermal relays on the contactors, and against short circuits by fuses on the disconnecting switches.

Switchboards are of dead-front, steel cubicle construction. The circuit breakers on the main 440-volt auxiliary power board are air-break type, having an interrupting rating of 20,000 rms amperes. The incoming breakers and the bus section breakers on this main board are electrically controlled from the main control room while the feeders are manually controlled at the board. Motor and heater circuits are generally electrically controlled at destination.

Wiring for auxiliary power circuits consists of single conductor cables insulated with 35-percent performance rubber, and covered with 60-percent tough rubber jacket. It is installed in steel conduits.

Communication

An automatic telephone system is provided in each generating station to provide communication, code call, fire alarm, police call, executive right-of-way, and conference service within the station, the switchyard, the dam, and the village. A manually operated key-type turret is located on the operator's desk in the main control room, through which connections can be made to the carrier current telephone system, establishing communication with other generating stations and with the load dispatcher's central office. The two outside phases, *A* and *C*, of the transmission system are used for the carrier telephone channel.

Lighting and Heating

The lighting and heating system originates at the two lighting and heating transformers, each of which is fed from a separate section of the main auxiliary power bus. Each transformer and its primary feeder has a capacity of about 75 percent of the combined lighting and heat-

ing demand. The transformers are normally operated independently on the two halves of the system, but manual switching is provided on the lighting and heating distribution board so that the entire system may be fed from either transformer. With this arrangement, 75 percent of the entire lighting and heating demand which includes all essential requirements for station operation can be carried indefinitely in case of outage of one transformer, one primary feeder, or one section of the main auxiliary power bus.

Emergency lighting from the 250-volt battery charging motor generator sets supported by the control battery is provided at all vital locations such as main control rooms, governor actuator boards, auxiliary power boards, pump rooms, electrical galleries, stairways, passages, and switchyard. The emergency lights form a part of the normal lighting system and burn along with the normal lights whenever lighting is required. The switching is so arranged as to promote the use of the emergency lights along with the normal lights, and in essential places the emergency lights are given precedence in switching. This assures that the emergency lights will be in service in case of a-c failure, and it stimulates the prompt replacement of burned-out lamps. Energy for the emergency lights comes normally from the motor generator sets which are driven from the a-c system, but in case of a-c outage the emergency lights are supplied by the battery without automatic or manual switching.

Short-Circuit Calculating Procedure for Low-Voltage A-C Systems

Discussion and author's closure of paper 41-67 by A. G. Darling, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1121–36.

R. H. Kaufmann (General Electric Company, Schenectady, N. Y.): The present tendency toward the use of circuit interrupting apparatus having shorter operating time, coupled with the more general application limitation by apparatus momentary current ratings, have given impetus to a more accurate method of evaluating maximum short-circuit currents, particularly within an interval of a few cycles following initial short circuit.

One outstanding feature associated with the proposed method of calculation procedure is represented by the ability to recognize and interpret the variable rate of decay of the initial d-c component of short-circuit current.

A brief discussion of the origin of the decrement curves and their significance would seem to be of interest.

In short-circuit analysis procedure there are several firm anchor points or bench marks which include:

1. Initial alternating component of current (I'') represented by E/Z''.
2. Initial d-c component which, at the most unfavorable switching angle may assume a value equal to the crest of the initial a-c component.
3. The initial transient portion of a-c current (I') represented by E/Z', to which value the initial total a-c component rapidly approaches following the short circuit. This quantity would represent the initial a-c current component were there no amortisseur effects in any of the rotating machines.

The d-c component of fault current decays exponentially at a rate controlled by the ratio of inductance to resistance in the a-c network between the internal generated voltages and the point of fault. Increased resistance in a given a-c network produces a correspondingly more rapid decay of this d-c component.

The subtransient component of alternating current ($I''-I'$) also decays exponentially at a rate controlled by the ratio of inductance to resistance in amortisseur effects within the contributing machines. It happens that the effective time constant of this subtransient component varies only over a moderate range for various types of apparatus which will be encountered. The short-circuit subtransient time constant for synchronous apparatus will generally be between the limits of 0.015 and 0.04 for machines having ratings up to 10,000 kva. The entire a-c short-circuit current contribution from induction machines is subject to exponential decay with a time constant generally between the limits of 0.02 and 0.04. The presence of external reactance in the a-c network between contributing machines and the fault tends to increase the effective time constant. However, as the external reactance becomes large, the magnitude of the subtransient current component diminishes to a small value and hence moderate inaccuracy of time constant is no longer significant. As a result of these conditions, it is proposed to include the entire induction motor a-c current contribution in the subtransient component and utilize a common time constant of 0.04 second in evaluating the time rate of decay.

The transient component of a-c current, disregarding subtransient effect ($I'-I_s$) is actually also subject to exponential decay, but at a much slower rate. During the first one-eighth second the reduction in total a-c component due to this effect, would be limited to less than ten per cent in practically all cases. The presence of considerable reactance, external to the a-c machines, and the operation of automatic voltage regulating equipment, if actually considered, would both function to diminish the magnitude of this effect.

In view of the fact that the present calculating procedure is limited to an initial time interval of about one-eighth second with the portion of greatest interest being below one-tenth second, it is proposed to disregard the reduction in current resulting from transient component decay.

In accordance with this premise, the total current consists of a d-c component

$$\sqrt{2}I_{a\text{-}c}''e^{-t/T_a}$$

plus an a-c component whose rms value is

$$[(I''-I')e^{-t/T''}+I']$$

The equivalent rms value of the combined current (representing the rms value of a steady-state current wave having the same d-c and a-c components as exist at the time t) becomes:

$$I_{\text{total}}\text{ rms}=\sqrt{(I_{d\text{-}c})^2+(I_{a\text{-}c})^2}$$

$$=\sqrt{(\sqrt{2}I_{a\text{-}c}''e^{-t/T_a})^2+[(I''-I')e^{-t/T''}+I']^2}$$

Since the effect of the diminishing d-c component is of much greater significance than the reduction in subtransient component, an approximation for simplification may be made as follows:

$$I_{\text{total}}\text{ rms}=K[(I''-I')e^{-t/T''}+I']$$

where

$$K=\sqrt{2e^{-2t/T_a}+1}$$

$$T_a=\frac{La}{Ra}=\frac{1}{\omega}\frac{Xa}{Ra}$$

$$=\frac{1}{377}\frac{Xa}{Ra}\text{ (at 60}r)$$

The factor K becomes a function of time and the ratio of inductance to resistance in the a-c network. The latter may also be expressed in terms of the ratio of reactance to resistance at a specific operating frequency.

In determining the reactance-resistance ratio, it is proposed to use subtransient reactance (X'') for simplification, which is justified by reason of the fact that X'' is substantially the same as X_2 and, furthermore, in the event that X_2 be actually higher, the initial maximum magnitude of d-c component would then be decreased, thus constituting a compensating effect.

Since the subtransient time constant (T'') may reasonably be taken at 0.04 second, the total rms current may be expressed as:

$$I_{\text{total}}\text{ rms}=K[(I''-I')e^{-t/0.04}+I']$$

$$=K[(I''-I')C+I']$$

where

$$C=e^{-t/0.04}$$

The resulting expression for total rms current becomes that which appears in the proposed analysis procedure. Included in the paper are curves giving values of the factor K and C as a function of time for various ratios of 60-cycle reactance to resistance covering the range of values to be encountered in practice.

It is not expected that the reactance-resistance ratio of the a-c network be accurately determined. At generating centers with current-limiting reactors in the major number of interconnected circuits, it would be expected that the 60-cycle reactance to resistance ratio might assume values in the order of 30, while in remote secondary switching centers the 60-cycle reactance to resistance ratio might assume values of three or even less. Primary distribution centers and primary load centers will be found to assume 60-cycle reactance to resistance ratios of intermediate value. The principal objective is to determine whether a given switching center may be reasonably considered to possess an X/R ratio not in excess of say 3/1, 5/1, 10/1, etc., rather than to accurately define the reactance-resistance ratio at a specific value between 9/1 and 10/1, for instance.

The proposed method of analysis requires the solution of the subtransient reactance network (including induction machine reactances), the transient reactance network, and the resistance network between the source or sources of short-circuit current and the point of fault. In making approximations in the solution of the resistance network, it should be the objective to determine a resistance value which is as low as can be obtained under any operating condition.

O. R. Schurig (General Electric Company, Schenectady, N. Y.): The basis of the procedure for calculating the magnitude of a short-circuit current is the well-known relation that the current in a circuit is the voltage applied divided by the impedance of the circuit as pointed out in the paper. The impedance of the circuit includes:

1. Those occurring in the power supply circuit including power sources, line, and step-down transformers, and
2. Those in the distribution circuit including conductors, circuit breakers, control equipment, and other devices.

Much has been written in the past of the impedance and short-circuit characteristics of rotating machines and of other equipment in the power supply circuit; and as further studies of this apparatus are made, their characteristics and impedance values will be even better understood.

On the other hand, the impedance values of the circuit elements in the distribution circuit, though fundamentally less complex than those of the power supply circuit, have not been so well understood. This is indicated by the fact that a number of approximations giving widely different results have been used to estimate their magnitude, or their effects on the short-circuit current. By recent investigations, the necessary impedance constants of the principal circuit elements in the distribution circuit have been established and are included in the paper. Now that the impedance values are available, as given in simple curves or tables (see appendix of the paper), there should remain no mystery as to the magnitude of the impedances such as those of flat bar conductors at various spacings or of channel bars used in busses. Nor should there be any uncertainty as to the order of magnitude of the impedances of current transformers of conventional design, of air circuit breakers, oil circuit breakers, and of other switching and control devices. There is no doubt that with the aid of the new data given, reasonably accurate calculations of short-circuit current in low-voltage circuit can be made, eliminating guesswork.

There have also been widely divergent ideas on the current-limiting effect of the arc at faults of different kinds in low-voltage distribution systems. Recent investigations have shown that the voltage drop at the point of fault may vary considerably, ranging from a negligible value to a magnitude in excess of the crest value of the circuit voltage, with a correspondingly wide range in current-limiting effect. The results of these investigations are summarized in the paper in table X. They have also been reported in full elsewhere.[1]

Suffice it to consider here how the arc voltage magnitude affects the magnitude of short-circuit currents to be used for the following purposes in typical modern switchgear and station design:

(*a*). As a basis for the mechanical design of main busses to resist short-circuit forces, and

(*b*). For the selection of the main-line protective devices.

The following basic considerations are of interest here:

1. Since large current-limiting effects cannot be depended on in the case of arc faults in enclosed congested structures typical of modern switchgear and station design, maximum short-circuit current values closely approaching bolted fault conditions may be expected.

2. While it is true that many arc fault conditions having substantial current-limiting effects may occur in less congested structures, or at points remote from the power supply source, the less severe fault conditions cannot be considered representative of the maximum short-circuit currents which determine the maximum stresses for mechanical design of main busses and which may need to be interrupted by the main-line protective devices in structures typical of modern switchgear and station design.

1. FAULT-VOLTAGE DROP AND IMPEDANCE AT SHORT-CIRCUIT CURRENTS IN LOW-VOLTAGE CIRCUITS, O. R. Schurig. AIEE TRANSACTIONS, volume 59, 1940, pages 479–87.

Wm. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): It has been brought out in the course of discussion that the actual deterioration of circuit breakers is generally less than would be expected from calculated short-circuit currents. This may be explained in part by the cable data used in making the calculations. I do not know to what extent the impedance of the cables affects the short-circuit current but I do not believe that much reliance can be placed in the cable impedance data given in the paper. Mr. Darling has undoubtedly used the best information available and if I were to try to write up a procedure such as his I would have used the same data. However, I would have added a note saying that the basis of the information presented is exceedingly questionable due to lack of adequate data on the reactance and a-c resistance of large cables in iron conduits. The principal field test data relied upon are those of L. Brieger whose tests were confined to size 4/0 and 500,000 circular mils. The Brieger factors, however, are used in table VII which goes up to 750,000 circular mils and it is in precisely the range between 750,000 circular mils and 1,000,000 circular mils that a rapid rise in impedance occurs.

A. G. Darling: Mr. Del Mar's point that actual deterioration of circuit breakers is generally less than would be expected from calculated short-circuit currents is well taken. The calculating procedure gives an anchor point in establishing the maximum short-circuit duty which the breaker may be called upon to withstand. The factors which will cause less duty are arc drop at the fault and an increase in impedance during the fault such as might be created by spreading of conductors. Since the breaker will usually be selected for a fault location giving minimum impedance, naturally the duty will be decreased as the fault location introduces more circuit impedance. The longer the circuit protected by the breaker, the less the chances are for a high percentage of severe faults, always remembering that there remains at least one chance of a fault of maximum intensity at the terminals of the breaker.

The subject of cable impedances has been given considerable study. Mr. Del Mar's suggestion that further study may reveal more accurate data is recognized as true and any contributions Mr. Del Mar or others can make to the cable and other impedance data will be welcomed by all concerned.

Electric Shock

Discussion and author's closure of paper 41-7 by C. F. Dalziel, J. B. Lagen, and J. L. Thurston, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1073–9.

Horatio B. Williams (nonmember; Columbia University, New York, N. Y.): For a long time the spectacular effects of large currents drew attention away from the fact that electricity can kill by stimulation as well as by destruction. Death due to fibrillation of the ventricles of the heart brought on by electrical stimulation is now generally recognized. The authors call attention to another manner in which currents of small size may become dangerous. Current passing from hand to hand, of strength such as to prevent the subject from releasing himself, may kill if the strength is sufficient to cause continuous contraction of the muscles of respiration; or by an effect on the nerves controlling these muscles which renders them incapable of conducting the normal nerve impulses. This effect was described by Einthoven some 25 years ago as an experimental fact, the nature of which is still obscure. Under experimental conditions nerves in this state may recover within a half hour. It is possibly in such conditions that resuscitation by artificial respiration succeeds most easily.

Currents of such magnitude as to "freeze" the subject to the circuit are very painful. An early effect of pain is to raise blood pressure, but if pain is long continued the pressure falls, fainting results, and if the cause is not removed recovery may not take place. The subject who is unable to breathe is also unable to make outcry and so may be unable to secure help even when it is near at hand. The increase of blood pressure due to pain is brought about by constriction of small blood vessels. When this occurs suddenly in a person with a damaged heart that organ, unable to contract against the sudden increase may dilate and this may determine a fatal issue. When the current is such as to produce a muscular contraction as great as or greater than that which the subject can normally produce voluntarily, then if both sides of the circuit are gripped with the palms of the hands he will certainly be unable to let go since the muscles which close the hand are stronger than those which open it.

The stimulation of these muscles will depend not on the current through the entire arm so much as on the current density in the arm. We should expect then that for a given total current the ability to let go would diminish with the size of the forearm. This is of particular importance in connection with the electric fence hazard since very small children are exposed to them and might be expected to be "frozen" by currents from which an adult could let go.

If Professor Dalziel still has access to many of the group who served as subjects for his investigation, it would be of great interest to have measurements of the maximum diameters of the forearms in those who had the greatest and least let-go values as well as in some of the others.

In determining the maximum safe current which may be permitted on an electric fence it would be most helpful to know the let-go limit when the current passes for one-tenth second and is interrupted for nine-tenths second, this being common fence practice. In order to insure effectiveness of these fences in all circumstances the makers desire a rather high current limit. It is assumed that interruption will always make it possible for a person to clear himself. If such experiments are tried I would suggest that current be not passed through the body, but from a hand to upper arm. Any difference might be evaluated by trying both arrangements at low current levels.

The authors' finding that stimulating effect is related to peak rather than to rms value of current is an agreement with current physiological observations as is also the observation that higher frequencies stimulate less effectively than commercial frequencies. There is a definite relationship between strength of current, duration, and stimulating effect and when time is made short enough stimulation will not occur when the current strength becomes so great as to destroy. For this reason physicians employ current of high frequency to produce deep heating of body structures, a procedure known as diathermy just now engaging the attention of engineers because it is a source of radio interference. The relatively smaller effect of direct current is also in agreement with physiological facts which it would take too long to develop, but its safety is only *relative*. The Bureau of Mines has recently reported numerous fatalities on 250 volts direct current in Alabama coal mines.[1]

1. *Information Circular 7120*, Bureau of Mines, June 1940.

M. G. Lloyd (National Bureau of Standards, Washington, D. C.): This paper contains very valuable data regarding the "let-go" values for men, and it would be very desirable if similar data could be obtained for women and children. The one woman reported in this paper gave results between about 20 per cent of the men on one side and 80 per cent on the other.

Such experiments have value in setting the limits for the amount of current which should be permitted in connection with the regulation of use of electric fences Several such regulations have been set up, one of which constitutes part of the National Electrical Safety Code. In the latter the limit of eight milliamperes is set for currents which can be steadily drawn from the fence without use of an interrupter.

More than two dozen fatalities have, to my knowledge, already occurred to human beings in connection with electric fences, most of which were equipped with home-made controllers, and probably none complied with present standards. One child was killed in Oregon last summer, in which case the child had wet feet and was reported to have been scratched by the barbed wire which penetrated through the skin, resulting in greatly reduced resistance through the child's body. It was found by laboratory measurements that eight milliamperes was delivered by the fence controller with a resistance of 2,000 ohms in circuit. The results in this paper today show that some men have a resistance lower than this when contact is made with wet hands, and if the child's skin was pierced, it is probable that the resistance was lower than this in the Oregon case, and the current consequently larger than eight milliamperes. It is noted that the authors conclude that a safe limit for men is eight to nine milliamperes.

Jellinek, who has written extensively on this subject in Europe, claims that electrocution of a child has occurred with as little as ten milliamperes.

In an experiment made years ago at the National Bureau of Standards by Dr. F. Wenner, the resistance of the body between two hands immersed in salt water approached a lower limit of 500 ohms.

Attention appears to be a defensive factor, so that a larger current can be tolerated when it is expected than when it is not expected, and fatigue may also be an element in this problem.

Walter A. Curry (Columbia University, New York, N. Y.): Several years ago the writer carried out some tests, with himself as subject, which were similar to those described in this paper. In particular, with 60-cycle potential applied between dry hands grasping the electrodes (large metal masses so that the whole palm was practically in contact) and an extreme limit of 50 volts was found, at which voltage the current was 10 milliamperes. With wet soapy hands, the extreme limit was 22 volts, with a current of 11 milliamperes. The conclusion was "a body current of about 10 milliamperes is extremely unpleasant and will paralyze the hands and arm muscles." In these tests, the criterion was not the "let-go" value, but the extreme discomfort which could be endured.

In addition, some 60-cycle tests were carried out with the subject sitting in an ordinary porcelain bath tub, with potential applied between ground (water piping connected to tub) and a tin plate which one or both hands grasped. The water level was about waist high. With one hand grasping the plate, the voltage was raised slowly to 25 volts, and the corresponding current read as 16.9 milliamperes, representing a body-path resistance of some 1,500 ohms. The test was made with clear water and when repeated with soapy water the current at the limit voltage of 25 volts was 18.3 milliamperes, corresponding to a body-path resistance of about 1,400 ohms; soapy water would thus be indicated as slightly increasing the body conduction and therefore slightly more hazardous. A second test was carried out with the soapy water, with both hands grasping the tin plate; in this case the current corresponding to 25 volts was 22.6 milliamperes, giving a body-path resistance of about 1,100 ohms. Under this condition there was a rather violent contraction of the arm and hand muscles, and there was a peculiar vibratory sensation in the chest. These bath-tub tests probably held a certain hazard due to the possibility of inducing ventricular fibrillation of the heart and have never been repeated. With a body resistance of 1,100 ohms, the current flowing with 110 volts will be 100 milliamperes; since many fatal bath-tub cases have occurred at the normal service voltage (110–20 volts) this substantiates the opinion that 100 milliamperes passing through the chest may cause death.

C. F. Harding (Purdue University, Lafayette, Ind.): This paper presents several new data and a unique contribution to the limits of "holding" or "letting go" of electrical circuits by human beings. Fortunately the medical profession is now assisting in the interpretation of many puzzling phenomena in connection with human reactions under electrical exposures. Further study should be undertaken of such conditions as: (1) the reported greater surface heating due to direct current as compared with alternating current of the same effective value and (2) the greater shock as direct current is broken when contrasted with the breaking of an equivalent alternating current. Can it be that there is an inductive reactance in the human being which results in effects comparable to the breaking of the direct current in a magnetized coil?

Although it has been made evident that it is the magnitude of the actual current flow through the body rather than the actual applied potential that causes shock, and no doubt death as well, it seems rather questionable to divert the mind of the layman from the probable danger of high-voltage circuits by the statement that "subjects received open-circuit voltages varying from 5 to 9,720 volts." Furthermore, the frequency of the supply and surface capacitance of the human body must be taken into consideration in determining the current *through the vital organs of the body* which may correspond to an applied high potential. The statement of the importance of current as opposed to potential measurement would seem to be somewhat neutralized by the later reference in the paper to the effects of peak versus effective values of various potential waves.

With respect to the effects of the higher harmonics in distorted wave forms it has often been noted that capacitors which tested satisfactorily on a sine wave soon puncture upon the distorted wave form which may be augmented locally by the connection of the capacitor itself to the circuit. Thus such circuits as electric fences with capacitors involved may prove to be additional risks on the distorted waves frequently found on rural power distribution systems.

Charles F. Dalziel: Most persons are aware of the danger incident to contact with high-tension circuits, and high-voltage warning signs generally command respect. There is no question of the shock hazard from power circuits, and it is regrettable that there is a tendency for this attitude to disappear when handling low-voltage circuits, especially ordinary lighting circuits. It is probable that many accidents with home appliances are due to ignorance, lack of appreciation, or disregard of safe procedure and the inherent dangers associated with electrical apparatus. This may assume importance in explaining accidents involving worn out or defective home appliances used near well-grounded objects, where excessive moisture is present, or when standing in water, such as in wet basements, laundry rooms, bathrooms, etc. There was no intention to divert the mind of the layman from the danger of contact with high-voltage circuits. Experiments in progress indicate that the maximum safe 60-cycle voltage is about 5 volts, and about ten times this value for direct current. Voltage is very important, but due to the variability of contact and skin impedances, voltage in itself may be relatively unimportant in producing or explaining damage. Muscular

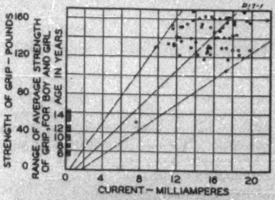

Figure 1. Muscular grip in pounds versus let-go current in milliamperes

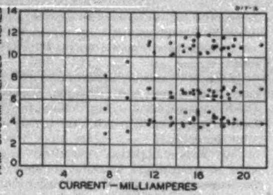

Figure 2. Arm circumference in inches versus let-go current in milliamperes

reactions and sensations are due to the current flowing through the body, and therefore current and *not* voltage is the proper measure of shock intensity. This is of special importance when considering the safety of electric fences, fly panels, insect traps, stock driving canes, etc. In these devices the open-circuit voltage may be several kilovolts; however, the hazard depends upon the maximum current output and has no relation to the voltage output.

The investigators have given thought to the determination of the let-go current for children. The essential contents of this paper were presented before the San Francisco section AIEE technical meeting on December 13, 1940. The question of testing children was also raised in the discussion following the presentation. Several attempts were made to obtain children, but only one was available. The child tested was a well-developed boy, nine years of age, weight 62 pounds. His 60-cycle let-go current was 7.6 milliamperes, and he released direct currents up to 15 milliamperes easily and without comment. Higher direct currents were not tried for reasons of safety. Mr. Royce E. Johnson, director electrical standards laboratory, University of Wisconsin reports that several years ago let-go current tests were made on a few subjects. Although the experimental procedure was slightly different the findings were within the range of our results. He reports that "a 60-cycle current of seven milliamperes was found to paralyze the grip of a five-year old boy who weighed about 45 pounds." These two values for children are valuable in connection with the permissible maximum current output for noninterrupted a-c fences.

An attempt was made to correlate let-go current and the strength of grip, with the hope that a simple and unobjectionable method of estimating probable let-go currents for women and children might result. The results are shown in figure 1. The wide scattering of points and the lack of data at low values preclude drawing definite conclusions. Possibly other investigators may be able to secure additional points for children, thereby settling the issue.

At the suggestion of Professor Williams, the maximum forearm and minimum wrist measurements were made on all available subjects, and are given in figure 2. It was thought that possibly let-go currents might be more closely related to the current density in the conducting tissues rather than to the over-all measurements. An attempt was made to estimate the amount of conducting tissue by subtracting the wrist values from those of the forearm. These values are also given in the figure. Although those having smaller measurements also had smaller let-go currents, the range of the arm measurements was so small that little can be said regarding the probable lower limits.

Dr. Williams and several fence manufacturers have suggested performing let-go studies using interrupted a-c shocks of 0.10 second duration followed by an off period of one second. Some tests were made using currents up to 26 milliamperes, and none of the subjects had difficulty in releasing the test wire electrode during the off period. Tests were not made at currents higher than 26 milliamperes due to the violent muscular reactions and painful sensations produced by currents of this magnitude. The entire subject of electric fencing needs further study and clarification, and our efforts are now being directed to this phase of the subject.

The interest and enthusiastic response accorded this investigation is much appreciated.

Powerton-Crawford 220-Kv Line—Design and Construction Features

Discussion and author's closure of paper 41-57 by M. S. Oldacre and F. O. Wollaston, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1108–20.

J. W. Milnor (The Western Union Telegraph Co., New York, N. Y.): The description of the Powerton-Crawford 220-kv line is of much interest as an indication of the variety of problems which must be met in the design of a line for transmission of high power.

It is regarding the problems of inductive co-ordination that I wish particularly to speak. The route of the power line is closely parallel to an important line of Western Union and of the Atchison, Topeka and Santa Fe railway, and exposures to two other telegraph lines occur at somewhat greater separations. Under the circumstances it is inevitable that the magnetic and electric fields of the power system should link with the telegraph circuits.

Fortunately, methods of co-ordination have kept pace with the power system developments. Some years earlier, an attempt of the power and communication interests to share this general route would have resulted in an impairment of most of the telegraph services west from Chicago. As the co-ordination has finally been applied, the interference has been controlled to an extent that the remaining effects into communication circuits thus far have been sufficiently small to be unimportant. These results have been obtained in part through considerations of design of the power system, for the purpose of reducing its inductive influence as far as practicable. What remained of the interference to telegraph is corrected by neutralizing equipment applied in each paralleling system. The co-ordination, of course, was not obtained without cost; but the expense has been small as compared with the total investment in the power and in the communication lines concerned.

The extent of the success in controlling interference will be better appreciated when it is considered that a high-grade telegraph circuit may be harmed by a small fraction of one watt, and that the total energy carried by the power system is six billion times larger.

Edwin Hansson (Pennsylvania Water and Power Company, Baltimore, Md.): The authors are to be congratulated on this very excellent paper. The line stands as a credit to its designers and they should be able to look forward to a very satisfactory performance.

In one respect I should like to differ with the Commonwealth engineers. This difference applies, however, more to execution than design. In order to obtain low tower footing resistances, ground rods were driven in the bottom of the footing excavations. I doubt very much if these rods influenced the final values of ground resistance sufficiently to warrant their cost. The four steel grillages comprising the foundations of the towers form a very large electrode when compared with the ten-foot rods, and overshadow their effect.

As far back as 1923 we found that an eight-foot ground rod driven within a few feet of a six-foot deep concrete footing had no appreciable effect on the combined resistance. In 1931 we tried driving eight-foot rods 50 feet from similar foundations and found that the connecting wire was just about as effective without the ground rod as with it. In 1932 we tried driving rods in the bottom of the excavation up to 16 feet below the concrete and again found them ineffective. After these trials we came to the conclusion that rods in connection with tower foundations are justified only where it is possible to reach soil of much higher conductivity than that directly adjacent to and surrounding the foundation.

J. T. Lusignan, Jr. (Ohio Brass Company, Mansfield, Ohio): This paper gives a splendid review of the various construction features of the newest 220-kv line. It particularly points out some interesting new factors that were considered in this line design and some new ways of treating old problems.

The development of the clearance envelopes to allow for conductor galloping is most interesting. I am wondering what wind velocities the authors counted on for this and how closely the conductors will approach one another under the worst galloping conditions.

It is stated that the flashover voltage between tops of the line and bus switch stacks must be about 20 per cent greater than the line-to-ground flashover voltage. The problem of running the tests to determine this was put up to our laboratory, as was the case for similar switch arrangements for the Boulder Dam lines. Literally the tests cannot be made as it is obviously impossible to put any more voltage, nonetheless 20 per cent more, on the switch than the flashover voltage to ground of each stack. Accordingly a compromise test was necessary which involved determining the flashover voltage to ground of the stack, then adding enough insulators to each stack to gain over 20 per cent more voltage. Following this the horizontal gap was adjusted for a flashover voltage in excess of this.

The authors point out one advantage of the long ground-wire suspension assemblies chosen. Another advantage is that the long suspension arrangement decreases measurably the angle of rocking and thereby the rubbing at the tower attachment. This obviously reduces the wear there appreciably.

In describing their studies of radio noise on their line, the authors, mention tests made on wet suspension strings, the results of which are plotted in figure 18. Our laboratory studies indicate that ordinary standard suspension units, wet or dry, give negligible radio interference. We know, however, that water drops on smooth metal surfaces, in intense electric fields, cause appreciable corona and streamer formations. We therefore wonder whether the small interference values, indicated on figure 18, cannot be attributed to such water drops on the conductor and hardware surfaces.

A. E. Davison (Hydro-Electric Power Commission of Ontario, Toronto, Canada): Mr. Oldacre and associates should be congratulated on supplying such complete and intimate data of a modern (1940) 220,000-volt line.

The transmission line is particularly interesting being located in a highly productive plain or river valley, there being some evidence that, considering the area on a 100-mile square basis, the line is in the most productive area in the world. Evidence of this important consideration is found in the special method of minimizing right-of-way rights and costs. Condemnation is provided only for the area directly under the tower together with the right of access to that area. Easements are provided apparently for the cables.

Special thought and study have been given to design for protection from sleet and following loads. Records are available which are indicative of what may happen to a line when involved in a gusty wind storm for which the recorded velocity was 50 miles per hour. It would seem that very few existing lines could successfully withstand velocities much above the gusts occurring in a 50-mile wind. This design provides for calculated loads for steady winds up to 150 miles per hour.

References made in the paper under "Basic Consideration and Design" to "practically lightning-proof" lines. Lightning proofing of transmission lines is a considerable undertaking. It would appear from the reading of other parts of the paper (for instance see the paragraph, beginning "Desired low level—less than 1 outage per 100 mile-years") that the writer of the article expects outages.

Referring to "Protection Against Sleet" a chart (figure 1) indicates the writer's interpretation of desirable loops (Lissajous figures) for the tower and normal sag which is described in the article. Superimposed are the loops or figures as prepared by the writers of the article (see figure 2c normal span). The point in recording these variations was to demonstrate variations in interpretations. As a matter of fact, the phases are so separated that the loops or figures for both interpretations are reasonably clear of one another.

There is some evidence that a combination of 220,000 volts and the normal electrical currents, found in lines such as those described by the writers of the article, will reject certain sleet loads. The amperes per square inch would appear to be of the order of 700. It is a fact that sleet has been rejected or practically rejected on at least two or three occasions when the amperes per square inch ranged from 700 to 800. Not all of these cases were 220,000 volts.

"Loops" are referred to under "Protection Against Sleet." The proving of any advantage there may be in using these was left to Mr. Oldacre who has done so quite satisfactorily (see figure 1) for 132,000-volt lines. If any reader is interested in securing copies of the article wherein loops are developed (see reference 1) these developments have been published in *The Bulletin* of the Hydro-Electric Power Commission for September 1939. Copies can be secured by writing the undersigned or by writing to *The Bulletin*, Hydro-Electric Power Commission, 620 University Avenue, Toronto, Canada. Some engineers looking at the group of figures (see figures 1 and 2) of the paper may be confused. A review of reference number (1) might assist further studies by interested engineers.

Under "Transpositions and Dead Ends" it is stated that there is no crossing of the wires in the spans of single-circuit transpositions (see figure 5*d*). Looking at this photograph it would appear that a ground wire and the upper phase do not cross at transposition tower. They may cross at some other tower. Heretofore mechanical failures and burning down of sky cables has occurred only at transpositions in one fairly large system having several thousand mile-years' operating experience.

Under "Tower Footings" it is a matter of experience of others as well as of the writer of the paper that hot galvanizing at the ground line lasts for a great many (33 or more) years.

Referring to tripod type of anchor, it is known that the existence of any complicated structure at or near the surface of frozen ground may account for extraordinary stress in the leg members between the frost line and the grillage due to frost heaving. It may be that leg members in this particular design are strong enough to raise the grillage and that it may settle back during the following warmer season. Considerable attention must be given to this feature where footings are set in certain clay soils.

INTERPRETATION FROM OLDACRE & WOLLASTON'S PAPER
INTERPRETATION BY DISCUSSER

Figure 1

Under "Vibration Protection" the absence of grading rings minimizes the anvil which a suspension clamp offers for the hammering action of vibrations carried into it by the cable.

The "Tower Lighting" described in the paper is interesting. The effect of lightning discharges if any, upon the lighting fixtures and equipment will be watched with interest.

The paper as information for use by engineers would be effectively supplemented if the writers could give some attention in their closure to the following.

METHOD OF SETTING OF FOOTINGS

Are footings set with a templet, with part of a tower as a templet, or are they set as four separate footings by instrument? The latter method seems to provide for the minimizing of internal stresses in the completed structure and may be a comparatively economical procedure. Were there any special methods adopted in setting footings in excavations where the sides of the excavations are not stable?

MICROVOLTS PER METER CHART

Referring to figure 19, it is not clear to the reader, from the text, whether these records apply to a single circuit or to one circuit of a double-circuit structure.

OPERATING PROCEDURES BY WHICH SLEET CAN BE KEPT OFF LINES

If there is some specific experience or procedure whereby operating organizations can so interconnect their lines during sleet periods, that sufficient current flows to cause sleet rejection, this data and information would be greatly appreciated by engineers who have to design and operate services like those described by the writers of technical paper 41-57.

F. O. Wollaston: Along most of the route of the line the location of the water is such that a ten-foot ground rod in the bottom of the anchor excavation will reach soil of substantially higher conductivity than would be contacted by the anchor grillage alone. It is felt that the ground rods were definitely worth while, since very low footing resistances were obtained for most of the towers.

The clearance diagrams for galloping were based on 0 degrees Fahrenheit, $^1/_2$-inch ice, and 30-mile wind. The minimum clearances between galloping wires are shown in figure 2 and are a few feet greater than the calculated flashover distance. It is agreed that, as Dr. Lusignan suggests, the radio noise values under wet conditions shown in figure 18 are probably due to water drops on the conductor and hardware.

The calculated outage rate of the line due to lightning is low, but finite, for the conditions assumed in the calculations. The assumptions were very conservatively severe, so that the phrase "practically lightning-proof" seems justified when referring to the line under actual service conditions. Mr. Davison is correct in inferring that one of the phase wires crosses under a ground wire in the single-circuit transposition. This was unavoidable because of the inset of the ground wires with respect to the outer conductors, but very ample clearances were provided.

In reply to Mr. Davison's question, all footings, except a few at the start of construction work, were set by transit. This proved more satisfactory than using templets, which were not rigid enough to hold the heavy anchors in line during installation. Where sandy soil was encountered, the sides of the footing excavations were supported with sheeting. This was either the usual $^1/_4$-inch corrugated steel type braced with steel channel wales, or wood sheeting with wood wales made to fit the job. Sheeting was driven into place with air hammers operated from portable compressors.

The radio-noise measurements of figure 19 of the paper were made on the double-circuit section of the line. Similar measurements have also been made on the single-circuit section. Although weather conditions were not strictly comparable, these measurements showed about the same order of magnitude of radio noise as on the double-circuit section of the line.

A discussion of sleet-prevention and sleet-melting procedures, outlining methods in use in our company, was given in an article, "When Sleet Comes," by W. R. Kunkel, *Electric Light and Power*, October 1940, page 52. Those interested in the prevention of sleet troubles on transmission lines are referred to this article.

Stability Limitations of Long-Distance A-C Power-Transmission Systems

Discussion and authors' closure of paper 41-73 by Edith Clarke and S. B. Crary, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1051–9.

C. Concordia (General Electric Company, Schenectady, N. Y.): In this paper it has been concluded that if 60-cycle electric power transmission is to be extended to distances very much greater than about 350 miles, series capacitor compensation of the line, with otherwise conventional apparatus is the most practical and feasible way of accomplishing such an extension. In view of recent work which has been done on possible negative damping produced by too much series capacitor compensation, a natural question is whether or not the amounts of series compensation required for reasonable increases of line length will be sufficiently within the safe operating regions as far as negative damping is concerned. We are therefore presenting approximate calculations on two bases, as shown by figures 1 and 2 attached.

Figure 1 shows the no-load damping torque coefficients[1] for a typical large water wheel generator, with an amortisseur, as affected by the amount of capacitive reactance compensation x_c. It is seen that only with an unusually high-line resistance ($r=40$ per cent on the generator base kilovolt-amperes) and high compensation does increased compensation cause a decrease in the amount of damping, and even then the damping is not less than that with no compensation. A 40 per cent line resistance corresponds to an uncompensated line reactance of about $(40/0.15)=270$ per cent of generator base impedance if the line (r/x) ratio is 15 per cent. The corresponding line length is then nearly as great as the lengths considered in the paper.

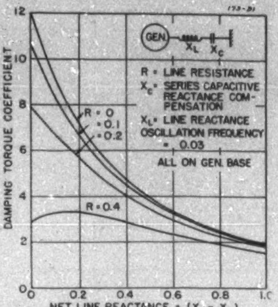

Figure 1. No-load damping-torque coefficients of typical synchronous generator as affected by capacitive-reactance compensation X_c

Figure 2 shows the self-excitation regions with constant generator speed as affected by series capacitor compensation,[2,3] and shows that the values of line resistance required for stability on this basis are not unduly large. From this figure it can be concluded that the per cent of line reactance which can be series capacitor compensated is only slightly affected by the relative length of line but tends to increase with line length. This may be seen by assuming any fixed line (r/x) ratio and determining the allowable compensation from the curves.

The lower limits to line resistance established by figure 2 and the upper limits established by figure 1 are sufficiently far beyond the range of compensation required for moderate increases in transmission line length, and the phenomena involved are sufficiently well understood, that negative damping should not prove to be a serious limitation to the gains in power transmission possible with series capacitors.

E. E. George (Ebasco Services, Inc., New York, N. Y.): This paper is probably the first to give a quantitative discussion of the electrical performance of transmission lines over 300 miles long. It is also the first to carry out the very effective idea of using the network analyzer to obtain the answers. While the authors' results are largely confined to electrical performance of long circuits, a brief correlated discussion of present economic limitations may help in evaluating the results obtained by the authors and in suggesting a field for future papers.

The authors state that no attempt was made to determine the economic feasibility of long-distance a-c power transmission. Perhaps future Institute papers will cover the economics of typical conditions, as well as technical limitations other than stability.

Although the authors refer to the present-day limit of straightaway high-voltage transmission as being about 300 miles, no particular explanation of this limit is given, and it might be inferred that certain technically feasible changes in design of the line and associated equipment would result in greatly extending this distance. The actual conditions are not this simple.

There is much evidence that most well-designed high-voltage lines reach the economic limits of voltage drop, power loss, and operating stability almost simultaneously at about present-day transmission limits. *To extend these limits, there must be a decrease in the cost of lines and equipment, or technical advances to permit maintaining the present percentages of line loss and regulation and the present stability margin with longer lines. Removing only one of these three limitations is not enough—the other two are close at hand to block further progress.*

The authors show that the stability limit decreases about 40 per cent when a 300-mile line is doubled in length. It must also be kept in mind that doubling the length of line more than doubles the per cent line loss and per cent voltage regulation in terms

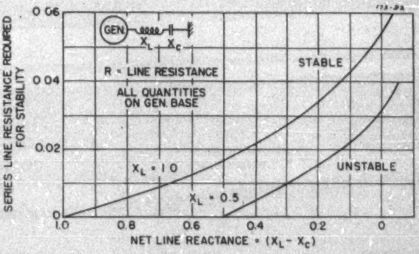

Figure 2. Self-excitation regions of a typical synchronous generator connected through series-capacitor compensated tie line to infinite bus—effect of line resistance

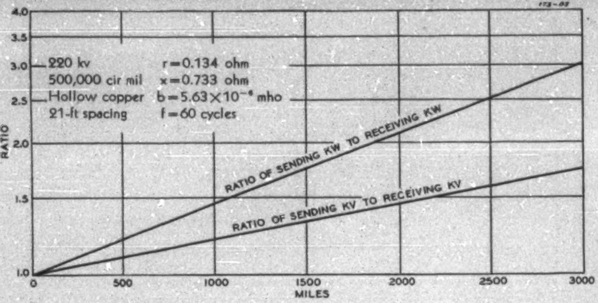

Figure 3. Performance of typical transmission line with load equal to characteristic impedance

To use chart for any conductor size other than 500,000 circular mils equivalent, change mileage in linear proportion to ratio of r to 0.134. Power and voltage ratios are substantially independent of voltage and other characteristics except conductor resistance

of maximum loading—regardless of voltage. To hold the same percentage loss it is necessary to double the conductor area. Therefore, doubling the length of line would probably treble its cost, if the same performance ratios must be obtained.

It is popularly thought that increase in voltage can offset the increase in line length, but this supposition overlooks several factors.

1. The economics of line cost tend to set a definite *per cent* limit of power loss. This is shown by the fact that long lines are designed to work at the maximum possible loading and the resulting *per cent* loss has about the same relation to power cost regardless of whether the line is 100 miles or 300 miles long and regardless of whether the voltage is 110 kv or 287 kv.

2. The economics of terminal equipment and the frequent necessity of tieing between existing facilities generally limit the permissible *per cent* voltage regulation regardless of distance and voltage. Economics likewise limit equipment reactance. Equipment of 25 per cent equivalent reactance on rating *including the transformer* would be prohibitive in cost and size if we may judge by recent discussions of standard short-circuit ratios.

3. The economics of line and terminal costs are such that a 220-kv line hauls energy at about the same cost per kilowatt-hour as for a 110-kv line; more power is hauled further by the higher voltage—that is the major difference.

4. Above about 250 miles distance becomes an increasingly serious obstacle. Even under the most favorable conditions of load and power factor, power loss and voltage drop are logarithmic functions of mileage and exceed a linear relation at a rate increasing with line length.

In view of the foregoing, it is apparent that in designing practical lines, *the cost of power and the cost of lines and equipment are necessarily major factors on one side of any equation for stability, regulation, or power loss.* As the authors show, stability can be increased, although the effect on the cost side of the equation is not clear without detailed study of typical or particular cases.

Concurrently with stability, regulation, and power loss must be studied. The present paper does not attempt to discuss these latter two factors. However the authors have laid the foundation for a quick and effective analysis of the technical relations thus facilitating a determination of the economic factors.

The authors present an equation for power loss for surge impedance loading. This is a form of a well-known communication equation. A similar communication equation provides a simple formula for voltage drop at surge impedance loading. (See analysis at the end of discussion.)

It is also known from communication theory that the loss ratio is a minimum and the voltage regulation is the best at surge impedance loading. The authors have therefore made an important contribution in showing that *most modern lines operate so closely to their surge impedance load that the performance of practical lines may be studied under this load condition.* This simplifies physical performance in every respect except as to stability. For instance, power loss and voltage drop become smooth exponential curves without any relation to wave length. As shown on the accompanying chart (figure 3), power loss and voltage drop may be drawn as straight lines on a semilog chart of distance against ratio of sending to receiving power or voltage. We can now see where *economics has placed a transmission limit much shorter than that set by stability.* This limit is substantially proportional only to length and conductor resistance per mile. The latter is limited by cost of supporting structures as well as by the cost of the conductor itself, and although it can be shown that the percentage power loss and percentage voltage drop can be maintained constant for any length of line by increasing the conductor area linearly with the line, our economic judgment tells us that it is no use to follow this relation very far.

We thus come back to where we started and with little hope of rapid progress unless some one overcomes I^2R loss—because present-day lines at maximum loading approach closely to the I^2R loss calculated on a d-c basis (equal current throughout the line length) and that the cost of that loss is ordinarily one of the three major economic limitations to long-distance transmission.

From equation A-12 in authors' paper:

$$P_R=\frac{1{,}000E_S{}^2\epsilon^{-2H}\cos PF_S}{Z_0}$$

$$P_R=P_S\epsilon^{-2H}$$

$$\frac{P_S}{P_R}=2.72^{2H}$$

$$\frac{E_S}{E_R}=2.72^{H}$$

$$H=\frac{Mr}{2R_0}$$

M=miles of line
r=resistance per mile
R_0= surge resistance=Z_0 times cosine of angle of Z_0
Angle of Z_0=2 to 10 degrees
H=real component of propagation constant times length

H. P. St. Clair (American Gas and Electric Company, New York, N. Y.): The authors of this paper are to be commended for bringing together in compact form a large amount of information, both practical and theoretical, on the performance and possibilities of long transmission lines. The many interesting performance curves based on exhaustive network analyzer studies would seem to answer almost any theoretical question (except economical ones) regarding the possibilities of transmission lines up to any conceivable length.

The authors' discovery or observation that most existing lines, 100 to 300 miles in length, are rated at a load corresponding to an impedance equal to the surge impedance of the line is rather striking; also, the conclusion that such a load, if a dead or a nonsynchronous load, can be carried over any length of line even 3,000 miles without overvoltage along the line. Somewhat more obvious, however, is the observation or discovery that existing long lines carry their rated loads at approximately unity power factor. This is necessarily true since even small components of reactive kilovolt-amperes carried over the high reactance of long transmission lines produce excessive voltage drops.

In connection with the very significant surge impedance loading described by the authors, it might be of interest to point out another characteristic of this same loading, perhaps inferred but not specifically mentioned by the authors, and, that is, that it corresponds to the load at which the I^2X reactive kilovolt-ampere loss in the line just equals or neutralizes the capacitance charging kilovolt-amperes of the line. This, of course, is the reason that a "dead load" of this amount could be carried over any length of line: the distributed shunt capacitance load is completely neutralized by an equal reactive kilovolt-ampere loss.

This value of loading, which I have called for convenience the "critical" loading, for a given voltage line is often very useful as a bench mark for checking purposes. For example, knowing that a 132-kv line has a charging kilovolt-ampere of approximately 9,000 kva per 100 miles, it is also apparent that at the critical loading of 44,000 kva the I^2X reactive kilovolt-ampere loss is the same amount, or 9,000 kva, and that for any other loading the I^2X loss will vary as the square of the loading. Thus, by simple arithmetic it is possible to determine the approximate power-factor requirements at the two ends of a line for any load condition. To illustrate, assuming that a 100-mile 132-kv line delivers 66,000 kw at unity power factor, what power factor or reactive kilovolt-ampere component exists at the sending end? This load is 1.5×

44,000 kva, so that the I^2X loss would be $(1.5)^2$ or $2.25\times9{,}000$, or approximately 20,000 kva. Subtracting the 9,000-kva charging current, there would remain approximately 11,000 lagging reactive kilovolt-amperes at the sending end. This is rather rough, of course, but at the same time quite useful for quick estimating purposes.

This criterion or bench mark is also useful in making network analyzer power flow studies where it is usually necessary to add or subtract corrections for charging kilovolt-amperes for each line entering or leaving a bus. By comparing the actual loading on the line with this criterion of surge impedance or unity power-factor loading, it is possible by inspection to determine whether the change in power factor between the two ends of the line is in the right direction and of the right order of magnitude and thus quickly discover possible errors in the application of the charging kilovolt-ampere corrections.

As mentioned above and as already brought out by other discussers, the economic aspects of extra long lines have scarcely been touched upon by the authors in this paper. Further consideration should be given to this phase of the subject, and in order to go into it more carefully we hope to submit a discussion on this in writing at an early date.

E. C. Starr (Oregon State College, Corvallis, Ore.): Miss Clarke and Mr. Crary have made a useful contribution to the literature on electric power transmission. They have summarized the present and probable future status of a-c and d-c transmission, and have pointed out the important limitations. As time progresses, occasions will doubtless arise for the transmission of increasingly larger blocks of power over distances greater than now practiced or deemed feasible. It is consequently important that we anticipate these requirements and be prepared to meet them adequately when the occasions arise.

A primary objective of all agencies dealing in electric energy is the delivery of that energy to the consumer at the minimum annual cost. This objective can be attained only when the sum of all the individual costs involved in the generation, transmission, and distribution of energy is a minimum.

Mathematical analyses have been made of a number of generating plants and their associated transmission systems. The results have shown that in every case involving lines of the order of 200 miles or more in length, the maximum possible loading of the transmission lines, based on their present accessories and operating practice, is not sufficiently great, by a considerable margin, to develop the minimum annual cost of delivered energy.

The cases examined involved lines operating at 220 kv or higher and employing conductors of the order of 500,000 circular mils, copper or copper equivalent. The equations of maximum economy indicate that the least costly of these lines should be loaded to approximately 600 amperes per conductor. The more costly lines require heavier loading. These values are based on the use of no additional auxiliary equipment over that already installed on the systems studied. Line currents of the order of 600 amperes are considerably below the heating limit of the conductors employed, but are very materially above the currents obtainable in these systems because of reactive kilovolt-amperes and power-limit considerations. Further studies have shown that the use of series capacitors, either in single or multiple circuits, will permit the currents of maximum economy to be obtained at a very moderate increase in total system cost. As a matter of fact, if the cost of necessary series capacitors is included in the solution of the equations for maximum economy, the current of 600 amperes named above is reduced only to approximately 550 amperes.

The line losses will, of course, be very materially increased, but the utilization of the investment is so increased as to result in minimum total annual cost. If the capacity factor of the line is less than unity, as it most always is, and if the costs of fuel or hydraulic storage are appreciable items, the current values named above, and consequently the normal rated power capacity of the lines, would be increased somewhat. The economic power limits named are from approximately $1^1/_2$ to 2 times the limits now obtainable on the systems examined, and the investment per kilowatt transmitted as well as the cost per kilowatt-hour of energy delivered is materially less than at present.

We are looking forward with a great deal of interest to the possible use in the not too distant future of series capacitors on transmission systems already in service, or planned for future construction, for the purpose of improving the economy of delivered energy or making possible the successful economic operation of lines now considered too long to be feasible.

High-voltage direct current also enters the picture at this point. The excessive reactive kilovolt-ampere requirements involved in the operation of 60-cycle lines at high-current densities as well as the stability limitations of synchronous equipment are not present. The transmission circuits required appear to be much less costly on a per kilowatt basis and afford an opportunity to attain the desired currents of maximum economy. On long circuits a very large saving in line costs would be available for added terminal equipment.

J. M. Barry (Pennsylvania Water and Power Company, Baltimore, Md.): It would seem desirable to amplify somewhat the first conclusion drawn by the authors regarding lines longer than 300 miles, namely that the only limitation to the distance that power may be transmitted to a static load corresponding to the surge impedance of the line, is the line resistance losses. This conclusion is based on curve *A* of figure 1 of the paper, which shows a load of approximately 120,000 kw being delivered (less losses) any distance up to 2,000 miles. Inasmuch as practical operating experience has been with lines under 300 miles in length the curves of figure 4 of this discussion were prepared to show some of the operating characteristics of longer circuits. This diagram shows a number of voltage regulation curves for lines varying in length from 100 to 600 miles. In calculating these curves conductor resistance was neglected, the load power factor was taken as 100 per cent and the sending end voltage assumed constant at 220,000 volts. It will be noted that all of these curves intersect at a common point, i. e., the surge impedance load. Since resistance has been neglected, the receiving end voltage is equal to the sending end voltage regardless of the circuit length at this particular load. However, these curves also indicate some of the difficulties which might be expected in the operation of lines of length of the order of 500 to 600 miles. For instance in the case of the 600-mile line voltage regulation would be very poor for loads approximating the surge impedance loading and at no load the receiving end voltage rises to nearly three times that of the sending end.

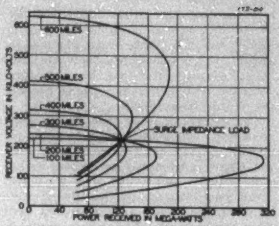

Figure 4. Voltage-regulation curves for 220-kv circuits

The curves of figure 4 are presented as a matter of general interest rather than criticism, as it is realized that the authors are not claiming that lines of such length are practical at present.

R. D. Evans (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The paper by Miss Clarke and Mr. Crary may be considered as two parts:

1. A presentation of steady-state stability limitations of a-c transmission systems as a function of transmission distance, and
2. A review of the present status of this problem.

The stability limitations of various systems are given in terms of the surge-impedance loading. Such a reference is convenient for general studies but not for a study of a particular project. The surge-impedance loading corresponds to the "critical load" used by Percy Thomas and Harold Goodwin in their papers before the Institute in 1909 and 1923, respectively. As would be expected from the scope, the second part of the paper reviewing the present status of the problem does not lead to conclusions presenting new thoughts.

The principal interest of the paper is in the discussion of measures to improve stability. High synchronizing power by low-reactance apparatus and high-speed fault-clearing measures are now accepted as standard for systems with long lines and the stability question narrows down to that of what supplementary measures are to be used. Mention is made of the quadrature-booster transformer scheme which appears to be based on the common but inaccurate statement that the stability limit occurs at an angular displacement of 90 degrees for a simple system without loss. Actually, the limit occurs at a displacement of 90 degrees from the displacement which corresponds to zero-load transfer. On this basis it becomes clear that the quadrature-booster scheme is not operative to produce the results claimed for it.

The authors conclude that the two most promising supplementary measures for improving stability are series capacitors and shunt synchronous condensers in the order named. With this view we agree. Series capacitors are particularly effective for increasing steady-state limits and have other applications. The curves given in the paper for the intermediate condenser would, it seems to us, be more useful (1) if based on condenser internal voltages higher than that of other machines as would be the practical case, and (2) if based on adjusting the machine kilovolt-amperes in accordance with the increased capacity made possible by the increased limits obtainable with the condenser.

This paper is of interest in its reduced emphasis on d-c transmission and its increased attention to methods for increasing stability limits of a-c systems.

R. Rüdenberg (Harvard University, Cambridge, Mass.): I would like to say a word in favor of the much abused inductance of transmission lines. Although I agree completely with the authors in regard to the favorable effect of series capacitors with respect to the stability limits of long lines, we should keep in mind that by the effect of the inductance we have a fortunate opportunity of compensating in a-c transmission systems the detrimental resistance voltage drop between sending and receiving stations. We have only to send over the line, as indicated in the accompanying figure 5, a flow of reactive power Q reverse to that of active power P in order to produce an inductive rise of voltage XI_q able to neutralize completely the ohmic drop RI_p in every section of the line.

Since for high-power overhead lines R is small compared with X, a moderate amount of back-flowing inductive power, easily produced by proper excitation, suffices to arrange for constant voltage in all stations over the entire system. This method[1] is used in a European transmission system, for which I served as consultant, over a total distance of more than 400 miles. In d-c transmission lines there is no such simple possibility of compensating the ohmic drop.

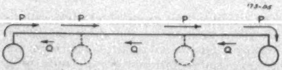

Figure 5. Reverse flow of reactive power for neutralizing ohmic drop of active power

If we neglect for a moment the resistance of the a-c line, we can easily clarify the significance of that special power which the authors call "surge impedance loading" or "unity power factor rating." On every transmission line, current as well as voltage consists of two sets of waves proceeding in opposite direction with velocity of light, as indicated in the accompanying figure 6, and constituting a power wave P proceeding in one direction and a second power wave P' traveling in the reverse direction. If the distant end of the line is open, both waves are equal in magnitude and P' is the reflected wave of P.

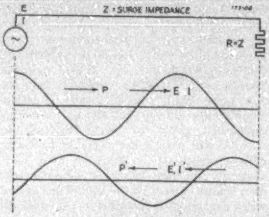

Figure 6. Avoidance of reflected power flow by proper end load

The maximum voltage on the line is given by the sum of both voltage waves and thus the line insulation can be a minimum if the reverse voltage wave disappears. The total current in the line is given by the sum of both current waves and thus the energy losses become a minimum if the reverse current wave disappears. Both conditions can be fulfilled simultaneously by preventing any reflection at the end of the line. This is attained if, and only if, there is an equivalent end resistance R equal to the surge impedance Z of the line, as indicated in the accompanying figure 6. The load is then wholly active and of the magnitude $P=E^2/Z$. The line and the end station are operating with unity power factor and with unidirectionally proceeding waves which have constant voltage throughout. With a surge impedance $Z=400$ ohms, we have for $E=220$ kv directly $P=$ 120 megawatts, an optimum load which I have called[1] for the transmission system mentioned above the "natural power" of the line. This special power can be transmitted over any distance without limitation due to the inductance or the wave length of the line. Such transmission requires relatively inexpensive means for angular stabilization at high loads and for power-factor compensation at low loads.

A. M. Taylor (Universal Power Transmission, Ltd., London, England): Clarke and Crary's paper contains a vast amount of information and withal excellently set out.

But the busy engineer will, the speaker fears, be rather bewildered by the abundance of the information. He wants to get some tangible figures for distance, voltage, and power transmitted, and may undervalue the paper because he does not know which of the many sets of curves represent practical conditions. The following remarks are intended to help.

Table I is exceedingly valuable as showing the effect of voltage in increasing the powers which can be put through—*must* be put through—lines, as they get longer, to make them pay commercially.

The speaker is very pleased to see 550 kv suggested. He is certain we shall have to come to it eventually for great distances.

Figure 1 deals with only "dead" loads and is therefore not suitable for practical conditions. Figure 2 deals with terminal generators and receivers which have no reactance whatever and are therefore not to be obtained practically.

Figure 4 comes to practical realities. Generator reactances of 40 per cent and receiver reactances of 25 per cent are considered. A steady-state stability factor of 25 per cent is introduced.

The curves tell us that, at 300 miles and 230 kv, we can transmit 122,000 kw with stability; and that at 550 miles and 330 kv we can transmit 163,000 kw.

Figure 7*a* gives very valuable hints as to effect of changing reactance values at generator and receiver stations and effect on stability. But on the whole, it makes no advance on figure 4—gives only 141,000 kw at 330 kv and 550 miles.

Figure 8*a* is for 600 miles (only) but with an intermediate synchronous condenser station. At 330 kv the power transmitted is increased to 354,000 kw as against 218,000 kw *without* an intermediate station. But synchronous condensers of four times the base power are required in the case of the intermediate station scheme, which largely discounts the advantage.

Figure 9*a* is for the use of 50 per cent of series capacitors in the line and gives the figure of 228,000 kw transmitted over 600 miles at 330 kv. Figure 10*b* combines 50 per cent of series capacitors with 75 per cent of line capacitance kilovolt-amperes canceled by shunt reactances, and obtains 228,000 kw transmitted over 600 miles at 330 kv with 25 per cent stability margin. The speaker, however, estimates that with quadrature boosters he can transmit 610,000 kw with a 50 per cent stability margin at same voltage and distance.

The speaker would here explain that his calculation for the figure of 610,000 kw mentioned above is arrived at by the use of Miss Clarke's figure 4 given in her Institute paper in February 1926. (This figure omits ohmic resistance.) The reason for his being able to get such an excellent result is that he normally employs the boosters not only to cancel out the reactance of the line, proper; but also that of the step-up and step-down terminal transformers.

If the line plus transformers are cut out in this way, we have:

$$P_{\max}=\frac{(1)^2}{\sqrt{\underset{(x_G)}{0.583}+\underset{(x_R)}{0.406}}}=2.055 \text{ per unit} =1{,}235{,}000 \text{ kw on a 600-megawatt base}$$

If reactance of line and transformers are *included*, the value of $P_{\max}$ immediately drops to 415,000 kw. This result is of the greatest importance.

It will no doubt be objected that, since the quadrature booster gives only a constant secondary voltage (i.e., boost), for the maximum steady-state stability current, a sudden increment in synchronizing current traversing the line would give increased reactive drop in the line and a consequent sudden lowering of voltage at receiver terminals, with a further demand for synchronizing current; and thus a "vicious circle" would begin; unless the ordinary regulating arrangements have had time to operate—say 0.5 second, at least.

Consequently, we must face this fact and assume (which is considered reasonable) that, at the moment prior to the sudden demand, the boosters at a steady fixed line load of 610,000 kw have just exactly canceled out the reactance of line and transformers. Now let a sudden increment of load—at receiver—demand momentarily ten per cent more current in the line (i.e., 61,000 kw); and reconstruct the Clarke diagram to take account of this "equivalent extra reactance" (and *only* this). The speaker finds, on doing this, that the value of P_{max} is now changed from 1,235,000 kw to 1,080,000 kw (i.e., by only 12.5 per cent).

He therefore concludes that, since $P_{max} =$ 1,235,000 kw is given by Clarke's formula, when *ignoring* said deficiency of boosters, it is absolutely safe to work at 610,000 kw which gives a 50 per cent margin. This particular value is taken because it represents the value at which the capacitive kilovar equals the inductive kilovar and suits the quadrature booster system. But a greater power may be taken if desired, under certain modified arrangements; and would undoubtedly be *quite* safe as regards stability.

The speaker has observed that the authors, in section III, subsection (*a*), of the paper state that the quadrature booster method "decreases the angular displacement at which pull-out occurs." Surely however, they must have overlooked that it is *not* the reduction of the angular displacement *in the line itself* that is the matter at issue; since the reduction of this, if any existed, would actually *increase* the stability. For instance, taking the extreme case, viz., that of a system in which the transmission line consisted only of a pair of bus bars, it will not be denied that here we have the conditions of maximum stability. It is not, therefore, the phase angle between the ends of the line that counts, but only that across the generator plus that across the receiver, which the authors would appear to have overlooked.

Consequently (even looking at things in their worst light) in a system which normally approaches the equivalent of a solid bus bar between stations, there will be only a loss of stability to a trifling extent; corresponding, in fact, with only a $12^{1}/_{2}$ per cent diminution (already established earlier) in the maximum pull-out power for a ten per cent increment in line power. Where, however, there is already a great phase angle between the two ends of the line, or parts of the line, as in most systems, the conditions are presumably very much less stable; because other factors than mere line inductance are at issue.

This very interesting paper is so full of extremely valuable matter that the speaker feels that these few remarks do not in the least represent all that he ought to have touched upon; but he ventures to think that they are important and hopes that the summary of the salient features of the several diagrams which he has presented may be acceptable to the authors—and to any engineers who have perhaps not fully assimilated the paper.

Edith Clarke and S. B. Crary: Several of those who discussed the paper have pointed out that the chief limitation imposed upon the transmission of power over long distances is an economic one. With this we agree. As stated in our paper, no attempt was made to present an economic study; it was thought that the technical features should first be thoroughly understood.

Messrs. George and St. Clair have indicated that they intend to present more complete discussion of the economic features at some future time. These discussions should be of considerable interest and value.

Mr. George is correct in stating that in addition to stability, regulation and power loss are important factors. In our paper the curves presented give directly the power loss in the line, as well as the reactive kilovolt-amperes at both the sending and receiving ends of the line required to maintain terminal voltages. The economic studies we have made for given sets of assumed conditions indicate that the cost of transmitting a kilowatt-hour per mile can be kept practically constant for distances from 200 to about 500 miles. As the distance increases, it is necessary that a higher voltage be used and a larger block of power be transmitted in order to keep down the transmission cost per kilowatt-hour per mile. For these longer distances, the series capacitor provides a means of maintaining a more reasonable transmission cost. As Mr. George has pointed out, the cost goes up with conventional transmission as the distance to which power is transmitted is increased. Without series capacitors, the cost per unit of energy per unit distance may be tripled when the distance is doubled. However, with series capacitors, if the distance is doubled, the transmission cost may be only doubled rather than tripled. Mr. George's chart shows clearly the limitations due to losses as the transmission distance is increased and the necessity of using lower resistance conductors for long distances.

Mr. Barry's curve shows the effect on the amount of power that can be transmitted by changing the resistance of a static receiver load. The values from his curve check those of curve *C* of figure 1 of our paper in that they indicate, for distances beyond about 400 miles, no increase in power above the surge impedance load without overvoltages along the line.

Professor Starr points out the interesting result that even for lines of existing lengths, series capacitors appear to be a worthwhile means of increasing power limits. Our economic studies bear out Professor Starr's, and indicate very definitely that series capacitors at present costs should be considered as a means of reducing transmission costs for either existing or new lines, greater in length than about 200 miles.

Mr. St. Clair has given an interesting application of the surge impedance loading concept in making power-flow studies.

Professor Rüdenberg points out the value of some reactance in the line. The considerations which Mr. Concordia has discussed place definite limitations on the amount of compensation that can be used. It is of interest to note that some reactance, as Professor Rüdenberg has pointed out, for control of voltage on a transmission line may be valuable; while as Mr. Concordia points out, with series compensation of line reactance, it is necessary that there exist some resistance between the two parts of the system as well as possibly some uncompensated reactance. The resistance in the line becomes a necessary factor only in the case of series compensation.

We are glad to learn that Mr. Evans is in general agreement with our conclusions. We would like to point out, however, that we believe series capacitors provide a much more effective method for increasing power limits than synchronous condensers, used for that purpose alone. Mr. Evans has suggested that our studies of the intermediate condenser would be more useful ". . . (1) if based on condenser internal voltages higher than that of other machines as would be the practical case, and (2) if based on adjusting the machine kilovolt-amperes in accordance with the increased capacity. . . . . ." The first consideration was taken into account in arriving at the results presented in the paper, for when the line loading exceeded that of the unity power-factor loading, the synchronous condensers were required to furnish the system with overexcited capacity in order to maintain the terminal line voltages; therefore, their internal voltages were appreciably higher than those of other machines of the system. The effect of the second consideration pointed out by Mr. Evans is taken care of on the curves, as figures 7 and 8 show the intermediate station kilovolt-ampere requirements as well as the intermediate station reactances. Thus it is easy to arrive at the required intermediate station kilovolt-amperes and reactance. Mr. Evans has taken this paper as an indication of reduced emphasis on d-c transmission. The intention was to restrict this paper to stability limitations of a-c systems, as it is believed that any rational conclusions relating to power transmission must be based upon a clear and accurate comparison of all available methods. Although series capacitors provide a means of overcoming some of the limitations of a-c transmission, this does not mean that d-c transmission will not find application under conditions favorable to d-c.

In closing we wish to thank all those who discussed the paper for the important contributions they have made to this subject.

Powerton-Crawford 220-Kv Line—System Operating Features and Terminal Design

Discussion and authors' closure of paper 41-26 by H. E. Wulfing and T. G. LeClair, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1084–9.

R. A. Hentz (Philadelphia Electric Company, Philadelphia, Pa.): Tabulation shows eight regulating transformers at the Powerton end, six for regular operation and two spares. The cost of one of these 3,000-kva regulating units must be considerable and it would be interesting to know why the second spare was preferred over permanent switching equipment by means of which one spare could be electrically connected in place of any one of the six regular units.

H. E. Wulfing and **T. G. LeClair**: Mr. Hentz is correct in the statement that the cost of the two 3,000-kva spare regulating units at Powerton was considerable. A careful estimate showed, however, that the use of two spare regulating units would cost less than one spare regulating unit and additional switching.

Two regulating units are needed for each single phase main transformer in regular operation because of the two low voltage windings. This is shown in figure 3 of the paper. To provide connections so that only one spare regulating unit is necessary, involves cable and disconnecting switches for the series and exciting winding to be connected in six different places. These connections would be in addition to those for substituting the main transformer spare for the main transformer on each phase.

The spare main transformer has a spare regulating transformer permanently connected to each of the secondary windings. This combination of main and two regulating transformers is treated as a single unit for switching. The number of facilities required for replacing the combination of transformer and regulating units is the same as the number required for a spare transformer alone. The complete unit will be taken out of service for any case of trouble regardless of whether it is in the main transformer or one of the regulating units.

Rural Automatic Telephone Networks

Discussion and author's closure of paper 41-47 by C. F. Ffolliott, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1079–83.

Emmett D. Talbot (Consulting Telephone Engineer, Rochester, N. Y.): The application of automatic switching methods to rural communication problems has resulted in increasing demands for service protection facilities. Some of the more important developments in service protection are:

Intercepting Service Facilities

In all telephone networks, it becomes necessary from time to time to change the subscriber's telephone numbers, and there are some subscribers who discontinue their telephone service. Number changes can be corrected and brought up to date with the issue of a new telephone directory, but during the interval between issues of the directory it is desirable to notify subscribers of number changes as economically as possible.

Notification of number changes can be accomplished in several ways, at the present time the preferred methods in use are:

Supplemental equipment is provided so that it is possible to cross-connect a changed or discontinued subscriber's number to this supplemental equipment, whereby, a subscriber calling a changed number will receive a tick tock tone indicating that the number called has been changed or discontinued. Where this method is used subscribers are advised that upon hearing a tick tock tone, they should hang-up and dial the operator, generally zero, the operator will ask the calling subscriber the number being called and will furnish the calling subscriber correct information relative to the status of the called number.

This method of intercepting has been found satisfactory in a number of rural areas and is not expensive to apply.

In many rural dial areas, intercepting service is provided through the use of supplemental equipment, to which changed or discontinued numbers are cross-connected, but instead of notifying the calling subscriber by means of a tone that the number has been changed the apparatus automatically connects the calling subscriber to a trunk to the zero operator. The operator furnishes the calling subscriber with the correct number or other information required to satisfy the calling subscriber. This method is somewhat more costly to apply but has the advantage over the first scheme of giving the subscriber direct connection to the zero operator.

Another important service protection that has been developed is in connection with the various alarms associated with a dial central office equipment. The more important alarms are those indicating a failure of the commercial power supply, blown fuses in battery and generator control circuits, and open fuses or heat coils individual to the subscriber's lines. Alarms are classified as major (power, battery, and generator supply), or minor (subscribers' line protection).

Means are provided so that when an alarm condition occurs in an unattended dial office, this condition is transmitted automatically over a trunk to the parent attended office. When such an alarm is indicated at the attended office, anyone on duty at the attended office can pick-up the trunk carrying the alarm signal and by means of a dial at attended office and special switch mechanism at the unattended office, determine by dialing a prearranged set of digits, what type (major or minor) alarm exists. If a major alarm condition is found, a trouble man can be dispatched to correct the condition, if a minor alarm is indicated, the condition is recorded and reported to the trouble man to be corrected as soon as it is convenient for him to visit the unattended office. The transmittal of the alarm conditions to the attended office insures against service interruptions being left uncorrected for any appreciable length of time.

One other feature that improves the service which is gaining favor is the use of time control equipment in connection with exchanges on a flat rate basis, especially those rural unattended areas having free call privileges into some nearby dial or manual area. The time control feature makes it possible to automatically control the length of line occupancy by a subscriber. If a six-minute use is desired the time control apparatus can be arranged so that at the end of a six-minute period, a connection is automatically cut-off. The control can be applied to all local or free service calls, and not be effective on toll calls. Where time control service is given, there are generally some subscribers who dislike this service, however, the majority of subscribers are pleased with the service. Time control tends to discourage long telephone conversations, which tie up the apparatus.

D. L. Solomon (Consulting Telephone Engineer, Chicago, Ill.): This paper describes one of the lesser known applications of automatic telephone switching equipment to the solution of communication problems in rural networks. While it is widely known that automatic telephone switchboards are available for use in small communities, it is not generally known that these automatic switchboards can be easily interconnected to form a practical and economical network.

Because of the more congested areas and higher density of population in European countries, with resultant problems of furnishing satisfactory and cheap telephone service in rural areas, this problem has been attacked to a rather amazing degree. There, in certain countries, notably Belgium, Holland, and Switzerland, not only have most of the rural exchanges been converted to dial operation, but a general plan has been developed for complete national dialing, where any subscriber can dial direct to any other subscriber in the nation, without the aid of an intervening toll operator. This has been accomplished by the development and use of automatic toll ticketing, a system wherein the necessary commercial details of the toll call, normally recorded by a long distance or toll operator, are stamped automatically on a slip of paper, thus dispensing with any human intervention in the progress of either a local or a long distance telephone call.

These European rural exchanges are quite similar in operation to those described in this paper, with the possible exception that provisions for party-line working are not provided, since party-lines are not in general use outside of the United States and Canada. They are also furnished in compact self-contained units, but the pole mounted type has not yet been used, so far as is known.

As the author has stated, much of the inter-exchange dialing in Europe is performed by the use of alternating currents, and standards for this method of long-distance dialling have been set up by the Comité Consultatif International Téléphonique, which is the governing body of the various telephone administrations in Europe and elsewhere.

F. E. Norris (Associated Telephone Company, Ltd., Santa Monica, Calif.): The economic considerations incident to the establishment of an unattended dial controlled switchboard must, among other things, recognize the possible effects on toll line investment and revenue. It is not unusual to find that the toll lines connecting the manual office under consideration for conversion with the "master" or control exchange are working to capacity or are actually overloaded. Both conditions indicate that all toll facilities are in use frequently. This may present a serious service problem after dial operation is established if the toll lines are not reenforced. The difficulty arises out of the fact that the "storing" possibilities existent with manual operation (and the subsequent release of such calls in the order received) do not exist in the unattended dial exchange. In other words, in a manual office the customer always is able to reach the operator to inquire the status of his toll call when all toll lines are in use, whereas in a dial office he receives an impersonal busy tone upon dialing the toll code. Furthermore, he may dial for the operator repeatedly but not at the particular moment a toll channel is available, and at that moment another customer may, upon the first attempt, seize the channel.

In anticipation of the service difficulties attendant to this situation, the usual practice is to compute the toll line facilities on a more liberal basis. For example, a delayed call probability of 20 in 100 may be adequate when the exchange under consideration is operated manually, but after the conversion of the exchange to dial operation, a delayed call probability of 6 in 100 may be necessary. To reduce the delayed call probability from 20 in 100 to 6 in 100 will indicate in many cases the necessity for increased toll line facilities and the cost of providing them should be reflected in the conversion to dial operation study.

The conversion to dial operation frequently results in an increase in stations served and consequently an increase in toll business. The possibility that the increased toll business may demand an increase in toll line facilities should be considered together with the increased revenue.

In some cases, nearby communities are served only from toll line stations (using toll lines other than those connecting the unattended dial exchange with the master exchange). These frequently present a special problem (and special equipment) as they may have a different toll rate to many points than the unattended dial office has to the same points. Other conditions may make it impractical to operate such stations on a dial (or common battery) basis. Special equipment to connect such lines with the toll trunk lines, when the receiver is removed or the magneto operated, is available. This special equipment involves an appreciable additional cost which should be considered in the conversion study.

In some instances the exchange to be converted may connect to a master or control exchange owned by another company. Further, the toll line facilities connecting the exchange to be converted with the master or control office may be owned by another company. There may be either or both traffic and terminal compensation agreements which will require modification when the conversion from manual to dial operation is made. It seems only reasonable that such agreements be reviewed and discussed with the connecting company and the conversion study made to reflect any revenue gains or losses resulting from possible contract revisions before proceeding to install dial equipment.

The manufacturers have steadily increased the operating range of their equipment as regards subscribers loop resistance. All of the longer loops should be investigated however to determine if they fall within the supervisory limits of the equipment under consideration. If some do not, an improvement in the line or special central office line equipment is required. The investigation of such lines should also be made with the possibility of high resistance joints in mind and such joints corrected.

Drop wires should be considered when a conversion to dial is contemplated as experience has shown in many cases that drops which may work with fair satisfaction in a magneto, and sometimes common battery manual exchange, are not satisfactory for dial operation. It is rather difficult to determine in advance of the conversion, particularly if the exchange considered for conversion is not magneto, which drop wires must be changed. For study purposes, some companies estimate that 10 per cent of all drops will have to be replaced following a conversion from magneto manual to dial operation, but this percentage, of course, may be varied upward or downward, depending upon a knowledge of the conditions within a particular plant. The need for such replacement may not become apparent immediately following the cutover, if the weather is fair, but low insulation may show up with the first rain if the drops are not in good condition.

C. F. Ffolliott: Mr. Talbot's comment is apt and covers services that are available for use on standard boards. Alarm supervision such as he describes is a standard feature of most unattended exchanges. Intercepting service and conversation timing are optional features that can be supplied with most boards if desired by the operating company. There is a considerable difference of opinion among operating men, supported by ample arguments on both sides, as to when or where these services should be used. They are available however for those who want them.

The points in Mr. Norris' comments are well taken and serve to emphasize the importance of planning for and providing adequate facilities in all departments of the telephone plant. As he points out and as I mentioned in my paper, both toll and local traffic invariably increase with the introduction of automatic. This point should always be kept in mind by those companies who are planning to convert existing offices to automatic and adequate provision should be made for outside plant improvement and extension. In passing it might be of interest to mention that as a general rule a rural exchange should never be engineered with less than two circuits to the toll center.

Mr. Solomon's comments are interesting since they call attention to current European practices as regards the rural telephone problem. It might be pointed out by way of extending his remarks that the European and American problems are somewhat different because of essential differences in the way of life in the rural communities of the two continents. In Europe, contrary to the practice in this country, the farmers live in small villages located at frequent intervals throughout the country. This characteristic of their rural life combined with the fact that most European administrations operate on a message rate and not on a flat rate basis tends in some cases to reduce the local telephone traffic to the vanishing point and leaves only toll traffic to be handled by the exchange. The absence of party lines makes line identification simple and allows the extended use of "multiple metering" for automatic toll dialing. Automatic toll ticketing mentioned by Mr. Solomon is a more recent development and as such has not been used in the past to the same large extent as the "multiple time and zone metering" scheme. It is, however an important advance in the art and will undoubtedly see more extended use.

Prolonged Inrush Currents With Parallel Transformers Affect Differential Relaying

Discussion and author's closure of paper 41-65 by C. D. Hayward, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1096–1101.

A. E. Flink (The Ohio Edison Company, Youngstown, Ohio): Tests such as those described by the author, both field and laboratory, are highly desirable for the application of relays protecting transformers on account of the infrequent occasions upon which their protective equipment is called upon to operate. No transformer failures requiring differential relay operation at Wood Street substation of the Ohio Edison Company have been reported during the past ten years.

Perhaps more attention should be concentrated from a transformer design standpoint on wide variations in normal magnetizing current of transformers of supposedly similar design. The single phase units at Wood Street are similar and of the same manufacture but were not all purchased together. One of them has an exciting current of greater than six per cent of its full load current, and after preliminary test to determine the cause of false relay operations it was suggested by the manufacturer (who is also the relay manufacturer) that one of the units was defective since the unusually high magnetizing current indicated the probability of a core short. This possibility was abandoned when a similar transformer located at another station showed substantially the same magnetizing current. Difficulties with differential protection on inrush current have occurred on units having unusually high steady state magnetizing currents.

The specific effects of parallel transformers described by the author were not foreseen by the relay manufacturer and were not suspected until after several conclusive false operations. During the few months in which harmonic restraint relays were left in service at Wood Street there were three incorrect operations of the harmonic restraint relays in which the substation load was interrupted with no other relay operations or system switching taking place within hours of the false operation. System conditions were normal, and the most plausible cause of any disturbance (none was noticed by operators or dispatchers) may have been faults or switching in the equipment of some minor industrial customer. With relatively new and untried relaying devices it is possible that there are other unknown special effects such as the one described by the author which should certainly be discovered and corrected before operators can have sufficient confidence in the relays to apply them extensively.

From the standpoint of the protection engineer a relay which may be subject to little known effects is particularly unfortunate when applied to a power transformer. Incorrect operations extending over a few weeks or months may require that the relays should subsequently give perfect performance for over a century in order to compare favorably with general relaying performance on the system. It is hoped, therefore, that the manufacturer will encourage extensive tests both of the relay network elements themselves and of different types of transformers and that this new type of relay may become thoroughly reliable.

Eric T. B. Gross (College of the City of New York, New York, N. Y.): The solution to the problem of prolonged inrush currents with parallel transformers has been known for many years. In 1913, K. Kuhlmann published a paper[1] which contains a very complete treatment of all the many questions concerned. He also reported on his experiments and published some of the oscillograms which proved the results of his circuit analysis. Kuhlmann's investigations were considered important enough by other authors to be included in textbooks on transient phenomena.[2]

In principle, there is no difference between the prolonged switching-in current in a single phase and in a three phase transformer. The magnitude of the greatest amplitude of the inrush current depends on the voltage at the time of closing the switch, and it is a maximum if the closing happens to be made at zero voltage. Therefore, in case of a single phase transformer, the chances for a heavy transient current are not very great. However, as the phases of a three phase transformer are shifted by $^2/_3\pi$, there will always be one phase near its zero voltage and a heavy, unsymmetrical transient current between the transformers will circulate. In 1925, I had the privilege of making investigations of this kind for transformers in actual service in the "Sokolska trida" substation of the Prague Electric Utility Power Company, Czechoslovakia, where several transformers of considerable size are installed. When another transformer was switched in, the prolonged inrush current was so heavy that the overcurrent relays operated and isolated both the transformer just switched in, and most of the other transformers which had been in service before. Fortunately, the relays were installed in two phases only, and disconnection did not always occur, because of the unsymmetry of the current distribution. Sometimes, the inrush current had died out before the very long setting of the relays was reached. However, the measurements of the currents in all three phases showed that nearly the same maximum currents occurred each time the transformer was switched in, which was in good agreement with Kuhlmann's analysis. The high inrush currents were due to the relatively high resistance of a long underground cable connection between the Holesovice Power Station and the substation mentioned. As a remedy, it was recommended that a second transformer be put in service by closing first the resistance breaker connected to the winding on the other side. One of the contacts of each phase of the resistance breaker consists of two parts, a short and a long finger, which are connected through a resistance. During the closing period, the resistance is temporarily inserted in series with the circuit, but the resistance is short circuited as soon as the shorter contacts have been closed. The later connection of the power circuit to the already magnetized transformer does not give rise to inrush currents. For the damping of switching-in currents, resistance breakers were used in Europe quite extensively for transformers, at that time.

Wm. R. Brownlee (Commonwealth and Southern Corporation, Jackson, Mich.): The inherent reliability of power transformers makes the accumulation of field experience data on transformer differential relays extremely difficult. Short circuits within the protected zone are rare, the interval usually being from five to twenty years, and of these faults a large proportion consists of bushing flashovers so that the sensitive action of differential relays is not required. This same inherent reliability makes it mandatory that transformer protective relays be much freer from false operations than transmission line protective relays. Coordinated economical system design based on observed failure rates results in the construction of many transmission substations consisting of only one transformer bank with two to four transmission lines. Therefore, the author is especially to be congratulated on his laboratory tests of model units after field tests became too cumbersome. Since the principle itself of the harmonic restraint relay for transformer protection is a relatively new application, it is earnestly suggested that tests be expanded so as to uncover other special difficulties and also to determine definitely whether the design sensitivity will actually be obtained in transformer faults which are of such a nature as to limit fault current appreciably.

The cancellation of third harmonics in certain instances is not confined to delta-delta or open delta transformer banks. When the power transformer windings are connected in wye it is practically always necessary to connect the current transformers on these windings in delta, either on account of phase relation with current from the other windings or to prevent false operation on external ground faults when a delta tertiary winding is provided but not brought out. Naturally a delta current transformer connection provides the same cancellation of harmonics as a delta power transformer connection. Since the only exception to the delta connection of either transformer windings or current transformers is the relatively rare case of a wye-wye connected (usually three phase) unit with no tertiary winding, it is suggested that no reliance should be placed on triple harmonics for relay restraint.

The author has not cited any supporting data for his statement that current due to an internal fault is nearly sinusoidal, containing little or no harmonic components. It is of little moment whether bushing or terminal flashovers result in a sinusoidal wave since current limited only by the power transformer impedance will practically always be adequate for the operation of even relatively insensitive differential relays. The occurrence of faults which limit the current to a fraction of its normal short circuit value is the chief reason for desiring a sensitive differential relay, and it seems entirely possible that the influence of arcs under oil or the presence of iron in a high reactance path between portions of transformer windings (in case of partial winding faults) might introduce sufficient harmonics to defeat the desired relay sensitivity.

It would be of interest to know details of cases which have come to the author's attention of transformers already energized being tripped falsely by their differential relays when another transformer was energized from the same bus. Aside from this possibility, the desensitizing of transformer differential relays during the inrush period either with time delay overvoltage relays or control switch connections is open to the very serious objection that transformers should be adequately protected at the time they are first energized.

Previous methods of transformer differential protection admittedly fall short of adequate performance. It is therefore hoped that the author will be encouraged to make exhaustive tests on the harmonic restraint relays, both to determine whether there are any other special effects which will naturally arise in connection with a new device or new principle and whether genuine sensitivity is secured on the type of internal low current, transformer short circuits for which sensitive relay operation is essential.

E. L. Michelson (Commonwealth Edison Company, Chicago, Ill.): Mr. Hayward's paper brings to light a very interesting case of magnetizing inrush currents, and his analysis should be of aid to power system engineers in avoiding difficulties due to this situation. In Chicago, there has recently

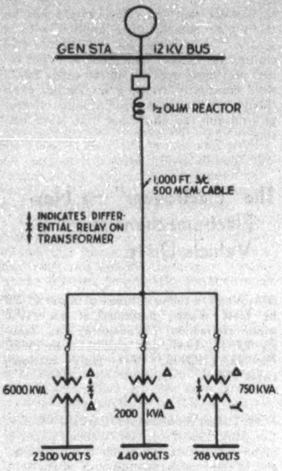

Figure 1

been experienced another unusual type of inrush current problem, which appears to be of a different nature than the one described in this paper. The system involved is shown on the attached diagram.

It was found that the magnitude of inrush currents varied considerably with a different number of transformers connected to the 12 kv line. When the three transformers were energized simultaneously, the differential relays (one set for each transformer) operated in a very large percentage of the trials, while with only one transformer being energized, the differential relays tripped only in a small percentage of the trials.

Oscillographic tests showed that the exciting current inrush was of the usual form regardless of the number of transformers being energized, and only the magnitude varied. Records made of the 12 kv bus pressure showed that there was no appreciable change in this pressure when the transformers were energized.

It appears that some type of mutual effect exists in this system to create the high value of inrush currents. However, it does not appear to be the same type of phenomenon described in this paper inasmuch as the resistance of the supply system in this case is extremely low.

W. K. Sonnemann (Westinghouse Electric and Manufacturing Company, Newark, N. J.): The fact that an inrush current will flow in the power transformer already connected does make a very good case for the use of harmonic components for the prevention of false tripping. The magnetizing inrush does have, at all times, a second harmonic component. From this standpoint, then, the use of the second harmonic in particular does have its advantages for identifying a magnetizing inrush. It should be noted, however, that in the event of a heavy internal fault which has a direct current component, d-c saturation of the current transformers may occur and thus introduce harmonic components of all frequencies at a time when the relay should trip. The point is that while utilization of the harmonics of the magnetizing inrush has its advantages, they must be used with care.

An important point to note is that the inrush in the connected transformer is not too severe when compared with the inrush of the transformer being connected. The paper indicates that a maximum crest of about $^1/_3$ that which occurs in the transformer being connected is experienced. This undoubtedly accounts for the reason that the field has not experienced more trouble with this condition than it has. There are in service any number of installations of more than one transformer bank, protected by differential relays, and connected to the same bus. These relays, more generally of the induction percentage differential type, have not been tripping their banks off of the bus every time a transformer bank has been energized. The evidence seems to indicate that the special conditions described by Mr. Hayward do not reach troublesome proportions except in the rarest of cases.

The mathematical formulas which are given in the appendix are quite long and involved and the derivations of these formulas are not given. It is presumed that the derivation has been omitted for the sake of brevity. The writer believes this is just as well, inasmuch as the formulas certainly should be considered with the utmost caution. The reason for this is that the formulas assume the inductance values to remain constant which is an assumption very far from the truth. Also, the inductance values for the two transformers have been assumed to be their normal exciting inductances, whereas, during inrush, the effective inductance is reduced as indicated by Mr. Hayward's figures, to approximately 2.5% of the normal excitation value. With such a range in values through the inrush period, and with a variation in inductance throughout any one cycle, the formulas certainly cannot be taken too literally.

It is believed that in figure 5, the curve for the "current in the line" is in error in that the ordinates should have approximately twice the value shown on the curve. At time, $t=0$, the d-c current in the line certainly equals the d-c current in the switched transformer, T_2. Further, the formula for the "current in the line" shown on figure 5 has a 2 in the denominator which is not present in the text.

The explanation given for the cause of a direct current component in the transformer already connected is quite valid, although we feel that it is a bit left-handed. It is felt that a more straight-forward explanation is given by the fact that the two transformers are, after all, connected in parallel and the voltage drop across one is necessarily the same as the voltage drop across the other one.

The voltage drop, e_2, across transformer, T_2, caused by the d-c component, i_2, is expressed by the following equation:

$$e_2 = i_2R_2 + L_2\frac{di_2}{dt} \qquad (1)$$

In this case, the inductive component of the voltage drop is both larger than and negative with respect to the resistive component, hence, the total voltage, e_2, is negative. The result is that a d-c current builds up in the transformer, T_1, in the direction shown by the dotted arrow in figure 2 of the paper.

C. D. Hayward: It is very gratifying indeed to have a paper received with so much discussion. Apparently the subject is new and interesting to many people even though to Dr. Gross it is "old stuff." Frankly, I was not aware that the phenomenon described had ever been identified and investigated before. None of a rather large group of engineers with broad experience in the relay and transformer fields with whom I conferred had ever heard of it before. While preparing the paper I checked several of the standard indices covering all the leading technical periodicals, both American and foreign, for twenty years back without finding any reference to the phenomenon whatsoever. Apparently the phenomenon, although described by Kuhlmann twenty-eight years ago, as Dr. Gross tells us, was not recognized in this country until the investigation described in the present paper was made. It is strange indeed that a phenomenon of such magnitude should remain unrecognized so long. Since publication of the paper, several operating engineers have reported cases of long duration inrush currents which have puzzled them in the past but which are now seen to be explained by the effect described. No doubt many other cases have been unreported or perhaps ascribed to other causes because the real cause was not understood. It would certainly seem true that in a great many instances when a transformer is magnetized there is another transformer already connected and carrying the load, whose presence may have had more to do with the inrush current tripping experience than the design of the transformers themselves. It would be interesting if other operating company engineers who have experienced inrush trouble would review the circumstances surrounding each installation and report those instances in which inrush tripping was experienced when other transformers were connected in parallel with the one being switched.

The case described by Mr. E. L. Michelson in his discussion appears to be one in which inrush currents of increased magnitude are set up when parallel transformers are switched on a line whose resistance is quite low compared with the transformer winding resistances. I am inclined to agree that the low line resistance would prevent the phenomenon as described in the paper from being set up in any appreciable magnitude, but to analyze the case further more complete data are needed.

Mr. W. R. Brownlee's discussion relates chiefly to the harmonic restraint relay rather than to the inrush phenomenon which is the main subject of the paper. I heartily concur in his opinion that devices employing new principles of operation should be thoroughly tested before being applied. The harmonic restraint relay has been so tested. It is rarely if ever possible, however, to anticipate completely all the special conditions which a new device will encounter in service. Sometimes it is a long time before these conditions are discovered. The subject of the present paper is a case in point. The percentage-differential induction relay is an old device, yet in all the years it has been applied no one of all the thousands of engineers and testmen intimately concerned with its use, employed in all the operating companies of the United States as well as in the manufacturing companies, ever before found out why it would trip more frequently on inrush current when another transformer was present in parallel with the one being switched.

With regard to the question concerning the possibility of arcs under the oil in the case of a partial winding fault so distorting the wave form as to reduce the sensitivity of the relay, it should be pointed out that the relay has a very nearly constant per cent harmonic slope characteristic right down to pick-up; that is, a current having a little less than 25 per cent third harmonic content (or the equivalent in other harmonics) and of a magnitude just above the pick-up setting of the relay will cause the relay to operate as readily as a current of sine wave form having the same magnitude. In general, partial winding faults introduce so much linear equivalent leakage reactance and linear resistance into the circuit in comparison with the nonlinear resistance of the short arc path that the current wave form is not distorted to the degree required to restrain relay operation.

The reference to possible current wave distortion produced by "the presence of iron in a high reactance path between portions of transformer windings" is difficult to comment on because it is not clear what is meant. If a high *reluctance* path is meant as, for example, the presence of the steel tank of the transformer in the stray flux field of a faulted winding section, it seems obvious that no appreciable distortion would be introduced due to this cause since most of the reluctance of the leakage flux path is through oil or air rather than through the iron. The flux density in the core itself will not increase, of course, due to the fault, since the applied voltage does not increase.

Mr. W. K. Sonneman in his discussion points out what appears to him to be an error in figure 5 of the paper. Actually, no error exists although perhaps the labelling of one of the curves is a bit confusing if one does not read the text of the paper too carefully. The curve labelled: "current in the line," shows the transient component of current which flows in the transmission line and divides between the two transformers, half flowing in one and half in the other if the two are identical. The curve is plotted at the half amplitude value at which the current flows in the transformers so that it can be directly added to the other transient component shown by the curve labelled: "circulating current" to give the current in the switched transformer T_2 as shown by the curve so labelled and subtracted from it to give the current in the parallel transformer T_1 also shown by a curve with the appropriate label. This is all explained in the appendix in the section headed "Case of Two Identical Transformers."

I have no objection to Mr. Sonneman using differential equations rather than a word description to explain the setting up of the transient currents if he prefers. However, if this is done a complete set of simultaneous differential equations, including the resistances and inductances of the line and of transformer T_1 as well as those of T_2, should be used. Otherwise the whole point of the control of the phenomenon exerted by the line resistance is entirely missed.

The derivation of the formulas in the appendix was omitted to conserve space, but I will be glad to send a copy of it to anyone interested. Since the derivation is the result of a rather straightforward application of the usual methods of the operational calculus it was felt that it was of little general interest. The correctness of the final equations may be readily checked by anyone by the simple process of substituting in limiting conditions; that is, by letting some of the resistances or inductances become zero or infinite in various combinations.

Mr. A. E. Flink in his discussion relates that in the tests at the Ohio Edison Co. Wood St. substation one of the transformers was found to have an exciting current in excess of six per cent of its normal full load current. This is explained by the fact that this exciting current was measured with 13 per cent overvoltage on the transformer and that no correction was made in the readings for this overvoltage condition. The overvoltage at which the transformers were being operated also explains the variation in exciting current measured on the different units since the exciting currents were measured at varying amounts of overvoltage. The transformers were being continuously operated with a high side line voltage in the neighborhood of 23 kv applied to winding taps rated at 19.82 kv. It is conceivable that at the time the three relay operations were reported without switching at the station the voltage may have for a short period increased to as much as 25 kv. This is equivalent to 26 per cent overvoltage on the 19.82 kv tap. With this degree of overvoltage the steady-state exciting current would increase to a magnitude sufficient to cause a current greater than the relay pick-up current to flow in the differential circuit. The third harmonic present in the exciting current would be cancelled in one phase due to the open-delta connection of the transformers and the relay in that phase would operate. The remedy for this condition would be to use a less sensitive pick-up setting of the relay or, if possible, to operate the transformer on a tap rated nearer to normal line voltage. Faults in the equipment of some industrial customer causing overcurrent to be carried through the protected transformers is not a plausible cause of the operations. In addition to harmonic restraint the relays are provided with the usual through current restraint of a percentage-differential relay. This adequately prevents operation on through faults as was definitely proved at the Wood St. station itself when a number of through faults occurred while the relays were in service.

It seems scarcely fair or logical to blame a new device for the existence of a phenomenon simply because the phenomenon was discovered by its use. Neither does it seem logical to hesitate to use a new device which overcomes the serious shortcomings of its predecessors on the grounds that it may possibly have shortcomings of its own as yet undiscovered. The conditions with regard to inrush currents at the Wood St. station are admittedly severe but during the course of the tests no evidence was found to indicate that the relays would not be thoroughly reliable when applied with a separate set of relays for each of the two transformer banks. The induction type relays previously applied, on the other hand, were constantly tripping on inrush even though they were set for a high current pick-up and the maximum time lever setting.

The "Electrogear"—a New Electromechanical Vehicle Drive

Discussion and author's closure of paper 41-28 by Ernst Weber, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (July section), pages 770–7.

F. M. Turner (nonmember, General Electric Company, Erie, Pa.): Dr. Weber's paper is highly interesting, inasmuch as it is indicative of the considerable amount of thought and effort that has been devoted during the past decade to the development of a continuous torque, fully automatic power transmission for use on large urban busses and other vehicles. Because we have been actively engaged for a number of years in the development of electric drive for busses, Dr. Weber's comparison of the Electrogear with the conventional electric drive is of the utmost interest to us.

We have accordingly made some preliminary calculations to compare an adequate Electrogear transmission with a conventional electric drive. This comparison indicates that the electrical machines of the Electrogear might weigh as little as 75 to 80 per cent of the combined weight of the motor and generator of a conventional electric drive. This comparison excludes the weight of the planetary gearing, which, of course, must be added to that of the electrical machines to obtain the total weight of the Electrogear. Cost of such an Electrogear, manufactured by comparable methods, might be about equal to that of the electric drive.

At first glance, the Electrogear might be expected to weigh considerably less than the conventional electric transmission. There are several logical reasons, however, why there is so little difference.

It is pointed out that with the Electrogear only part of the power is handled electrically while a large part flows directly through gearing from the engine to the drive shaft. The optimum point is when the reducer is standing still and all the power is being transmitted through the gearing. However, at this point the reducer must provide sufficient reactive torque to hold the planet spider at standstill, and it requires a considerable current flow through the reducer to develop this stall torque. It is well to keep in mind that in electrical apparatus the size of machine is closely related to the torque which it must develop and that heating of the machine will occur whenever it is maintaining torque, even though there is no power output involved, as at standstill.

It will be noted that during the course of an acceleration, the booster torque does pass through zero, but in this case another condition exists which is unfavorable to electrical apparatus. At this point the field of the booster is zero, which accounts for the zero torque, but it is necessary that a large amount of current flow through the booster armature in order to maintain the torque of the reducer, since the booster and reducer are connected in series. Thus, although the torque of the booster passes through zero, heating still continues due to the continuing flow of current through the machine.

Thus, the electrical machines of the Electrogear must not only contribute some share of the total torque multiplication obtained, but must also provide the reactive torque, or the fulcrum, if you will, for the torque multiplication that is obtained through action of the planetary gearing. Therefore, it may be deduced that the Electrogear fundamentally would have to be approximately the same size and weight as a conventional electrical transmission to handle the same torque conversion at the same rotative speeds. The corollary to this is that the principal contribution toward any weight reduction which might be possible with the Electrogear design is due to the higher rotative speeds of the reducer unit driving through the planetary gearing, which permits some reduction in the physical size of this portion of the equipment. The development of standard rear axles having correspondingly higher gear reduction would allow equivalent reductions in the weight of the conventional generator-motor transmission by permitting the electrical apparatus to be designed for operation at higher rotative speeds.

Compared with the conventional electric transmission, we believe that the ultimately successful Electrogear will offer little, if any, advantage in weight, cost, or efficiency. The feature of electric braking can be incorporated in the conventional electric drive, and, in fact, this has been done in a number of recent applications. The Electrogear has the disadvantage of requiring a mechanical connection between the engine and the rear axle, which limits the flexibility of the power plant mounting to isolate vibration and noise.

Dr. Weber has stated well the five principal requirements of an ideal power transmission. However, durability and low maintenance are not demonstrated satisfactorily by a comparatively few test operations of a few experimental vehicles. In these characteristics, no other fully automatic transmission has even remotely approached the record made by the conventional electric drive in approximately one billion miles of revenue operation.

In closing this discussion, we should like to register one small observation relative to the speed-time curves shown in figure 7 of Dr. Weber's paper, particularly to the curve indicating performance of the bus equipped with the manually-shifted, step-gear transmission. This curve indicates no loss of momentum nor time allowed for shifting from one gear to another. It has been repeatedly proven that the performance of a bus with a step-gear transmission is no better, even under optimum testing conditions with a highly skilled driver, than the performance of a similar bus equipped with electric drive; and further, that under ordinary service conditions, the electric drive bus enjoys a margin of superiority over the mechanical drive bus. In fact, this statement is confirmed in the text of Dr. Weber's paper.

Albert A. Nims (Newark College of Engineering, Newark, N. J.): The equipment described in Dr. Weber's paper is of especial interest to the writer because it confirms conclusions reached by him some twenty years or more ago. At that time experience with electric vehicle drives and a consideration of steps to improve them pointed to a combination of a motor, a generator, and a planetary gear as the most hopeful means of providing the desired flexibility, with a minimum of power translated back and forth between electrical and mechanical forms. It is hoped that, in solving so happily the problems of flexibility, power control, weight and fuel economy, the mechanical difficulties usually attendant upon the use of a planetary gear have been as effectively overcome.

It is noteworthy that both the motor and generator involved have series excitation instead of shunt. Series motors, of course, have practically a monopoly in the traction field, but series generators are a bit unusual. When it is realized that the motor and generator functions interchange, a reason for the series excitation of both machines is apparent.

The use of a small generator, driven by the final output shaft, to stabilize and regulate the speed-torque relationship is also worthy of note. The possibility presents itself, however, of separately exciting this regulator from the vehicle battery instead of by a series field; would the effect on the performance be satisfactory, and sufficiently desirable, to warrant the extra drain on the vehicle battery? The low voltage and high current rating of the regulator suggests the speculation as to whether this might be a possible application for a homopolar generator.

It may be of interest to recall one or two other equipments which were developed prior to the gas-electric drives for present day busses. One of these was covered by the Entz patents and featured the Owen magnetic automobile which had a brief vogue some 20 or 25 years ago. As in the subject of today's paper, there were two electric machines, arranged so that only part of the engine output was converted into electrical power. Both armatures were rigidly connected to the propeller shaft. The field structure of the motor unit was mounted upon the car frame. The field structure of the generator served as the engine fly wheel. The generator speed was the slip between the crank and propeller shafts and the motor armature was permanently connected to the generator armature. Speed control was obtained through the engine throttle, and regulation of the field strengths of motor and generator gave the equivalent of a flexible gear ratio. High initial cost and weight, inadequate torque range, and high operating costs militated decisively against a drive which for those days was exceedingly flexible and easy to handle.

Some thirty years ago Messrs. Macfarlane and Burge described before the Institution of Electrical Engineers a drive which was developed by Crompton and Company for battery-driven busses. The heart of this system was the CMB auto-converter, a four-pole d-c machine with a ring-wound armature and four brushes. One pair of field poles was magnetically independent of the other, so that the voltage of one half of the armature could be increased or decreased or even reversed without affecting the voltage of the other half. One half of the armature was connected across the battery, while the other was in series with the driving motor. By a foot controlled rheostat the voltage of the series portion of the armature was made to buck or boost the battery voltage and so control the speed.

The same controller could also be connected to a constant speed engine and the field excitation of the parallel half of the armature so compounded that, in starting, or in slow speed, heavy torque driving, its voltage was lowered, and the battery discharged; then when a higher speed was attained, the voltage of this part of the armature increased and the battery was charged.

It was claimed that, with the frequent and repeated cycles of charge and discharge thus associated with every stop and start or every hollow in the route, a comparatively small battery was of sufficient aid to a comparatively light engine to give very satisfactory and economical performance. In comparison with the Electrogear, this arrangement suffered from the handicap that all the driving power was translated from mechanical power to electrical and back.

From the description in the present paper it appears that the electrical equipment of the vehicle in question consists of the three machines of the Electrogear, the starting and lighting battery, its generator, and the engine starting motor. Quite a multiple unit plant. Since only part of the driving power is handled electrically in the Electrogear, it would seem profitable to consider the possibility of eliminating the charging generator and starting motor and incorporating a somewhat larger battery into the driving unit in such a way as to get frequent charging and discharging cycles. This mav result in some simplification of the complete power plant, a slight increase in the peak output with a given engine, and the automatic assurance of proper polarity of all circuits at starting.

E. Weber: The comments by Mr. Turner on the Electrogear try to prove theoretically that the Electrogear transmission should be essentially as heavy, inefficient, and uneconomical as the gas-electric drive, notwithstanding the fact that the actual performance data presented in the paper, and corroborated during the oral discussion, demonstrate beyond any doubt the outstanding superiority of the Electrogear on all these points, namely, at least 38.5 per cent lighter weight, 15 per cent better efficiency, and 22 per cent better fuel economy. The only conclusion that one can rightfully draw is that Mr. Turner's theoretical discussion completely fails to understand the principle and function of the Electrogear in spite of ample opportunity to inform himself more accurately of actual facts and test results; indeed, the following will serve to bring out the obvious confusion and inconsistency in Mr. Turner's remarks.

Mr. Turner states that the electrical machines of the Electrogear might weigh about 75 to 80 per cent of those used in the conventional electric drive. Against this stands the fact that the comparative weights accepted by mutual agreement between the J. G. Brill Company, the General Electric Company and ourselves were 18,000 pounds for the mechanically, 18,500 pounds for the Electrogear, and 19,200 pounds for the electrically equipped bus. (See the paper.) This, by mutual agreement, defines the Electrogear as 500 pounds heavier than the mechanical transmission, but also defines the gas-electric transmission as 1,200 pounds heavier than the mechanical transmission.

The actual fact is that the complete Electrogear installation in the test bus weighed only 61.5 per cent of the gas-electric drive as admitted by Mr. Turner on another occasion. But even this would not be the most economical weight for the Electrogear since as stated in my paper, the design specifications were not followed closely, and the electrical machines could have been built about 10 per cent lighter, as admitted by Mr. E. R. Martin of the Delco Products Division of General Motors, the company which built the electrical machines for the bus Electrogear. It is, therefore, absurd to suppose that the cost of manufacturing the Electrogear should be equal to that of the gas-electric drive.

The deductions with respect to weights and sizes which Mr. Turner makes based upon torque and heating conditions do not apply to the Electrogear, as design data would clearly show. For the purpose of this discussion, however, it is sufficient to say that electrical machines have an unmistakable way of expressing themselves, if they are not built to stand the loads—they break down. As stated in the paper, under no condition of testing, even under most severe schedules of 13 stops per mile, when the engine overheated and the brakes were smoking hot, did the Electrogear machines ever refuse to give the accelerative torques required, and their temperatures always remained far below permissible values as standardized by AIEE.

Mr. Turner's claim that the lighter weight of the Electrogear machines is due to their running at higher speeds than the gas-electric drive is disproved by the General Electric Company's own data which were plotted in figure 8 and clearly show that the engine speed of the gas-electric drive is continuously higher than the actually observed speed of the Electrogear.

The lower cost and weight of the Electrogear must in themselves offer considerable advantages over the gas-electric drive. As to fuel economy: The paper presented by Mr. R. H. Stier of the Philadelphia Rapid Transit Company and published in AIEE Transactions, volume 57, 1938 (June section), page 318 and in the *General Electric Review*, volume 41, page 229, favors the gas-electric drive and admits that its fuel consumption determined by their tests indicated an increase of 22.9 per cent at four stops per mile and of 23.1 per cent at eight stops per mile over the mechanical drive. Since the Electrogear tests showed better fuel economy than the mechanical drive for four or more stops per mile, its advantage over the gas-electric drive with respect to fuel economy is self-evident. As to overall efficiency: Actual tests show the Electrogear efficiency to be over 90 per cent which is about the same as the mechanical drive efficiency, and certainly much higher than the efficiency of the gas-electric drive could ever be.

The all-around advantages of the Electrogear over the gas-electric drive were brought out during the oral discussion relating the experience with the Electrogear in the ACF bus.

The mechanical connection between the engine and the rear axle is not a disadvantage, in fact, it is desirable as it avoids undesirable free wheeling. The isolation of vibration and noise is taken care of in the same manner as in the gas-electric drive, where a solution had to be found with respect to coupling the generator to the engine. There is no doubt that the gas-electric drive has an impressive record with respect to maintenance and durability, but it is only natural that one should expect the same type of record for the Electrogear, since the same principal elements are involved, namely electrical machines.

Finally, the full throttle acceleration curve for the bus with mechanical transmission as given in figure 8 is the curve submitted by the J. G. Brill Company and represents their actual test results admittedly obtained under optimum conditions. It is not my opinion that one should choose performance curves of a rival device obtained under unfavorable conditions in order to gain additional advantage. That under ordinary service conditions the schedule speed of the gas-electric drive is higher than that of the mechanical transmission has been stated in my paper and is readily admitted by proponents of the mechanical transmission, in fact this is one of the main reasons why the interest has centered upon automatic transmissions in recent years.

Professor Nims' discussion is singularly interesting since on the basis of theoretical reasoning he came to the logical conclusion that the prohibitive weight, high cost, and low efficiency of the gas-electric drive can only be reduced by reducing the amount of circulating electric power through the use of a planetary gear, which is exactly the principle embodied in the Electrogear. The possibility of eliminating the charging generator and starting motor has been considered in application to the Electrogear, in fact in smaller models of the Electrogear the starting motor has actually been eliminated with satisfactory results. This, however, is a matter of economic consideration.

System Lower-Harmonic Voltages—Methods of Calculation and Control by Capacitors

Discussion of paper 41-74 by W. C. Feaster and E. L. Harder, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1060–6.

A. C. Monteith (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors are to be congratulated on the completeness with which they have analyzed this complicated system problem. The problem is not new, but to the best of my knowledge this is the first attempt at an approach by other than more or less cut and dry methods, rounded out with confirming field tests. There are two points that might bear emphasis, one the use of the a-c network calculator and the other the new data on harmonic characteristics of the magnetizing currents of transformers.

It has been of interest to watch how new uses for the a-c network calculator have been devised beyond the original conception of studies of regulation, system stability, and short circuit currents. It has been adapted for use in transient analysis and now in this paper, for the analysis of fifth harmonic conditions on systems. This method of attack should be useful for the solution of the problem on other systems.

The authors have also presented some new data on the magnetizing characteristics of transformers as they are applied on systems. Considerable data have been published on the magnitude of the different harmonics in exciting current but this is not consistent, there being a range of 10:1 in the data. These inconsistencies may be due to a difference in the way the iron is worked and also to the fact that a single phase test has been made on the actual system, delta's are present that act as a short circuit to the third harmonic component. The authors' data should be of use in connection with this problem as it has been carefully taken in the laboratory for stated conditions that are believed average for actual systems. Their development of equivalent circuits should also be helpful in solving specific cases.

C. T. Pearce (Westinghouse Electric and Manufacturing Company, Philadelphia, Pa.): This study has been of special interest to me in view of participation in one of the cases of local resonance to harmonics coming from the main system. This was one of the instances of capacitor heating which led to the general study. It would be of interest to know whether the authors feel that the methods of calculation developed give equally good results on other systems.

S. C. Miller (The Chesapeake and Potomac Telephone Company of Baltimore City, Baltimore, Md.): The novel arrangement described in the paper by Messrs. Feaster and Harder will naturally be of interest to engineers concerned with the inductive coordination of supply and telephone systems at noise frequencies. It is, therefore, the purpose of this discussion to present the available facts relating to the coordination aspects of the capacitor installation at Winchester, Virginia.

It is evident from the information in the paper under discussion that the capacitor-reactor arrangement is, in reality, a 300-cycle resonant shunt across each phase at the Winchester 33-kv bus and is designed so as not to affect the system impedance to residuals. Such a shunt would, of course, be expected to reduce the fifth harmonic voltage on the 33-kv circuit at Winchester and at other points when applied to the bus as compared to conditions that obtain when the capacitor is not energized. It was to be expected that the application of the capacitor would cause a considerable increase in the fifth harmonic current in one or the other or both of the 33-kv circuits which supply Winchester. In general, the line impedance drop of this current would tend to hold up the 300-cycle voltage somewhat at points remote from Winchester; hence the most pronounced changes in fifth harmonic voltage and current on the 33-kv system would be expected in the neighborhood of the capacitor, except in situations where the effects of phase change are important at 300 cycles.

The 300-cycle voltage on the 4-kv bus at Winchester would, of course, either increase or decrease when the capacitor is applied depending, among other things, upon the relative magnitudes of the reactance of the tuning reactor and the transformer leakage reactance.

With the foregoing considerations in mind, the interested power and telephone engineers decided to make a few observations on a cooperative basis to investigate the effects produced by the installation on telephone noise metallic in some of the exposures which might be affected. It was decided to make these observations during the daylight hours of a normal week day because experience has shown that daytime wave shape conditions on this power system are fairly indicative of effects to be expected during the hours which are most important from the standpoint of telephone traffic.

In order to obtain data on the effects produced in the vicinity of the capacitor noise measurements were made on the open-wire telephone toll circuits in the exposures to the 33-kv circuits between Winchester and Martinsburg, West Virginia, and between the latter point and Hagerstown, Maryland, with the capacitor energized and deenergized. Observations were also made at the Winchester central office on local telephone circuits exposed to the four-kilovolt system with which the capacitor is associated and simultaneous measurements were made of harmonic voltages and currents in various supply circuits at the Winchester substation.

It was found that the 300-cycle voltage at the Winchester 33-kv bus dropped nearly 70 per cent, while the 300-cycle current in the Martinsburg-Winchester 33-kv circuit increased by a ratio of about 3 to 1 when the capacitor was applied. The 300-cycle current in the Stephens City-Winchester 33-kv circuit decreased by a ratio of almost 10 to 1. The phase-to-neutral 300-cycle voltage on the four-kilovolt bus at Winchester increased by about 35 per cent. It should be kept in mind that these data were obtained during the day and are, therefore, somewhat different from comparable measurements referred to in the paper which were made during the night.

Despite these relatively large percentage changes in 300-cycle magnitudes in the power system no important changes were observed in the noise metallic on the telephone circuits tested although a few minor changes were noted in the magnitudes of some of the frequency components which comprise the noise. This phenomenon can be attributed to the fact that the 300-cycle components of the noise were relatively unimportant in the presence of controlling magnitudes of higher frequency components which were not materially affected by the capacitor in this instance under power system conditions which obtained at the time the observations were made. Some effects on telephone noise would have no doubt been observed had the higher frequencies not been present, but the indications are that such effects would not have been important in this case.

It appears that, in future installations of the type described in the paper, consideration should be given to the usual possibilities of undesirable inductive effects presented by any primary capacitor installation, but it should be kept in mind that such devices may be quite helpful in reducing telephone noise over fairly wide areas in situations where induction from fifth or seventh harmonics is important and no serious adverse effects are produced in exposures near the capacitor.

R. D. Evans (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): I wish to comment briefly on the factors which affect the fifth harmonic voltages which may appear on systems. The field form of generators and the operation of six-phase rectifiers may produce fifth harmonic voltages of appreciable magnitude. These sources were unimportant in the case investigated by the authors who found that the cause was transformer exciting current. Yet all systems have transformers but the harmonic voltages vary through quite a range of magnitude. There are a number of factors which may contribute to this. (1) The exciting current magnitudes vary widely, particularly in relation to system constants. (2) On some systems, certain transformers may be operated at considerable overvoltage, particularly under some load conditions. (3) Resonant conditions on the system may increase or decrease the harmonic voltages in the external circuit. (4) The phase positions of the harmonic sources in the transformer may vary considerably in respect to each other since they are controlled by fundamental frequency voltages which are displaced by different amounts in different parts of the circuit and under different load conditions. (5) The actual transformer connections may have an important effect. For example, if a delta-star transformer is replaced by two equal transformers, one connected delta-star and the other star-delta, the combination will substantially suppress all of the fifth and seventh harmonics. While such a method is not advocated, it should be recognized that such connections do affect the magnitudes of harmonics, especially on systems.

The accepted method of determining the distribution of harmonic exciting currents and voltages in the external circuit of a transformer, is by the use of a familiar equivalent circuit of the transformer with the exciting branch replaced by a harmonic source and a harmonic impedance. This arrangement proposed by Dr. H. S. Osborne in 1915 appears to work well for the third harmonic. The present authors have shown a method for accurately determining the fifth harmonic voltages. For appreciable higher harmonics the use of a simple but accurate equivalent circuit does not appear possible, a circumstance which may be due to the interaction of the important lower-harmonic exciting currents.

My last point deals with the effect of capacitors on harmonics. A capacitor does not, of course, generate harmonics but if harmonics are present in the source, the connection of a capacitor to the circuit may decrease or increase them. If a long feeder is supplied from a source with harmonics and if a capacitor is added at the supply end, the harmonic voltages may be decreased by a filtering action, or if the capacitor is added at the far end, the harmonic voltages may be increased by a resonant action. On the system investigated by the authors the addition of capacitor kilovolt amperes was accompanied at first by increases in harmonic voltages. This raised a question as to the effect of adding a large capacitor bank to the system. The analytical studies showed that the effect would be to reduce the harmonic voltages. Confirmation of this result by installation and test is most reassuring in connection with capacitor applications. The method developed by the authors using analytical work, simple field tests, and the a-c network calculator will have application to other systems.

Television Transmission Over Wire Lines

Discussion of paper 41-42 by M. E. Strieby and J. F. Wentz, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1090–6.

A. P. Godsho (Bell Telephone Company of Pennsylvania, Philadelphia, Pa.): A striking feature of the high frequency transmission art in the paper by Mr. Strieby and Mr. Wentz is the development of the technique for its application to the common everyday variety of telephone plant—the paper insulated cable. The significance of this feature cannot be overemphasized, for the cable plant reaches everywhere television programs are likely to originate and of equal importance where they may be received. Fundamentally, it would appear, therefore, that the framework of a basic television program pick-up and distribution system is already available.

The past decade has seen cables originally designed to carry voice frequencies adapted to transmit frequencies up to 60,000 cycles and now we have this new art making the transmission of frequencies up to 3,000,000–4,000,000 cycles practical over the same fundamental type of plant. Presumably, given enough time, opportunity, and justification, this band may be further extended.

Just as the analytic approach to developments of this type is taken for granted, the Strieby-Wentz paper indicates that methods of measurement have had to be devised simultaneously with the main objective. To those of us who have had any experience in the conditioning of plant for television transmission, involving such items as the elimination of bridged taps, obtaining proper signal-to-noise ratios at various locations along the transmission path, etc., this is a familiar story.

To introduce a speculative aspect into the Strieby-Wentz presentation, perhaps a day will soon be here where cables to many locations, at least in the metropolitan centers, will be provided with a small number of pairs which will be free of all bridges, with intermediate amplifiers in strategic locations, so that the pick-up of television programs will be the commonplace rather than the unusual thing. Technically, the present paper reveals that much progress has been made towards this objective. Of course, there are many other features, mostly of an economic nature, which still require formulation and development.

Volt-Time Areas of Impulse Spark-Over

Discussion and author's closure of paper 41-75 by J. H. Hagenguth, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (July section), pages 803–10.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): Mr. Hagenguth's paper contributes one more important step in the coordination of laboratory testing technique. For several years there has been a large discrepancy between the different laboratories on front of wave flashover of a simple rod gap, and we, who build transformers that occasionally have to be tested on the front of wave basis using the rod gap as a voltmeter, were rather discouraged because no satisfactory explanation for the wide variation in the flashover values could be given. Now that we have the explanation, it should be possible to drop the rod gap as a voltage measuring device and make front of wave tests by kv—the same as is being done with long wave tests.

The second point I wish to bring out is the unreliability of the rod gap, as brought out in the data in the paper, for coordination or protective purposes. The rod gap not only has a faster turn up for short times to flashover than insulation but, its wide variation in flashover voltage for any given time less than approximately two microseconds makes it almost useless as a practical protective device unless set so low as to be prohibitive from outage standpoint. For example: the 20-inch and 50-inch rod gaps show from 40 to 45 per cent variation in flashover at two microseconds as compared with 20 per cent variation at 8 microseconds (figure 7). Plus or minus 20 to 22 per cent flashover, coupled with the larger turn up of the gap at two microseconds than for insulation, explains why it is necessary to use such low spacings—as low as 50 per cent of the spacing for long waves—to give any protection to transformers against steep waves.

P. L. Bellaschi (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): This paper calls attention again to the question on wave form and to definitions, to the significance of wave form in impulse testing and the problem on insulation coordination. While the subject at large lends itself to theoretical treatment, the difficulty lies in translating the larger problem into practical and simple form that is both effective and feasible in engineering application.

An item of great significance is the question of definitions. I wish to confine this discussion largely to this question for it provides the constructive approach to the larger problem. The following example will illustrate the point.

Up to the time impulse testing and insulation coordination were confined to critical flashover and relatively long chopped waves (1.5x40 microsecond wave), the front of the wave remained of secondary importance. Therefore the definitions established for the front were quite adequate. As front-of-wave testing made headway, it became clear to the writer and to others that a better and more complete definition of the front was essential, if large apparent variations at the same laboratory and at different laboratories were to be reduced to acceptable limits. Theoretically, the complete shape of the wave defines the wave best, but obviously this method does not lend itself to the necessary simplicity required in engineering.

Two important steps were considered. First the 30 per cent–90 per cent method of defining the front proper was proposed, as inherently by this method the definition assumes greater physical significance and furthermore variations present at the foot of the wave (below 30 per cent) would automatically be excluded. Second, to define the wave beyond the 90 per cent point, it was proposed that the ratio of the virtual front to the effective front (virtual zero to point of breakdown) should not exceed 0.80. Rather infrequently are ratios of 0.90 or 0.95 exceeded in actual testing. Thus a rather simple definition was evolved and formulated which practically is significant in the engineering sense, and which should eliminate much of the difficulties encountered in the past.

Other distinct benefits can acrue from establishing suitable and practical definitions. For instance, in the case cited, large variations in results could be narrowed down to the point where it became clear that measurement was not the decisive factor.

It would take the length of another paper to adequately discuss the pros and cons of the various points to which Mr. Hagenguth calls attention in connection with insulation coordination. Surely the question discussed above on the definition of the wave form is an important related consideration.

P. H. McAuley (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Hagenguth has presented a detailed quantitative analysis of the possible variations in volt-time curves due to changes in impulse voltage wave shapes. To this extent it appears that a concept which was much discussed qualitatively in the early days of impulse testing with the oscillograph has been revived. Attention is called to the following articles: "Surge Testing of Suspension Insulators," F. D. Fielder, *Electric Journal*, July 1931; "Time Lag of Breakdown," by Fielder and McAuley, *Electrical World*, November 23, 1929; "Time Lag of Insulators," by Wade and Smith, *Electrical World*, August 18, 1928. Fielder in the 1931 article stated: "Naturally, with variations in both rate of rise and rate of fall, an infinite number of wave combinations are possible, making it necessary to use some arbitrary standard in the laboratory. A review of the other articles will indicate that these authors knew and appreciated the effect of changing wave shapes many years ago.

With full appreciation of the situation, the standardizing groups adopted the 1.5x40 wave, thereby reducing the flashover band to a curve. It has been possible to forget until recently, the changes in effective wave front with change in time to flashover. The change in circuit arrangements of the General Electric surge generators has revived the problem. As long as all laboratories were using similar waves and testing circuits, fairly good agreement in test values were obtained. The change in technique of some laboratories brought the problem forcibly to the attention of the laboratory subcommittee of the EEI-NEMA joint committee on coordination of insulation in 1938 and it has been studied by this subcommittee in connection with the correlation of laboratory data. Mr. Hagenguth advocates investigation of the complete band of impulse sparkover, which greatly complicates testing and application. Undoubtedly, it would be much simpler to standardize testing circuits or to define the test wave more rigidly. This would appear to be a reasonable and practical simplification of the problem.

In the early days of insulation coordination, it was considered desirable and necessary to grade the apparatus insulation in the station in steps of the order of five per cent. In this way, any flashover which would occur would take place at points where the least damage would be caused. It was soon found that due to the many steps and to testing tolerances required, the range in insulation strength from the incoming lines to the internal insulation of apparatus was so great as to be impractical. Insulation coordination now means that all the apparatus of the station is above a certain level of strength which is, of course, above transient values permitted by the protective apparatus. Insulation levels are based on tests with the 1.5x40 wave. Most of these tests involve only the critical flashover or withstand values for equipment. Actually, the critical flashover voltage, as used in the past, might be regarded as a band rather than a point or line, since it is usually obtained by averaging several test points. However, it has not been found necessary to work with the maximum and minimum regions of this band for the purpose of coordinating insulation. In view of the satisfactory experience on this point, Mr. Hagenguth's statement that this type of coordination "cannot be effective" seems very pessimistic. It is always desirable to keep testing procedures as simple and inexpensive as possible and any attempts to explore the complete band of values possible with different types of impulse waves on different apparatus seem somewhat complicated and impractical. Furthermore, it is possible that other factors such as lead lengths under conditions of installation may have a greater influence on the performance of gaps and insulation in parallel for very short times to flashover than moderate changes in the testing wave. This possibility was discussed briefly in the *Electric Journal* for February 1939, page 56.

It seems apparent that difficulties will be encountered in checking values from different laboratories as long as it is possible for different groups to make different interpretations of the definition and procedure for using the 1.5x40 wave. Therefore, either the definition and procedure must be tied down by further standardization or a wave which cannot be varied by different interpretations must be used. This step has been suggested, first, I believe, by Ohio Brass engineers. If a one microsecond front were used instead of a 1.5, there should be less change in front for different parts of the volt-time curve. This would tend to reduce values obtained with surge generators with the shunt capacitor and to raise, slightly values obtained on generators with only series resistance. At least, this is one procedure which shows much promise at present and it seems worthy of a trial. In addition, it has the merit of agreeing more closely with the International standard wave which is 1x50 microseconds.

J. J. Clark (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): As Mr. Hagenguth points out in his paper an accurate knowledge of the impulse strength of all apparatus on a system is necessary for proper coordination. For apparatus involving solid insulation only the withstand strength test is practical, since a breakdown destroys the insulation. Apparatus which uses air as a dielectric, such as bushings, insulators and rod gaps, all have electrode arrangements giving a nonuniform field.

Comparing the limiting values for negative waves as given in figures 4, 8, 9, and 10 of the paper shows the following spreads between the $T_1/T_2=1$ and $T_1/T_2=0$ curves at 2 microseconds. For the 20-inch rod gap the spread is 47 per cent, for three suspension insulators 41 per cent, for two apparatus insulators 28 per cent, and for a bushing 32 per cent. Since these limits are not actual test values but extrapolated from data obtained at other ratios, the agreement is remarkably close. This would indicate that the change in sparkover voltage with change in wave shape is not greatly different for the electrode arrangements in different apparatus. Hence, volt-time curves taken with the same wave are, for practical purposes, directly comparable even though the effective front does not remain constant for all times to sparkover.

Either of the impulse generator circuits of figure 12 of the paper can be used to obtain volt-time curves suitable for coordination, though the results obtained with the two circuits cannot be compared directly. Most of the generators in use at the present time use the circuit of figure 12*a* not only because of the high cost of a load capacitor but the addition of a large capacity load reduces the voltage which can be supplied by a generator of given rating.

To secure agreement between different laboratories either the testing circuit can be standardized and the wave front allowed to shorten as sparkover time decreases or the wave front can be maintained constant. The latter course would necessitate constant readjustment of the surge generator circuit and increase the time and expense of impulse testing without securing greater accuracy of coordination. In this case, it appears technical perfection might be sacrificed for practical reasons.

L. Wetherill (General Electric Company, Pittsfield, Mass.): Mr. Hagenguth's paper brings out clearly the inadequacy of volt-time curves based on the 1.5x40 microsecond wave except in cases where waves of substantially this form are being considered. Most existing impulse volt-time data covering high-voltage bushings probably are based on the 1.5x40 microsecond wave.

The volt-time characteristics of bushings are of interest in connection with the protection of the bushing from flashover, for which case the curve of $T_1/T_2=0$ is useful, or in connection with the use of the bushing as a protective device in which case the curve of $T_1/T_2=1$ is useful. Thus it would appear that future volt-time data covering bushings should be obtained not on the 1.5x40 microsecond wave but rather for the area boundaries represented by the expressions $T_1/T_2=0$ and $T_1/T_2=1$.

One result of Mr. Hagenguth's paper is that the usefulness of a bushing as a protective device can be more accurately evaluated. Another result is to show that furnishing of anything approaching adequate protection by this means is considerably more difficult and more expensive than was previously thought to be the case. This results not only from the increased margins which would be required to allow for the wide range of flashover performance represented by the volt-time areas in comparison with single curves, but also from the need for an increased amount of impulse test data to determine the volt-time performance of various types and sizes of bushings on the more complex basis of volt-time areas.

These considerations indicate that the use of a bushing as a protective device is becoming more difficult than ever to justify. Furthermore, with the bushing removed from the protective device picture, the lower boundary of its volt-time area ($T_1/T_2=0$) assumes the place of chief importance while the upper boundary becomes unimportant from the co-ordination viewpoint. Therefore, we may find that in the future most volt-time data on bushings will be taken for the condition $T_1/T_2=0$, and that data of this type will supplant the former volt-time curves taken with the 1.5x40 microsecond wave.

J. H. Hagenguth: The discussions of the paper cover two principal points:

1. The effect of volt-time areas on the co-ordination problem.
2. The problem of impulse testing.

Mr. Wetherill's conclusion that the most useful volt-time curve for a bushing will be the lower boundary of the volt-time area ($T_1/T_2=0$) is quite correct. Similar considerations apply to apparatus such as transformers where the breakdown phenomenon is initiated by corona streamers only to a minimum extent, and which represent apparatus in the transmission system which are to be protected against breakdown or flashover. On the other hand, apparatus such as lightning arresters which are used to protect costly equipment require tests which will show the upper boundary ($T_1/T_2=1$) of the volt-time area. Finally, there is a group, such as insulators, which requires the knowledge of both boundaries to fully understand the interrelation of different parts in the system as far as sparkover characteristics are concerned. Unless it is questioned that only co-ordination according to figure 13 will give complete protection, it is necessary to investigate lower volt-time area boundaries for apparatus which is being protected and upper boundaries for protective devices. Any volt-time curves which extend within the volt-time areas, such as the volt-time curve of figure 6 of the paper labeled $T_1=1.3$ microseconds = constant, are of no practical significance from the point of view of co-ordination where considerable margins are required between maximum voltage permitted by the protective device and the minimum permissible withstand voltage of the protected apparatus. It is, therefore, rather immaterial what kind of impulse generator is being used to determine the sparkover characteristics of greatest interest from the point of view of co-ordination as long as these most important volt-time curves can be obtained.

Mr. Clark discusses the question of impulse generator and arrives at the conclusion that the best type of generator is one similar to figure 12*a* of the paper for practical reasons, although its use will sacrifice technical perfection. Mr. McAuley believes that a change in wave front of the standard wave from 1.5 microseconds to 1 microsecond would provide better agreement between results obtained in different laboratories. I believe, as pointed out above, that it is much more important to definitely settle on which of the limiting volt-time curves are to be obtained for different types of apparatus and then to obtain these curves than to standardize on impulse generators or wave shapes. Mr. McAuley points out that early experience in impulse testing showed variations in sparkover voltages with wave shape. Many more references can be found showing similar experiences. However, as far as I know, it has not been possible to identify the change in sparkover voltage with simple factors expressing wave shape and, therefore, the solution to use a standard wave was chosen as the best way out. Of course, the choice of a standard wave was made principally because measurement technique in the early days of impulse testing was not so very good and, also, for comparisons between laboratories. Furthermore, the 1.5x40 wave was a good average of all lightning waves measured on transmission lines with cathode-ray oscillograph.

Mr. McAuley quite correctly states that other factors may upset the co-ordination picture such as lead lengths. I fail to see that on account of this we should close our eyes to the wide sparkover variations possible due to difference in wave shape. For best results we must take into account all the factors involved and should gradually modify our standards accordingly. I do not believe that it is pessimistic to say, as Mr. McAuley states, that co-ordination according to customary volt-time curves cannot be effective. For instance, the complete sparkover band for a 20″ rod gap at one microsecond comprises the volt-time curve points of all rod gap spacings between 16″ and 24″. Likewise, the band for a 50″ rod gap at two microseconds corresponds to rod gap spacings from 43″ to 64″. Such large spreads are entirely too great to be ignored. The reason for obtaining sparkover characteristics of apparatus is to obtain a basis for co-ordination of different types of apparatus. The function of the laboratory is to obtain the required data in such a form that they are useful for co-ordination purposes. Therefore, the different laboratories can devote their energies to determine those sparkover characteristics which are most useful for co-ordination purposes, especially since the question of measurement accuracy for times to sparkover of one microsecond and longer has practically been settled.

Mr. Clark contends that, since the volt-time areas of figures 4, 8, 9, and 10 of the paper do not deviate much from each other, single volt-time curves taken with the same wave are directly comparable, especially since apparatus involving solid insulation receives only a withstand test. I would remind Mr. Clark that a withstand test is a test which proves that a given apparatus will not break down under given conditions. The type of generator used for the withstand test, especially if this test involves the use of a rod gap for chopping the wave, is therefore, very important. It can be shown that certain types of transformer insulation would withstand a test with a 20″ rod gap, for instance, using an impulse generator of figure 12*a*, while, when using figure 12*b*, a rod gap of only 17″ spacing can be used to protect the same specimen. This is one of the reasons why Mr. Montsinger's suggestion of dropping the rod gap as a yard stick for front of wave tests on transformers is logical. In this same connection, Mr. Bellaschi's suggestion of using closer tolerances on the wave shape, allowing a minimum ratio of $T_1/T_2=0.8$, is a step in the right direction. However, even with such seemingly close tolerances, differences in sparkover potential of a given rod gap spacing of as much as 10 per cent at 0.5 microsecond and 6 per cent at one microsecond to sparkover will occur. At these short times to sparkover the question of accuracy of voltage divider also becomes more important.

In the paper discussion was limited purposely to sparkover at one microsecond and longer to eliminate the question of divider influence on the measurement.

Messrs. McAuley and Clark are concerned about practical means of impulse testing. From the point of view of practical testing, it is very difficult with present impulse generator designs to obtain either the lower or the upper boundaries of the volt-time areas directly. As shown in the paper, it would not be difficult to obtain these limits for a few voltage ratings of types of apparatus as indicated by figure 11 for the rod gap. Even though these boundaries may not be determined with very great accuracy, they would much more nearly represent the required information for co-ordination than any other single volt-time curves obtained according to present practice.

Whenever single volt-time curves are needed to demonstrate a specified strength of an apparatus in the laboratory, generator of figure 12*b* is preferable because it produces a constant effective front throughout the volt-time curve range. Only such curves are directly comparable for different types of apparatus with different electrostatic fields. Any other impulse generator will be satisfactory, provided that its discharge circuit is changed to maintain a constant effective wave front. With generator figure 12*b* no changes are necessary since the effective wave front is automatically maintained practically constant. It also seems necessary to allow smaller tolerances for the front than have been used when defining the standard wave. The present tolerances of $\pm 1/2$ microsecond for the front will result in sparkover voltage differences of 15 to 20 per cent for sparkover at two microseconds.

In answer to Mr. Clark's objection, a load capacitance which is required for generator figure 12*b* represents only a relatively small expense compared to total cost of impulse generator equipment. The use of a load capacitance keeps the effective test wave front practically constant. While the test voltage at critical sparkover is a few per cent lower for impulse generators of figure 12*b* than for 12*a*, at sparkover at two microseconds and less the available test voltage from generator 12*b* is considerably greater than that of generator 12*a*. A volt-time curve obtained with generator figure 12*b* can be used directly to obtain the upper and lower boundaries of the volt-time area since it almost diagonally cuts across the whole area (see curve T_1, figure 6). By taking a few points on either side of the curve with different wave shapes, the area is established.

Field Testing of Generator Insulation

Discussion and author's closure of paper 41-17 by the EEI subject committee on generator insulation and testing, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (December section), pages 1003–11.

R. E. Hellmund and **P. H. McAuley** (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): It is evident from the data given in the paper, as well as from similar studies, that a great deal more investigation will be required and that considerable time will elapse before it will be possible to evaluate the conditions of the complicated insulation structure of large machines by such factors as ionization, insulation resistance and power factor. Much progress has been made, however, and these tests are valuable in detecting moisture and other defects, where it is possible to detect and analyze insulation deterioration by periodic observations over long periods of time. Continued study of these methods is to be encouraged and they are already of great assistance in maintenance problems for certain types of apparatus.

The general problem is complicated by the fact that one weak spot may make a machine unfit for service but has little or no effect on many tests which must include the whole mass of the insulation of a machine. A typical case is punctured solid insulation through which a few thousand amperes of impulse current have been passed but which tests perfectly good as far as megger and similar low voltage indicators are concerned. For similar reasons, none of the non-destructive methods suggested so far furnishes a dependable indicator in advance of actual breakdown. This in turn means that dielectric overvoltage tests will have to be depended upon for quite some time. It would, therefore, seem well worth while to give considerable attention to improving this method of test.

The conventional one-minute a-c test does not necessarily indicate resistance to surge voltages. Also, on large high voltage apparatus, it may produce corona and other disturbances which result in voltages in different parts of the conductors that differ from the impressed test voltage. Inductance and capacity of the windings and harmonics in the test voltage lead to similar effects. Consequently, the possibilities of d-c testing, which are mentioned briefly in the paper, seem worthy of serious consideration. The use of a d-c test voltage with definitely limited and properly controlled rates of voltage rise and fall would eliminate many of the disadvantages of high voltage a-c testing. For test values below 100 kv the equipment using thermionic rectifiers is not unduly complicated by comparison.

D-c testing has been given a great deal of attention in connection with cables, principally because, with their high electrostatic capacity, tests with a-c voltages were found impractical where portable equipment was required. For large generators the problem is somewhat similar with the additional complications previously mentioned. In view of the greatly varying ratio of d-c to a-c breakdown which have been found to exist for different kinds of insulation structures, there is, of course, a question as to the d-c voltage to be used. This, however, should not be considered a deterrent if it is realized that the widely used a-c values have been selected entirely arbitrarily and without any theoretical background.

In considering suitable tests, especially tests for machines which have been in service, it seems worth while to strive for a type of test which more closely approximates conditions to be met in actual service than the conventional one-minute a-c test with a relatively high overvoltage. In actual practice machines are likely to be operated with a-c voltages moderately in excess of the rated voltage and, therefore, a one-minute a-c overvoltage test with a voltage 125 or possibly as high as 140 per cent of the rated voltage would be justified. In addition to the normal frequency voltage stresses, machines and apparatus not directly connected to the line and, therefore, not subject to lightning surges, are likely to be subjected to switching surges of perhaps two to four times their rated voltage. These switching surges are usually of very short duration, and the first suggestion might, therefore, be to subject the machines to the more or less standardized impulse waves of 40 to 50 microseconds duration. Such tests, however, again have the disadvantage that it will be impossible to determine the oscillations and voltage stresses in different parts of the windings. For this reason it might be of advantage to investigate the possibilities of a d-c test of one or several seconds duration, with properly limited and controlled rates of increase and decrease of the voltage. Such a test, with suitably chosen amplitude, might be effective in detecting mechanical weaknesses in the winding, which are the usual cause of breakdown in service. The reason is that, in the case of mechanical difficulties, there is usually at least one part of the breakdown path through air. Some evidence to this effect is given in the paper. If proper means for reliably indicating a breakdown during the short period of test can be devised, the main object of locating weakness in the insulation has been accomplished without stressing other parts of the winding unnecessarily and without danger of introducing unknown overvoltages in any part of the insulation structure.

All operating engineers are vitally interested in a suitable method for proving the adequacy of the insulation of machines in service, and in connection with insulation to ground or between windings, it is believed that the method suggested here will be very helpful. However, the question may arise as to how many breakdowns in service are caused primarily or initially by a breakdown to ground or between windings. Especially for class *A* insulated conductors, it would not be surprising if a large percentage of failures were originally caused by breakdown between turns resulting from mechanical deterioration of the insulation due to heating. None of the methods of insulation test suggested so far is likely to give any indication in advance of an actual breakdown, except that possibly a surge test may stress the insulation of the end turns sufficiently for this purpose.

F. C. Knowles (Evershed and Vignoles, Ltd., London, England): In attending this convention it was not my intention to take any part in the discussion, but I am pleased to respond to the request of some of your members to give my views on the practice in England.

The splendid work which has been done over here in the matter of the consideration of electrical insulation has been followed with much interest by engineers in England. From time to time we have received reports issued not only by this Institution but by other authorities on this side, dealing particularly with the question of ascertaining the condition of the insulation of electrical apparatus by non-destructive tests.

The particular aspect of the subject in which I am most interested is that which has been termed over here "dielectric absorption tests." These tests are based on the continuous application of a steady voltage over a period of time, and in that respect it reminds me of the tests which telegraph and cable engineers have carried out for over half a century and which are termed "electrification," it being common practice to specify cables for telegraph and submarine work as having a certain insulation after so many minutes' electrification, and in many specifications there is a statement of the decrement of the reading on a galvanometer for successive minutes' electrification.

I have had the opportunity of discussing this question of dielectric absorption as it may apply to the insulation in generators with a number of prominent British engineers, but have not yet found enthusiasm for the application of such a method. It is quite possible that conditions in our country are quite different from yours. For example, we do not have such extremes of temperature and humidity. It is our practice to measure the insulation of a transformer, generator, or other large electrical unit before putting it into service, noting the temperature and weather conditions and then to repeat that test when the apparatus is taken off circuit under hot conditions. The results of these insulation tests are recorded usually on a card and are compared with previous readings. If there is any considerable disparity, the matter of the insulation is then investigated.

After reading the paper which has just been presented and talking to some of the members of the committee on this subject, I shall return to England with a better appreciation of the work that you are doing and will endeavor to present it to engineers on our side in the hope that we may be able to do something to add to the good work already done.

The question of what is meant by dielectric absorption, I feel has been very ably expressed in the contribution to the discussion just made by Mr. R. J. Woodrow. Both the diagram and the formula which he gives seem to me to be a basis for the production of a reasonably simple method for the operating engineer not only to understand the basis of the tests, but also to be able to obtain an empirical formula based on the theoretical formula which should enable him to ascertain quickly whether there is any unreasonable decay or change in the insulation of the apparatus under test.

I would also like to add my appreciation of the bibliography given at the end of the paper, but would suggest that possibly a paper given before the British Institution of Electrical Engineers by J. Lindley Thompson and H. Walmsley on the drying out of transformers might be of some interest in this connection. The paper will be found in the IEE *Proceedings*, volume 64, page 505.

I would also like to add that it is the common practice in England to take spot insulation test readings during the drying-out process of cables, generators, and motors.

M. S. Oldacre (Commonwealth Edison Company, Chicago, Ill.): This paper is a report on a valiant effort that so far has brought mostly negative results. The investigation has eliminated some tests as of little or no value, but a definite indication of a really reliable non-destructive test has not yet been found.

I do not see under the heading of "conclusions" in the paper an item recommending that the work be continued to find a definite test to show the condition of the insulation. I think that it should be continued. It may be that this work could be divided into two parts: first, to determine whether the winding is free enough from moisture to permit safe operation; second, to determine whether the internal insulation is satisfactory. Probably some of the insulation resistance tests with high-voltage d-c supply and sensitive instruments for a suitable length of time will take care of the first part.

Some and most likely a fairly high proportion of failures are initiated by weakening of the internal insulation before the insulation to ground will permit failure at the usual test voltages. It has been suggested that for multi-turn coils a high-frequency voltage applied across the winding would give a better test than any now used. We do not know enough about the insulation effects under such conditions and would like to urge the generator insulation engineers to study the possibilities of such tests and help lay out a test program, particularly on old coils. Such a test might provide for the second item mentioned above.

In either case, some sort of voltage test will still be required to show up the really weak spots due to damage, poor workmanship, and deterioration of the main or ground insulation.

One manufacturer has specified in certain cases that a high-voltage d-c insulation resistance test be made for a fairly long time with the further requirement that the insulation resistance continue to increase for at least ten minutes, this test to be followed by the usual dielectric test. Some of the committee results seem to indicate the value of such tests, and this should be explored still further.

V. J. Egan (Commonwealth and Southern Corporation, Jackson, Mich.): We believe the EEI committee is performing a service of inestimable value to the electrical industry by consolidating the various methods of insulation testing and assisting in interpreting the test results. Practically all companies now make some kind of generator insulation tests but the recorded data usually have not contained enough information to allow comparison with later test results. By following a standard procedure very little additional work is required to obtain results which will be valuable to the company making the test and which will also contribute to the development of the testing routine.

Although the original objective of the committee as stated was to correlate non-destructive test results and the dielectric strength of generator insulation, it seems possible that there is no particular correlation between the dielectric strength of a generator winding and the useful years of life remaining in the winding. However, with the proper cooperation of the operating companies making insulation tests the committee should eventually be able to determine whether it is dielectric strength, d-c resistance, power factor, or some other factor that indicates the expected life of the generator winding.

R. J. Woodrow (Philadelphia Electric Company, Philadelphia, Pa.): Since the data were collected for the paper on "Field Testing of Generator Insulation" some additional tests have been made which expand somewhat the total sum of information as presented in the paper. These tests were made on a 30,000 kva synchronous condenser, 13.6 kv, 60 cycles, 720 rpm with class *B* insulation throughout. The stator of the machine was completely reinsulated and tests were made just after the reinsulation was completed. Approximately a year after the reinsulation the previous tests were repeated and some additional tests were performed, and it is the purpose of this discussion to analyze the difference in results of the two tests and to present some of the interesting features of the recent tests.

Shown in figure 1 of this discussion are curves of insulation resistance versus temperature for various periods of voltage application. The insulation resistance is that measured to ground of all three phases in parallel. The points taken on the original tests just after reinsulation fell exactly on

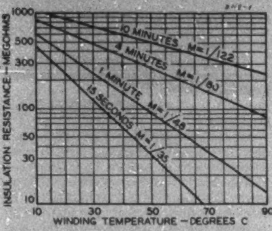

Figure 1. Insulation resistance versus temperature for different periods of voltage application

Data taken at 2,500 volts

the curves plotted from the recent test results showing that the volume insulation resistance to ground had not changed. The values secured for M to be inserted in the equation of insulation resistance agree very closely with those given in figure 3 of the paper for a large turbo-generator after 2 years of service. It might be pointed out that the equation given in the paper is in logarithmic form whereas the exponential form is generally easier to use, where

$$R_{T_2}=R_{T_1}\epsilon^{-2.3M(T_2-T_1)}$$

The values secured from tests all followed very closely the average curves shown in figure 1 except for one set of values taken at 30 degrees centigrade. However, the set of points taken at 30 degrees centigrade which did not conform to the rest of the curve were taken early in the morning after a night of high humidity ($RH=90$ per cent) whereas all the rest of the points were taken at a much lower humidity ($RH=40$ per cent to 60 per cent). Since there was another set of tests made at the same temperature but at the lower humidity it is interesting to compare the two sets to note that a theory can be developed which will explain the difference.

The dielectric absorption phenomenon can be explained by assuming that insulation responds to the application of a constant d-c voltage as if it consisted of a leakage resistance (value of insulation resistance after infinite time of application) in parallel with a complicated system of distributed resistances and capacitances (an internal insulation property producing the response of apparently increasing insulation resistance with time). However it is well known that almost any system of distributed resistances and capacitances can be closely approximated by two or at most three resistance-capacitance branches in parallel. Such a circuit is shown in figure 2 of this discussion, with the equations for current and insulation resistance given.

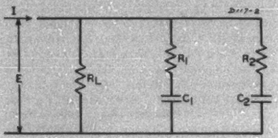

Figure 2. Equivalent circuit for insulation resistance versus time

$$I=E\left[\frac{1}{R_L}+\frac{1}{R_1}\epsilon^{\frac{-t}{R_1C_1}}+\frac{1}{R_2}\epsilon^{\frac{-t}{R_2C_2}}\right]$$

$$\text{Insulation resistance}=\frac{E}{I}=\frac{1}{\frac{1}{R_L}+\frac{1}{R_1}\epsilon^{\frac{-t}{R_1C_1}}+\frac{1}{R_2}\epsilon^{\frac{-t}{R_2C_2}}}$$

By applying the equations for the circuit of the accompanying figure 2 to the test results at low humidity and determining the constants to be inserted, curve A of figure 3 results. It will be noted that the curve follows the test values, which are also plotted, very closely, thus showing that the use of only two resistance-capacitance branches as in figure 2 of the discussion is sufficiently accurate. If the test had been run until constant conditions were reached it is possible that a third resistance-capacitance branch would be necessary to simulate the results, which would have meant one additional term containing R_3 and C_3 in the equation for insulation resistance.

Turning to the test results secured at the same temperature but at much higher humidity, it will be noted from curve B of figure 3 of the discussion that the test points start approximately the same for a short time but level off much more rapidly. It is believed that this effect is due to particles of moisture at the outer surface of the insulation and not due to any infiltration of water vapor into the insulation structure. If this is true then the only term which would change in the equation of insulation resistance is R_L, which represents the final leakage resistance. This final leakage resistance would be reduced due to improved contact between the outer layer of insulation and ground by means of the conducting property of the moisture in contact with it. No change should be noted in the terms R_1, R_2, C_1, or C_2 since these are assumed internal properties of the insulation. In accordance with this explanation a new value of R_L can be calculated for the test results taken at high humidity, and, assuming the other constants remain the same, curve B results. It will be noted that curve B follows the test points as closely as does curve A, showing that the theory given does explain the results.

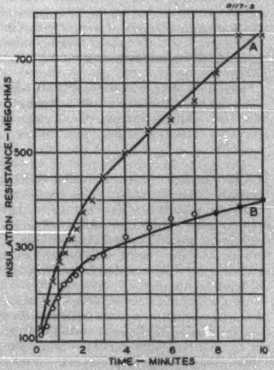

Figure 3. Insulation resistance versus time by theory and test

Data taken at 2,500 volts at winding temperature of 30 degrees centigrade

$$\text{Insulation resistance}=\frac{1}{\frac{1}{R_L}+\frac{1}{R_1}\epsilon^{\frac{-t}{R_1C_1}}+\frac{1}{R_2}\epsilon^{\frac{-t}{R_2C_2}}}$$

$R_1=455$ megohms
$R_2=125$ megohms
$R_1C_1=$ 6 minutes
$R_2C_2=0.48$ minute

A—Insulation resistance at 40 per cent relative humidity; $R_L=1{,}110$ megohms

B—Insulation resistance at 90 per cent relative humidity; $R_L=475$ megohms

In addition to the tests described above on all three phases in parallel to ground, additional tests were made on the same machine for each phase to ground with the other two phases connected to ground. These tests showed little correlation with the values for all three phases in parallel to ground, and were in every case much less than what might be expected i.e. three times the values for all three phases to ground. The reason for this is that the insulation resistance between phases and also additional leakage over the end turns to ground acts in parallel with the volume insulation resistance and reduces to a large extent the overall measured resistance. In order to remove the last two mentioned effects the other two phases were connected to the guard circuit of the test instrument to secure as accurate a measure as possible of the volume insulation resistance of one phase to ground. After this was done the dielectric absorption curves had values for periods of time from 15 seconds up to 10 minutes almost exactly three times the values for three phases in parallel.

In comparing the results on individual phases from the tests just after reinsulation and from those a year later, no change was noted in the volume insulation resistance measured with the other two phases connected to the test instrument guard circuit. This checked the results on three phases in parallel. However a definite increase in the insulation of each phase was noted when the other two phases were connected to the guard circuit. This was believed due to drying out of the varnish on the end turns which reduced the leakage over the end turns.

In conclusion it might be said that further application of the theory which has been used to explain differences in dielectric absorption due to humidity may also be used to determine differences in other insulation properties, which may show up as a change in the initial response instead of as a change in the final value. Measurement of individual phase resistances with the other two phases connected to the test instrument guard circuit can be used to check the phase volume resistance, and with the other two phases connected to ground to check end turn conditions.

Wm. B. Creagmile (James G. Biddle Company, Philadelphia, Pa.): There are two widely separated points in the paper to which I wish to call attention.

Under "Instruments," it is stated that any one of several types of test instruments appear to give satisfactory insulation resistance results and the following types of instruments are mentioned:

> Commercial forms of insulation resistance testers (presumably of the cross-coil ohmmeter type with self-contained generator).
>
> Voltmeter insulation resistance testers.
>
> Electronic rectifier sets using a voltmeter and a microammeter.
>
> Kenotron test sets.

In connection with commercial forms of insulation resistance testers, it is stated they will perform satisfactorily, provided they are calibrated periodically and tested to assure their voltage output is proper. It should be noted that this statement would appear to apply with equal force to the other types of test sets mentioned.

In the cross-coil ohmmeter type of instrument, readings are not affected by considerable deviations from normal test voltage. Of course, it is understood that the voltage must be steady during dielectric absorption tests. Furthermore, we see from figure 7 of the paper that deviations in the voltage of as much as 10 per cent or even more from the normal value, affect the indicated insulation resistance to only a slight extent. Accordingly, considerable departure from the rated voltage and slight lack of calibration will have but little effect on the general form of dielectric absorption curves.

Under "Conclusions," we believe there is general agreement that a single "spot" reading of insulation resistance may be misleading; however, it is sometimes all that can be had. Also, it is a fact that many intelligent conclusions have been arrived at from such readings, augmented no doubt by intimate knowledge of the apparatus under test and good judgment on the part of the man making the test.

The paper under discussion deals particularly with large machines, generating for the most part 11,000 volts or more. There are countless smaller generators as well as motors and other electrical apparatus whose small size and low voltage rating make dielectric absorption tests not worth while, or where, for lack of time or other reasons, the maintenance personnel does not apply such tests.

For many years and on hundreds of machines, periodic "spot" readings of insulation resistance have been taken after a fixed time interval of electrification, such as 30 seconds or 1 minute. These "spot" readings may be taken monthly or at any other convenient interval, and plotted in a curve against time, to give a continuous record of the changes occurring. Such curves appear very definitely to indicate a trend of the general condition of the insulation, when consideration is given to temperature and other common factors.

The EEI subcommittee is to be congratulated on the progress made toward a nondestructive method of testing generator insulation which will give as full information as possible. It seems likely, however, that if resistance-time curves (showing dielectric absorption) are to be of maximum value, they should also be taken periodically over a long period of time, and values of insulation resistance plotted in a curve against time, for subsequent interpretation. This of course is not so easily done as if a single reading is taken at each test period, but possibly, for example, sufficient data may be recorded by plotting three curves in different colors on the same sheet or card, showing insulation resistance values at the end of 1, 3, and 10 minutes.

H. W. Bousman (General Electric Company, Schenectady, N. Y.): The vast amount of work done by the committee in collecting this information is bound to be helpful even though we do not yet know fully how to use the facts brought together.

I should like to suggest an interpretation of the observations on the appearance of dielectric absorption in the insulation resistance measurements as machine insulation dries. This is that the absorption current is present all the time but masked by a larger leakage current in some cases. Consider for example the curves shown in figure 5 of the paper. If the constant temperature parts of these curves, say the final 50-hour portions, are plotted in terms of insulation conductance instead of insulation resistance, the separation between the 1-minute and 10-minute curves is constant, indicating no change in the absorption current. This comment is made merely for what value it may have in showing the physical phenomena underlying the direct experience gotten from the measurements. The practical man with a machine to dry may still prefer a resistance plot such as figure 5 in the paper.

Dielectric strength testing at routine time intervals has not been greatly used because of the likelihood of damaging entirely serviceable insulation. It may be that different sorts of dielectric strength tests cause deterioration at different rates. For this reason, the committee in its future work on the dielectric strength of generator and motor insulation should include consideration of any difference in the deteriorating effect of various sorts of high-potential testing short of breakdown. That is, does a d-c test or an impulse test to 80 per cent of breakdown voltage have less deteriorating effect than a 1-minute a-c test to the same percentage of breakdown? Some work done in England[1] on cable testing rather points this way, even to the extent that routine d-c high-potential testing at several times operating voltage was done at regular intervals on an extensive underground cable system.

1. Routine Overvoltage Testing of High-Voltage Cables, C. **Kibblewhite**. *Journal* IEE, volume 79, July 1936, pages 82–7.

R. W. Wieseman (General Electric Company, Schenectady, N. Y.): Insulation resistance readings of armature windings were considered by some to be a haphazard compilation of unrelated numbers. One reason for this was that insulation resistance readings were rarely taken under the same conditions. In the past few years, however, an effort was made to measure insulation resistance of armature windings under specified conditions regarding the applied voltage, the time of voltage application, and the winding temperature. This procedure indicated that insulation resistance readings are not simply a set of erratic numbers with the result that more confidence is being given to insulation resistance testing.

This paper is further evidence of the importance of insulation resistance as a winding maintenance index. Unfortunately insulation resistance itself cannot be an absolute criterion of the condition of a winding because it gives only a relative indication of the amount of foreign matter in or around the winding.

One of the interesting features about insulation resistance is the manner in which dielectric absorption aids in evaluating insulation resistance readings. If the absorption effect is small, the insulation contains foreign matter of one kind or another, but if the absorption effect is large, the insulation as a rule does not contain foreign matter. This phenomenon is very clearly shown in figures 1 and 5 of the paper.

If the insulation resistance curve is drawn as in figure 1 of the paper, the winding is usually bone dry when the slope of the curve is about 45 degrees at one minute of voltage application. In fact, a dry winding can be determined by observing the slope of the curve as well as by the insulation resistance itself. Thus the insulation resistance combined with the absorption effect offers a double check on the condition of the insulation. The manner in which insulation resistance varies with the applied voltage, figure 7, is still another check on the winding. It follows that the manner in which insulation resistance varies with both time and voltage aids greatly in interpreting insulation resistance readings.

In conclusion, insulation resistance will not indicate when a winding will fail, and judgment, therefore, must be used in deciding when a winding should be reconditioned or reinsulated. Insulation resistance, however, is an excellent maintenance barometer as shown by figures 4, 5, and 6 of the paper.

H. L. Wallau (Cleveland Electric Illuminating Company, Cleveland, Ohio): Technical paper 41-17 presents in concise form an account of research work done by a group of interested engineers in an endeavor to develop non-destructive electrical tests for application to machine windings for determining the condition of their insulation to forestall the development of faults in service.

Definite tests of such character would be of inestimable value to engineers operating and responsible for the service continuity of rotating electrical machinery. To dismiss the possibility of their development as chimerical, because as yet no conclusive answer has been reached, would be puerile in the light of the data submitted in this paper. Too much praise cannot be given the members of this subject committee for their unflagging efforts in exploring any and all trails which might lead to the coveted goal. The subject is one involving many variables making it most difficult to devise methods by which all variables but one are maintained at constant values while the effect of variations in that other one are studied.

The curves of figures 1 and 6 of the paper show a qualitative indication of relative winding dryness, the steeper the slope of the insulation resistance-time curves during the initial period of electrification the higher the ultimate ten-minute insulation-resistance values become.

In one of the committee's early reports to the electrical equipment committee EEI was a plate showing a series of such curves taken on a 68,750 kva generator after a heat run and at relatively small differences in winding temperature while the machine was cooling off. This family of curves led to speculation as to the possibility of establishing the relation between insulation resistance and winding temperature changes. If this could be established, then the author believed a ten-mile spot check at, say, yearly intervals, could be corrected to some standard reference temperature, average operating temperature of the windings, for example, and any change evaluated. These notions were communicated to Mr. Webb who went into them with the results indicated in his figures 2 and 3. Unfortunately, as figure 3 indicates, the slopes of the curves for the longer electrification periods of four and ten minutes, respectively, may change materially as a result of a generator's service history. That the resistances for all electrification-times and temperatures are higher in the second test is within expectancy; that the slopes for the longer electrification periods have changed so greatly is to be deplored, since what gave possible promise of an easily applied and reasonably reliable test is shown to be vain.

In closing, I wish to congratulate Mr. Webb and his committee for painstaking work over a period of five years, and for an enthusiasm as yet undimmed.

C. F. Hill and L. J. Berberich (Westinghouse Research Laboratories, East Pittsburgh, Pa.): The paper by Messrs. Gilt, Van Ness, Jr., and Webb, on generator insulation tests, shows that the operating engineer has not been very successful in evaluating insulation quality in this apparatus. Here the arrangement of conductors and insulation and the nature of materials limits the type of tests that can be used, but more important is the fact that insulation failures are no doubt due chiefly to mechanical causes and these are not detectable by the usual electrical method.

Surface contaminations can be detected, and, of course, do the insulation no good, but for a machine kept dry by continuous use, it appears a visual inspection is still one of the safest measures of condition, at least when coupled with operating experience. Such results as reported in the paper are not to be taken as negative, however, as they may lead to more emphasis on the mechanical properties of such insulation to withstand thermal cycling, vibration, and other mechanical causes of insulation defects. What we would actually anticipate is that there must be an optimum compromise between electrical and mechanical properties. It is, however, highly desirable to find some electrical method adaptable to the evaluation of such insulations in machines. To date it appears that the dielectric absorption method coupled with a continuous history of a particular insulation to detect changes is the best available. We hope the authors and their co-workers will continue such a search and we assure them of our interest in the problem.

Some of the data on generator insulation are of special interest fundamentally.

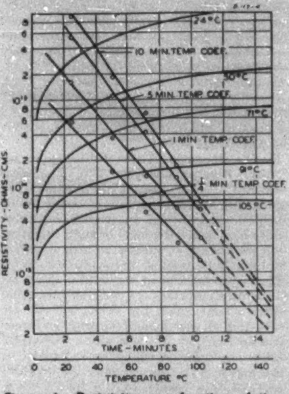

Figure 4. Resistivity as a function of time and temperature for 6,600-volt mica folium measured at 500 volts

Figure 3 of the paper shows the expected increase in resistance as well as an increase in dielectric absorption as the insulation is cured in service. This family of temperature coefficient curves, however, shows abnormal behavior in that if extrapolated the curves appear to intersect in the neighborhood of 25 degrees centigrade. This would indicate that the insulation resistance is independent of the time or that dielectric absorption is absent at this temperature. Such behavior would be inconsistent with dielectric theory. A more normal behavior in this respect is illustrated in figure 4 of this discussion which gives the results of our measurements of insulation resistance against time over a range of temperature on mica folium removed from a machine after eleven years of service. The temperature coefficient curves quite definitely converge at the high temperature end and should become asymptotic at some temperature above 150 degrees centigrade. Most all insulation follows this pattern, that is dielectric absorption decreases as temperature increases until finally ionic conduction becomes so large that the dielectric absorption current is completely masked and the resistance becomes independent of time.

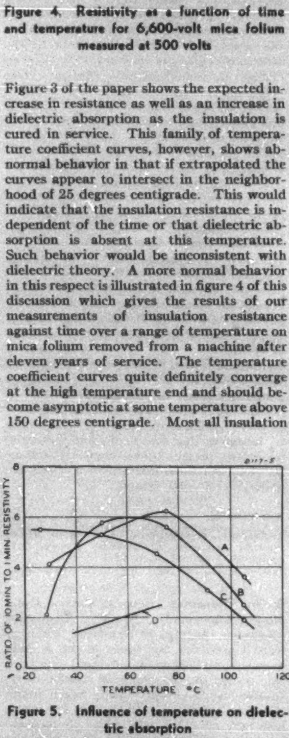

Figure 5. Influence of temperature on dielectric absorption

A—Mica tape—asphaltic-type bond
B—Mica tape—asphaltic-type bond
C—Mica folium—shellac bond
D—Data from figure 3 of paper on generator insulation

We have used the ratio of the ten minute resistivity to one minute resistivity as a crude measure of dielectric absorption. When this ratio approaches unity the dielectric absorption becomes small and the resistance becomes independent of the time. The variation of this ratio with temperature is shown in figure 5 of this discussion for a number of samples of generator insulation. The data for curve *D* were taken from the second family of curves of figure 3 of the paper. Curve *C* is taken from our figure 4. Curves *A* and *B* are for two experimental samples of a newer type of mica tape insulation. Again the normal expected behavior is illustrated by curve *C*. Curves *A* and *B* show the very unexpected abnormal behavior in which the ratio goes over a maximum as the temperature increases. Curve *D* probably also would have shown a maximum had the data covered a wider temperature range. The power factor data did not help to explain these results which, incidentally, show samples *A* and *B* to have a considerably lower power factor than that of sample *C* over a wide range of voltage and temperature. This is introduced merely to show that a careful fundamental study of this complex insulation is necessary before the insulation resistance data can be interpreted more intelligently.

We have also investigated insulation resistance over a range of voltage from 5 to 175 volts per mil at temperatures up to 105 degrees centigrade on a considerable number of samples of both the newer and the older type of generator insulation. The a-c peak operating stress on these types of insulation averages only 60 volts per mil. The power factor data indicated that some of the samples contained internal voids which might influence the high voltage d-c measurements. It was found, however, that the insulation resistance was substantially independent of voltage over the whole range on all samples. The samples with voids gave somewhat unsteady readings. When the charging current under high voltage d-c was amplified and fed into a loud speaker the more or less periodic discharging of the voids could be heard distinctly. It should be remembered that there is an important difference between measurements in a machine and measurements made on samples cut from the slot section and equipped with guard rings. A measurement in a machine on a single phase with the other two phases grounded involves three components: namely, (1) the volume resistance of the slot section, (2) leakage resistance of the end winding, and (3) leakage resistance from the phase group under test to the other two phases. In our work only the first entered, but in a machine all three are in parallel and might result in quite different behavior.

We were much interested to see the results of d-c and a-c breakdown strengths compared on generator insulation. The data show the d-c and a-c peak breakdown strengths to be of the same order of magnitude. This suggests the possibility of substituting d-c for the a-c overvoltage tests now required.

The question of corona in a-c proof testing bringing about voltages much higher than the sphere gap setting through resonance should be considered. A d-c overvoltage test would eliminate this possibility. We wish, therefore, to encourage obtaining more data comparing a-c and d-c breakdown strengths.

R. L. Webb (chairman of committee): We are greatly pleased by the interest shown and by the extent of the discussion aroused by this paper. It is our hope that the paper will help to stir further interest among field maintenance groups when it is printed and made available to the industry.

Suggestions have been received from many interested engineers from time to time and these have assisted to guide this study. The matter of studying temperature effect was suggested by Mr. Wallau more than a year ago. Some of the data collected are presented in the paper. It is obvious that further attention to the characteristics observed will be necessary before all available information can be correlated and fully explained.

Mr. Woodrow's figure 1 shows data similar to those in figure 3 of the paper. Both sets of data were obtained on modern shielded insulation made by the same factory. His theory and formula which conveniently simulated, by equivalent circuits, the different current paths in an insulation structure will prove a valuable tool for analyzing data to determine where changes are occurring in the dielectric.

We agree thoroughly with Messrs. Hellmund and McAuley regarding the advisability of continuing to investigate the possibilities of high voltage d-c testing. This type of test has the advantage of light weight testing apparatus and it shows some promise of giving an index of insulation condition at non-destructive voltage values. We shall continue this phase of the work vigorously.

It was a privilege to have Mr. Knowles present and to hear a few words from him. His review of insulation resistance versus time testing on telegraph cables as long as 25 years ago is interesting and points to the early attention given this type of test at low voltages. Mr. Knowles and his company deserve much praise for the attention given to low voltage d-c testing for the last 30 to 40 years and for the manufacture of fine test instruments which have been so broadly used throughout the world in checking insulation resistance. We appreciate his suggesting the additional paper to supplement the bibliography.

Mr. Creagmile is quite right in stating that it is equally important for the voltage output to be proper in all types of test instruments. However, a continuous voltage indication is provided the operator, so he may easily supervise the voltage during the actual testing, where battery equipments, electronic sets, or Kenotron outfits are used. In the case of the cross-coil ohmmeter the voltage output is not indicated and must be taken for granted. An occasional check on the voltage output of these instruments will suffice since any reduction will likely occur slowly. The insulation resistance of a machine may be sensitive to and may vary inversely with impressed voltage. Readings taken at voltages different from that anticipated will give inaccurate data not comparable with past or subsequent test information if the voltage has changed appreciably. He is also quite right about the need for spot readings in the general run of testing. We are concerned here with improved accuracy for supervision of the insulation on relatively large and important machines.

Mr. Oldacre's suggestion on testing turn to turn insulation is on our calendar for attention as time permits.

Mr. Bousman's observations agree with those of Mr. Woodrow and they appear to be quite consistent with the test data on hand. His recommendation that tests be made to determine the relative effects of a-c and d-c testing as well as impulse testing shall be given early attention.

As stated in the paper, data have been obtained similar to that shown in figure 4 of the discussion by Dr. Hill and Dr. Berberich. The data in figures 2 and 3 of the paper show the convergence of the curves at the low temperature end. The curves of figure 1 by Mr. Woodrow show the same characteristic. We agree this deserves further study and testing to determine the cause of these discrepancies. The data in the paper and in Mr. Woodrow's discussion were taken on modern shielded insulation manufactured by the discusser's company. They may wish to do further testing on some factory samples. We agree fully with the interest expressed in a-c and d-c testing. We shall continue work on this phase of the investigation at every opportunity.

The slope of the dielectric absorption curve at one minute, does as Mr. Wieseman states, give an index of insulation dryness. His other comments apply correctly to low voltage insulation testing. We are hopeful that better and more accurate indices will be obtained using higher voltages.

Mr. Egan has touched on an important point—namely, "Industry Co-operation." The subject committee needs more and more test data taken according to the procedure already set down. Copies of this procedure can be obtained from J. O'R. Coleman at the Edison Electric Institute, 420 Lexington Avenue, New York, N. Y.

Atmospheric Variations and Apparatus Flashover

Discussion and author's closure of paper 41-35 by P. H. McAuley, presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941, and published in AIEE TRANSACTIONS, 1941 (July section), pages 798-803.

L. Wetherill (General Electric Company, Pittsfield, Mass.): The total effect of atmospheric conditions, combined with the presence of dirt, can undoubtedly reduce the flashover strength of a bushing or other similar insulator to some fraction of its normal strength. However, under usual operation conditions, the decrease in strength of a bushing which may result from such factors is not quite so great as it would first appear.

For example, extreme variations in air temperature may account for a 39 per cent variation in the flashover strength of a bushing. However, as compared with the reference temperature of 77 degrees Fahrenheit, the range of variation of flashover of 39 per cent consists of six per cent possible decrease and 35 per cent possible increase. The danger of flashover of a bushing caused by variation in air temperature appears to be slight. Most of the effect of variation in air temperature appears as an increase in strength which to many operators is not undesirable.

While the flashover strengths as affected by air density may decrease 30 per cent at 10,000-feet altitude, we are primarily concerned only with an 11 per cent decrease at 3,300-feet altitude, since at altitudes exceeding 3,300 feet it is the usual practice to furnish bushings with increased external strength. It is not clear whether the curve for effect of altitude refers to 60-cycle flashover or impulse flashover. What little data are available on characteristics at densities encountered at high altitude seem to indicate that the impulse flashover is affected somewhat less than the 60-cycle flashover. The result of such a condition would be that for bushings in service at high altitudes the actual impulse flashover strength would be somewhat in excess of the value which would otherwise be expected.

Fluctuating atmospheric humidity may cause variation of 20 per cent in flashover strength. However, the high atmospheric humidity which usually accompanies lightning conditions is on the favorable side and tends to increase the flashover strength of a bushing with the result that the effect of humidity on flashover strength may, on the whole, be beneficial in preventing flashovers due to lightning which is the chief source of extremely high overvoltages in service.

R. E. Hellmund (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Although it must be conceded that the change in flashover voltage with weather conditions is troublesome to users and manufacturers alike, a study of Mr. McAuley's paper indicates that in general there is not much that can be done about it. The present standards and practices applying to bushings in particular are reasonable both from an operating and an economic point of view. There is, however, one possible inconsistency in the voltage de-rating curve shown in figure 2 of the paper, which is taken from existing standards. This curve shows how apparatus is de-rated above a certain altitude. It is obviously not very practical for users to change the line voltage in a given transmission system as it goes from one altitude to another. Therefore, since small increments in flashover are only possible when gaps can be used to reduce excess flashover margins, it becomes more practical to make applications in a series of steps at selected levels rather than by means of a smooth curve.

Standards co-ordinating committee 1 (reference values for standardization) is investigating the possibilities of establishing standard limiting ranges of altitude for applying apparatus about as follows:

0– 3,300 feet
3,300– 6,600 feet
6,600– 9,900 feet
9,900–13,200 feet

Assuming that these standard ranges were established, it would seem possible to determine to which ranges each of the standard voltage classes of apparatus apply and where it would be expedient to use special apparatus or bushings, or in some cases, higher voltage apparatus with reduced flashover by means of gaps.

Considering the effect of temperature upon flashover, certain limited risks may be taken because lightning surges, which might overstress internal insulation on account of the higher air densities with low temperatures, occur but rarely at the lower temperatures.

J. H. Hagenguth (General Electric Company, Pittsfield, Mass.): The paper shows clearly the effect of atmospheric variations on the flashover of bushings. As pointed out, similar effects occur on rod gaps, insulators, or other apparatus with non-uniform fields. This effect, of course, has been recognized clearly since many years and correction factors have been obtained experimentally, an example of which is figure 3 of the paper. At low vapor pressures a correction factor of 1.2 is shown if the standard humidity of 0.6045 inch of mercury vapor is used. That means that the rod gap sparkover would be reduced from 100 at standard humidity to $\frac{100}{1.20}=83.5$ at vapor pressure 0. Humidity affects apparatus flashover regardless of what value of standard humidity is chosen. Therefore, the principal use of a standard value of humidity is that of permitting comparison of flashover values of different types of apparatus on a common basis.

The whole range of humidity corrections for different types of apparatus, of course, should be known. However, for laboratory tests, it always is desirable to make tests under as nearly standard conditions as possible. This is desirable, especially where large correction factors are involved and, furthermore, where correction factors are not known within any great degree of accuracy as is the case with humidity corrections. The humidity variations at the Trafford and Sharon laboratories of the Westinghouse Company have been shown in a graph, figures 6 and 7, in a previous paper by Mr. P. L. Bellaschi and the present author. A similar curve is shown in figure 1 of this discussion for the Pittsfield high-voltage engineering laboratory of the General Electric Company. This figure also shows the average vapor pressure for the year to be 0.31 inch, for the period of 7 months (November–May) 0.2 inch mercury, and for the five-month period (June–October) 0.45 inch mercury. Only during two months of the year—July and August—the present standard vapor pressure of 0.6085 inch mercury is exceeded for an appreciable time. Similar conditions exist in the author's laboratories as shown in reference 1.

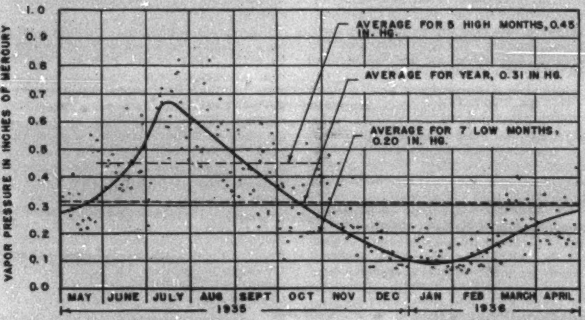

Figure 1 (above). Humidity data obtained in high-voltage engineering laboratory, Pittsfield works, General Electric Company, during the period from May 1, 1935 to April 30, 1936

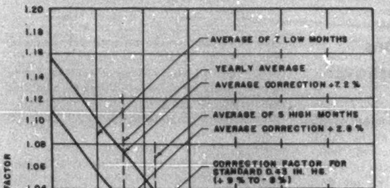

Figure 2 (left). Humidity correction curves for suspension insulators. Positive polarity

In figure 2 (of this discussion) the humidity correction curve for impulse flashover of insulators has been plotted on the basis of standard vapor pressure of 0.6085 inch mercury (curve *A*) and on the basis of 0.43 inch mercury as the standard condition (curve *B*) (ICE standard conditions). Superimposed are the dotted vertical lines indicating the average vapor pressure for the year, seven winter months, and five summer months. By shifting the correction curve—which, of course, is merely a mathematical procedure and the effect of vapor pressure on flashover is not changed by this procedure—three advantages result:

1. The yearly average correction to be applied to test flashover voltages to calculate standard flashover voltages has been reduced from 7.2 per cent at 0.6085 inch mercury to 2.8 per cent at 0.43 inch mercury.

2. Taking the maximum variation of vapor pressure during the year from figure 1 (this discussion) as 0.8 and 0.05 inch mercury, the maximum corrections for a standard vapor pressure of 0.43 inch mercury are +9 per cent and −9 per cent as compared to +14 per cent and −4 per cent for a standard vapor pressure of 0.6085 inch mercury. While the overall range is the same, the maximum correction is reduced by 5 per cent.

3. A humidity of 0.42 inch mercury in the laboratory is not nearly as objectionable from the point of view of physical comfort and the general health condition of the laboratory men as a humidity of 0.6085 which creates the impression of a tropical jungle when artificially created in the laboratory. Therefore, it would become practical to maintain a nearly constant humidity of 0.43 inch mercury for all flashover tests. The high-voltage engineering laboratory of the General Electric Company in Pittsfield is equipped to maintain a constant humidity up to approximately 0.6 inch mercury. Clearly accuracy of measurements on this basis would be greatly increased.

There are two principal objections against a change in standard conditions:

1. As mentioned in reference 2, the flashover voltages established under the 0.6085 inch mercury standard would all be lowered—as shown by figure 2 (this discussion) for impulse flashover voltages of insulators a reduction of 4.5 per cent would result.

2. The humidity during conditions favorable for thunderstorms is mostly at or above the present standard condition of 0.6085 inch mercury, and, therefore, standard values of flashover at 0.6085 inch mercury are more nearly representative of actual service conditions.

However, as pointed out previously, the fixed standard level does not influence the flashover of a given apparatus. Therefore, apparatus flashover of 96.5 kv at 0.43 inch mercury indicates the same performance characteristics as 100 kv at 0.6085 inch mercury for any apparatus with humidity correction as shown on figure 2. As long as the whole range for different apparatus groups is investigated, flashover voltages for all conditions of humidity are known regardless of the standard chosen. However, the lower standard value has the advantage of giving lower corrections during tests and permits testing at more nearly standard conditions throughout the year, and, therefore, results in greater accuracy of measurements.

The paper points out the great variations in flashover voltages caused by conditions of the air. It is also pointed out that "the internal insulations of apparatus is not affected by the changing dielectric strength of the ambient air." The large variations in flashover voltages due to air conditions together with the large variations in flashover voltages due to impulse wave shapes as shown in my paper presented at the convention[2] clearly indicate that apparatus with non-uniform fields are not suitable for coordination purposes of costly station equipment. Since internal insulation is not affected by air conditions, the means of protection employed should also be unaffected and the only device of fulfilling this condition is the modern lightning arrester.

P. H. McAuley: The discussions consider and amplify many practical points related to the general subject of the paper and require no further comment for the most part.

The correction curve for altitude is given in Standard 19, apparently with 60-cycle flashover in mind. The derating factors actually are applied to the standard voltage rating of apparatus. However, similar variations seem to occur with critical impulse voltages. This is recognized in the corrections for impulse sparkover of rod gaps and sphere gaps given in Standard 4. It is probable, however, that the phenomenon was not investigated over a wide range of pressures such as encountered up to 10,000-feet altitude. Fielder (*Electric Journal*, December 1935) found that the correction for relative air density decreases with the time to flashover. This applied as well to humidity and, in this case, current laboratory practice makes allowance for the effect.

Mr. Hagenguth's data confirm a situation discussed in the paper on reference values. The question of changing a reference value is a matter for thorough and wide discussion in view of the many standard values, catalogue data, and insulation levels which would require adjustment.

Factors Influencing the Mechanical Strength of Cellulose Insulation

Discussion and author's closure of paper 41-44 by F. M. Clark, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (July section), pages 778–83.

J. G. Ford (nonmember; Westinghouse Electric and Manufacturing Company, Sharon, Pa.), and **C. F. Hill** (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): A stable period, similar to that reported by Clark in which cellulose tends to retain its mechanical strength at the beginning of a heating cycle has been observed in our studies in the presence of oxygen. We have assumed it due to the formation of oxidation products of cellulose, possibly by hardening of residual resins. The existence of a stable period due merely to thermal action is, I believe, not a previously known behavior. I am wondering if the technique used by Clark completely eliminates the action by oxygen. A dormant period as a phenomenon distinct from the stable period is rather surprising as it would indicate two rather independent mechanisms in cellulose due to the application of heat. So far as I know, the cellulose chemist has not anticipated two such independent effects.

In general, the deterioration of cellulose due to thermal action at high temperature and deterioration due to oxidation are well recognized and known phenomena, and so far as I can see, Clark's results are in general agreement with other results. There is one conclusion in Clark's paper, however, which I have been unable to justify from his results. I refer to conclusion 7 in which it is stated that there is no substantial difference in the rate of mechanical deterioration of oil-immersed cellulose in the presence of nitrogen and of air. It would be my interpretation that in Clark's method the oxygen of the air is captured rather quickly by the oil and that in effect the amount of oxygen is too limited to produce sufficient acid concentrations in the oil to affect the cellulose appreciably, so that the tests are both run essentially in a nitrogen atmosphere. At the elevated temperatures of 100 degrees to 130 degrees centigrade or more, the oxygen would disappear from the gas space within a very few hours. It seems to me this conclusion would only be justified if the oxygen supply in the gas were kept constant. Then the effect of oil oxidation products on the cellulose should become the dominant factor and not the direct action of oxygen on the cellulose. Figure 8 of Clark's paper shows an appreciable effect with five times as much oxygen as in his figure 9 and it would appear that the effect due to oxygen is about proportional to the available oxygen. Acidity measurements on the oil itself would have been of value.

A quantitative comparison of our own results with those of Clark may be of interest. We have used the bomb test in the form of a sealed glass tube very similar to that used by Clark. Figure 12 of my paper presented two years ago before this group was obtained on a Manila paper in a fireproof transformer liquid in such a glass bomb. The residual tensile strength after 96 days at 140 degrees centigrade was about 15 per cent of the initial strength. Clark reaches less than six per cent residual in that time in oil. Since publishing my paper, I have had my technique of using the sealed bomb questioned by cellulose chemists in that by-products of the decomposition may react on the cellulose. Previously we had made tests on cotton base materials in oil and a nitrogen atmosphere in which 25 per cent of the initial strength was retained after two years at 140 degrees centigrade, but in that case the by-products could escape at one atmosphere. These results were demonstrated in figure 8 of my paper. I would be interested in Mr. Clark's comments on this effect of residual by-products and particularly to know if he has made any studies in which the action of such by-products and also of oxygen are both eliminated.

An interesting experiment upon condenser paper heated in a vacuum is of interest in this general problem of thermal resistance of cellulose. Samples of the paper were heated one month at 125 degrees centigrade in vacuum and then the temperature was raised to 150 degrees centigrade for one month in vacuum. The initial strength of this paper was 3.91 pounds for a $^{1}/_{2}$-inch strip and the strength after heating was 2.37 pounds. The paper had thus retained 60 per cent of its initial strength. From such results as just quoted and from results of some transformer life tests, we have therefore, concluded that the bomb tests which we made some three years ago are questionable so far as practical application is concerned.

V. M. Montsinger (General Electric Company, Schenectady, N. Y.): I would like to discuss this paper from the standpoint of application of the data on the rate of aging of insulation to the operation of transformers.

In the first place, the data show quite conclusively that even though an oxidizing agent is excluded from contact with either the insulation or the oil in which the insulation is immersed, the tensile strength of the insulations when subjected to temperatures in excess of approximately 100 degrees centigrade decreases rapidly with time and eventually becomes unsuitable as an insulating material. This obviously means that the insulations in oil-immersed transformers having either conservators or cushions of inert gas over the oil cannot carry heavy overloads for indefinite periods of time without their life being seriously shortened.

In the second place, let us see how the aging of the insulations versus temperature bear out the eight-degree rule which was published in my 1930 AIEE paper on "Loading Transformers by Temperature." It is true that all the curves do not follow the eight-degree rule, and it would be rather surprising if they did. Mr. Clark clearly shows that there are two important factors causing the deterioration of fibrous insulation, one of these being oxidation, and the other chemical decomposition. We should not expect to find any logical correlation between these two factors.

Excluding the tests in which the insulation was aged in oxygen, since it is not a practical operating condition, an examination of the curves shows that in general the aging doubles for approximately each 8-degree increase in temperature, the range being from about 7 to about 15 degrees although most of them are quite close to the 8-degree rule. For example:

Figure 2 shows that the relative times to produce the same aging are, 90 days at 125 degrees and 20 days at 142 degrees. The eight-degree rule would show 22.5 days ($^{1}/_{4}$ of 90) at 141 degrees (125+16). Therefore, it is quite close to the eight-degree rule.

Figure 4 shows that the relative aging for 120 degrees and 135 degrees follows the 7 to 7.5-degree rule.

Figure 11 shows that to reach 12 pounds per square inch the 100-degree and 135-degree temperature curves follow the 9-degree rule. Comparing the 100-degree and 120-degree curves, the rule is approximately 7 degrees. Comparing the 120-degree and 135-degree curves, the rule ranges from 15 to 17 degrees. The over-all average rule is approximately 10.5 degrees.

Comparing the curves given in figures 15 and 16, it will be noted that when increasing the temperature 15 degrees, that is, from 120 to 135 degrees, the aging of oil-treated insulation doubles for each 3.5-degree increase in temperature, while the aging of the untreated insulations doubles for each 7.5-degree increase in temperature. This, of course, is comparing the aging in air and in nitrogen. Other tests, however, figure 9, show that the aging is essentially the same in air and in nitrogen.

Taken as a whole, I think it is safe to say that the data given in Mr. Clark's paper come fairly well within the seven- to ten-degree rule. This is fortunate for without some kind of rule it would be practically impossible to determine the effects of either short-time or continuous overloads on the life of transformers.

Wm. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): Mr. Clark states in the introduction to his paper that the tensile strength of the insulation has been accepted as a gauge of its mechanical properties. Some years ago I made tests of somewhat similar character but gauged the mechanical condition of the oil-impregnated paper not only by tensile strength but also by folding endurance and tearing strength. I found that when cable paper was aged in air at high temperatures the tensile strength tended to remain constant, even at temperatures almost up to the charring point of the paper. However, it was noted that long before the charring occurred, both the tearing strength and folding endurance, particularly the latter, fell off quite rapidly.

I therefore question whether the "stable period" described by Mr. Clark deserves to be known by that name and I question its value as an indication that cellulose insulation may be subjected to overloads corresponding to this stable period without sensible deterioration, unless the insulation is not to be bent.

I realize that both the tearing strength and folding endurance are somewhat more erratic than the tensile strength and that it is not so easy to get a good-looking curve of deterioration, but would not such a curve be more useful even though depending upon somewhat more erratic points?

Mr. Clark's oxidation tests were made with oxygen gas and I believe that this is entirely justifiable for evaluating the oxidation of low-voltage insulation. If, however, high-voltage insulation is to be evaluated it would seem that ozone should be used as ozone is the principal deteriorating agent in such cases and produces entirely different chemical effects from ordinary oxygen.

Mr. Clark's data on the relative effects of oxygen and nitrogen are exceedingly interesting. I should like to ask whether he considers that the deterioration in nitrogen is due, in large measure, to oxygen occluded or dissolved in the insulation.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): The contrasting data and views presented by different investigators show that there is still need for such carefully controlled studies as reported in Mr. Clark's paper. In figure 9, he shows that there is practically no difference between the effects upon the mechanical properties of paper of heating impregnated paper in the presence and absence of air. This finding is apparently in contrast with the views of several other investigators. The Swiss oil specifications ("Conditions techniques pour huiles isolantes," Publication 124 of the Association Suisse des Electriciens) use in the oil oxidation test as a criterion of the oil deterioration the decrease in tensile strength of cotton yarn kept in contact with the oxidizing oil. C. F. Hill (AIEE TRANSACTIONS, volume 58, page 484) reports that oxidation products of the oil peroxides in particular and perhaps some of the low-molecular weight acids react with cellulose to cause its decomposition. Putman and Dann (AIEE TRANSACTIONS, volume 58, page 505) report that test results showed that insulating materials in oil protected against contact with air will withstand appreciably higher temperatures than in open oil. It is noted that Mr. Clark's tests on impregnated paper were made in sealed tubes, i.e., with a limited supply of air or oxygen. Possibly this fact is the reason for the apparent discrepancy between Mr. Clark's findings and those of other investigators. What was the ratio of gas and insulation volume in these tests in sealed tubes?

The data on the dormant and stable periods are of considerable practical interest. The table shown in the paper shows that for 120 degrees centigrade the stable period is 101 hours. Are there any comparable data available as to the total number of hours of intermittent heating before the end of the stability period is reached? In service, obviously, the hours at high temperature during each emergency will usually be a small fraction of 101 hours.

Aging tests of oil-filled cables in Chicago produced apparently less mechanical deterioration of the paper than indicated by figure 11 of the paper. In the Chicago tests the inner tapes of the insulation were subjected to temperatures in excess of 120 degrees for over 2,000 hours, but not more than 100 hours continuously in most cases. After these tests the mechanical strength of the tapes was found to be decreased to about 50 per cent of the original strength as determined by tearing tests, while according to figure 11, 120 degrees for 2,000 hours would cause a decrease in tensile strength of 81 per cent.

What is the limit of temperature below which thermal decomposition in the absence of oxygen becomes negligible? According to figure 11, thermal decomposition takes place even at 100 degrees centigrade. It is noted, however, that after 16 weeks no further deterioration occurred. Could it be possible that residual acids or other oxygen-carriers in the oil and paper were responsible for the deterioration that stopped after these agents were used up? This opens another question, namely, whether the deterioration is taking place in the cellulose or is due to noncellulose materials in the paper.

The statement is made based on figure 5 that for temperatures below 100 degrees "the oxidation effect is of negligible importance." As at these lower temperatures thermal decomposition is probably not of great importance, does the statement imply that at such lower temperatures deterioration of paper is practically absent? E. J. Murphy presented test results before the 1938 meeting of the Conference on Electrical Insulation of the National Research Council showing that decomposition of dry paper under vacuum is appreciable at 75 degrees centigrade with no electrical stress applied. It is possible that the deterioration found by Mr. Murphy was due to residual moisture being driven out by the combined effect of a very high vacuum, 10^{-4} millimeters of mercury, in combination with an elevated temperature, 75 degrees. However, serious deterioration due to oxidized oil has been found in some transformers that have operated at temperatures below 100 degrees.

F. M. Clark: The deterioration of cellulose insulation resulting in a mechanical weakening is definitely the result of a chemical change and as such presents a difficult problem for its commercial control. To adequately discuss the various phases of the problem raised by the discussion presented would justify another paper of equal length as the original. The following paragraphs attempt to outline explanatory suggestions in answer to the more important points raised:

1. There is not sufficient evidence at present available to determine whether the existence of the commercially important stable period is due to the initiation of a favorable (resin hardening) reaction as suggested by Dr. Hill or to the occurrence of a period of inhibition. We have observed its occurrence in a variety of cellulose insulations of widely different resin content.

2. The dormant period should not be considered as an independent phenomenon but merely as the culmination of a series of preceding pyrochemical reactions which eventuate in a simple decomposition, one of whose products is gaseous.

3. The explanation that the protective action of mineral oil is due to its preferable reaction with the oxygen present does not appear tenable, since reactions under high oxygen pressure where an excess of the oxygen is always present lead to the same general conclusions as are drawn from deterioration studies at lower gas pressure.

4. The deterioration of cellulose is definitely accelerated by the presence of the decomposition products. This has been demonstrated in a previous publication (ELECTRICAL ENGINEERING, volume 54, number 10, pages 1088–94). This effect is present whether the insulation be aged in the presence or absence of oxygen. From studies recently made it would appear that the mechanical deterioration of cellulose proceeds along the same chemical trend whether gaseous oxygen be present or absent, possibly due to the oxidizing action of the products formed as a result of pyrochemical decomposition. I refer Dr. Hill to the article mentioned for a more complete description of the action of heat on capacitor paper under reduced pressure.

5. It is gratifying to note that the rate of cellulose deterioration recorded in this paper agrees with the so-called eight-degree rule already described by Mr. Montsinger. This eight-degree rule may have many important practical applications within the range of commercial practice. Its extension to include a wider range of temperatures than those described by Mr. Montsinger, however, can be expected to be difficult because of the initiation of chemically different types of reactions as the extremes of temperature are encountered.

6. Mr. Del Mar cites an interesting case with reference to cable paper which retained an approximately constant tensile strength almost to the point of charring. This phenomenon has not been observed in the series of researches of which the data of this paper are a part. Serious deterioration in tensile strength has always been observed long before the deterioration has proceeded to the point of charring.

7. The tearing and folding strength of papers have invariably been found to be extremely erratic and do not lend themselves to reliable analysis. Al-

though the deterioration in tensile strength is slower than that for the folding or tearing test, it is more constant in its behavior and has, therefore, been considered as a more reliable test tool although for certain electrical applications information regarding the tearing and folding strengths of the paper may well be demanded.

8. In any study of the mechanical deterioration of cellulose insulation, careful attention must be given to the conditioning of the insulation before the aging test. Many of the discrepancies reported in the literature and referred to by Mr. Halperin can be traced to neglect of this important factor.

9. In a general sense, the intermittent exposure of cellulose insulation to a deteriorating temperature gives an additive effect.

10. The cable experiments cited by Mr. Halperin are of interest, but it must be remembered that the extent of the mechanical deterioration of cellulose insulation caused by pyrochemical effects is not only determined by the temperature and the presence or absence of oxygen or oil, but also by the mechanical conditions of the exposure. Like many chemical reactions of this type, environment has such an important effect, that it is impossible to transfer the exact results obtained in a laboratory setup to the deterioration obtained in commercial practice. The loss or retention of the products of the initial cellulose deterioration, for example, is a factor which greatly influences the type and rate of all subsequent reactions and effects.

11. Paper will deteriorate from many causes and the statement that the effect of oxidation is of negligible importance below 100 degrees centigrade certainly must not be interpreted to mean that paper cannot be made to deteriorate at a lower temperature. The statement merely indicates that at low temperature the presence or absence of oxygen is not of major practical importance in determining the rate of the deterioration observed. The effects of vacuum applications and other factors not included in the paper cannot be anticipated from the data presented.

Classification and Co-ordination of Short-Time and Intermittent Ratings and Applications

Discussion and author's closure of paper 41-13 by R. E. Hellmund, presented at the AIEE winter convention, Philadelphia, Pa., January 27-31, 1941, and published in AIEE TRANSACTIONS, 1941 (July section), pages 792-8.

Wm. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.): The case of cables differs from that of other apparatus due to the fact that cables are generally associated in a thermal way, with the structure in which they are carried, such structure being unrelated to the cable itself.

In many cases the structure is so extensive that the element of time for heating it is of prime importance. The heat capacity which comes into play, therefore, depends on the rate of change of load. For instance, cables in underground ducts will have a high thermal capacity for overloads lasting an hour or more, due to the heat capacity of the ducts and ambient earth. In fact a cable in an underground duct will never attain the ultimate temperature rise corresponding to the balance of its steady heat generation and dissipation. On the other hand, for overloads lasting a second or less the available heat capacity will be little more than that due to the copper conductors.

It is advisable to consider the cases of impregnated paper cable and of rubber and varnished cambric cables separately.

The rule that each eight degree centigrade rise in temperature halves the life of insulation does not apply to paper cables, because this rule seems to apply only to insulation exposed to air, whereas the insulation of power cables is generally out of contact with air. Furthermore, the rule is based on the assumption of thermo-chemical deterioration only, whereas in high voltage paper insulated cables, which constitute the bulk of those used for wholesale power work, the effect of high temperature is to promote ionization through cyclic expansion and contraction.

The cases of rubber and of varnished cambric insulations are important in the present connection because such cables are directly connected to rotating machinery, and station apparatus. The voltage, in general, is low and, in most cases, a considerable part of the cable does not have the advantage of thermal association with any structure. In such cases, only the thermal capacity of the copper, insulation, and coverings come into play and, in the absence of metallic sheathing, chemical deterioration of the insulation will be a prime factor in its life, if subjected to high temperatures.

Available data on the connection between life and operating temperature of cable insulation do not fall into any well defined pattern, so that the applicability of the eight degree law is undetermined. An example of such data, carefully determined, will be found in Mr. S. Rosch's paper on "The Current Carrying Capacity of Rubber-Insulated Conductors" [AIEE TRANSACTIONS, volume 57, 1938 (March section), page 157]. Code grade rubber insulation was aged at 50 degrees and 60 degrees centigrade. According to the eight degree rule, a difference of 10 degrees centigrade should multiply the aging by 2.3. The above data however, indicate a four-fold decrease in tensile strength. The data on elongation at break depart even further from the eight degree centigrade rule.

This, of course, raises the question of what is to be the measure of aging and that will depend on the application of the cable. In one case tensile strength may be the criterion and in another, flexibility, or, perhaps, some electrical characteristics.

In general, Mr. Hellmund's proposed rule permits conductor temperatures five degrees centigrade in excess of the normal values. This rule does not seem to be applicable to Code grade rubber insulation with a permissible temperature rise of ten degrees centigrade from an ambient of 40 degrees, as the table is based on the assumption of a 10 degree centigrade rise as base. In other words, the rule would eliminate Code rubber for connection to apparatus with overload rating, unless much heavier copper were used than would be required for normal load. I doubt whether the industry is prepared to endorse this. Of course, the standard carrying capacities of code wire are based on 30 degrees ambient but when co-ordinating the carrying capacities of wires and apparatus connected thereto, one should, obviously, use the same ambient.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): Mr. Hellmund's paper gives some very useful information on determining under load cycle conditions either the safe continuous rating (service factor rating), or the permissible short-time overloads in terms of a continuous rating.

The paper makes use of both the root-mean-square method and the temperature integration method. The rms method is, of course, easier to handle than the temperature integration method that I used in my papers, references 1 and 2. As pointed out by Mr. Hellmund, the use of the rms method should be limited to conditions where the range in temperature is moderate. The reason for its limitation is that the deterioration of insulation is not proportional to temperature.

As is probably well known, the mechanical deterioration of class *A* insulation doubles for each 7 to 10, or 8 to 12 degrees centigrade increase in temperature. I have used eight degrees in my work.

I wish to show under what load-cycle conditions the root-mean-square method is applicable to transformers, and when the temperature integration method should be used. For purposes of comparing the two methods, I have assumed four different load cycles, starting with 10 per cent overload for one hour and gradually increasing the overloads to 40 per cent and the time to six hours.

Figure 1 shows the calculated oil and hot-spot temperatures for a transformer operating under these four different load cycles. The transformer has the following assumed characteristics at rated load:

1—40 degrees oil rise
2—65 degrees hot-spot
3—3:1 ratio of copper to iron loss
4—time constant of 3
5—30 degree ambient

Table I gives the equivalent rms load for each load-cycle, the load-cycle and continuous rms load hot-spot temperatures, the relative aging of the insulation, and finally the life of the insulation under load-cycle operation in per cent of the life under continuous operation at the rms load. The

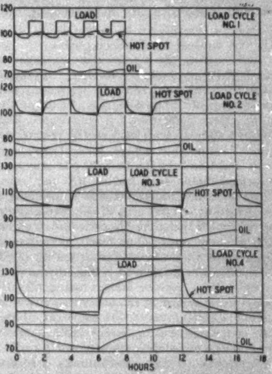

Figure 1. Hot-spot and oil temperatures for a typical power transformer operating under various load cycles—in 30 degrees ambient

Table I

No.	Load Cycle: Percentage Load	Load Cycle: Time in Hours	Equivalent RMS Percentage Load	Ultimate RMS Load Hot-Spot Degrees C	Max. Load Cycle Hot-Spot Degrees C	Aging Units for 1 Cycle Resulting From: Load Cycle	Aging Units for 1 Cycle Resulting From: Cont. RMS Load	Life on Load Cycle in Per Cent of Life on RMS Load
1	110 100 repeat	1 1	105.12	99.0	102.0	10,656	10,280	96.5
2	120 100	2 2	110.5	104.0	110.7	36,920	31,800	86*
3	130 100	4 4	116	109.5	119.5	126,220	101,000	80
4	140 100	6 6	122	115.0	132.0	382,280	245,000	64

* 92% for 12 degree rule.

temperature areas were integrated "by parts" using the formula:

$$A = txe^{kT}$$

where

A = aging units
t = time in hours
k = 0.0865 for 8 degree rule
T = temperature degrees centigrade
e = 2.718

It will be noted that for the first load cycle of 110 per cent load for one hour and 100 per cent load for one hour, the two methods differ by only 3.5 per cent. If used for load-cycle 2—120 per cent load two hours, 100 per cent load two hours, the difference is 14 per cent. If the 12 degree rule had been used for load-cycle 2, the difference in the life expectancy would be only eight per cent. It appears, therefore, that the rms method could be used for load-cycle 1 and possibly for load-cycle 2. Where the overloads (coupled with the times shown) exceed these, the temperature integration method should be used. The rms method can, of course, be used for heavier overloads if the time is shorter and the range in temperature is small. That is, the magnitude of the overload alone is of little importance. In other words, both overload and time should be considered in determining when the rms method is suitable for use.

When using the temperature integration method in my paper, reference 1, I found that the peak load could be expressed as a percentage of the load-factor. Based on the most severe condition, i.e., maximum load on part time and no load on the rest of the time, I found that a peak load of three per cent could be held for each 10 per cent that the load-factor was below 100 per cent. That is, if the load-factor was 50 per cent a peak load of 115 per cent of the rating could be held with the same life expectancy as for 100 per cent continuous load. This would correspond to a service factor rating of 87 per cent of the peak load. The rms method would give a service factor rating of 70.7 per cent, or looked at the other way it would permit a peak load of 141 per cent of the safe continuous rating, which is 23 per cent more than the other method gives.

Referring to Mr. Hellmund's paper—he states that the curves shown in figure 6 have been calculated to give a life of insulation equivalent to that obtained with a continuous operation at 60 degrees rise, but he does not state how the calculations were made. I assume that he used the eight degree rule in integrating the temperature areas.

P. H. McAuley (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The author has classified different types of load conditions and given a procedure for selecting apparatus to fit these conditions. In this connection, it is interesting to observe how different types of motors perform under different periodic operating conditions. The table gives test data on a single frame size motor with different designs of the windings and ventilating systems and different cooling conditions. The weak field motor had a low magnetizing current, the strong field motor a relatively high value, and the no-load losses differ accordingly. Under changing ventilation the motors were stopped during the no-load period of the cycle. With constant ventilation, the motors ran continuously but carried no load for part of the duty cycle, although the no-load losses continued. The relative effects of these losses and of the ventilation are indicated by the rates of drop of temperature (by resistance) of the windings. The significance of the ratio R was discussed in reference 3 of the paper.

7.5 Horsepower 30-Minute Frame Size

	Rate of Temperature Change Near 60 Degrees Centigrade in Degrees Per Minute				
		Changing Ventilation		Constant Ventilation	
	Rise	Drop	R = d/r	Drop	R
Weak field open	1.9	2.5	1.32	4.2	2.2
Strong field open	1.15	1.6	1.38	1.0	0.87
Strong field closed	2.7	0.95	0.35	0	0

For the weak field motor, the magnetizing current is low and the winding cools 1.7 times as fast running light as it does standing still. A similar figure was given for another motor in the closing discussion of reference 3. For the strong field motor, the no-load losses are not compensated by the continued ventilation and the rate of cooling running idle is only 63 per cent of that in the stopped position. When this same motor is enclosed the no-load losses maintain it at the limiting temperature rise and no continuous rms rating is available. This means that the motor cannot be applied advantageously to any service where the motor is connected continuously to the line. It can be used, however, to good advantage for applications where the motor is disconnected during the idle periods. It, therefore, follows that for this enclosed motor case, the simplified methods in the present paper cannot be used. Either slight modifications will be necessary or it is possible to resort to the fundamental methods given in the previous paper of reference 3.

Comparing the open cases, on loads which permit stopping between load cycles, the two motors will perform similar service as indicated by nearly identical values of the ratio R. Where these motors run between load cycles, that is, with constant ventilation, the weak field motor will function satisfactorily on heavier load cycles, as indicated by the larger R constant, which permits larger values of k. Thus, although the 30 minute ratings in all cases are practically identical, there is a wide difference in performance of the motors under the different conditions of periodic service.

P. L. Alger (General Electric Company, Schenectady, N. Y.): Mr. Hellmund has made a considerable contribution to our knowledge of the increasingly important subject of short time rated apparatus. What he has said may be divided into two distinct categories. The first category is that of rating of apparatus. In this connection, he recommends the use of somewhat higher temperatures for the short time rating tests than for continuous apparatus to obtain the same total life, on the basis of our modern knowledge of insulation aging. Also, he recommends the use of service factors to express the ratio of the continuous to the short time ratings. Both of these ideas seem sound and desirable for adoption in various standards.

The second category is that of application. Under this category come all the discussion of intermittent duty cycles, thermal time constants, and their associated effects. These ideas, as well as those expressed by Mr. V. M. Montsinger in his various articles on temperature aging of transformer insulation, are very helpful in the selection of the proper rating of apparatus to operate on a particular duty cycle, but they do not form a part of the apparatus rating itself.

It seems to me that these two questions of rating and application ought to be kept quite distinct. The former requires the setting up of simple methods of rating apparatus that are definite, commercially convenient, and easily proven by simple performance tests. The rating thus establishes the manufacturer's responsibility and permits ready comparison of different makes of apparatus. The latter or application method permits the user to select the proper rating and judge its probable performance under any particular conditions, but forms no part of the guarantees or acceptance tests.

R. E. Hellmund: Since this session was held under the auspices of one of the Standards co-ordinating committees, it is very gratifying to have engineers interested in different types of apparatus and conductors participate in the discussion. Mr. Del Mar's remarks concerning cables are very pertinent; however, conditions in connection with cables are after all not so very different from those encountered in apparatus and machines. Frequently various types of apparatus are associated in a thermal way with their supporting or enclosing structures and with other apparatus; machines and transformers often have their insulation out of contact with air; and many times there are problems arising from expansion, contraction, and ionization. Whenever such modifying conditions are of practical importance, they must of course be taken into account regardless of whether they apply to cables, apparatus, or machines.

I agree with Mr. Del Mar that the methods in my paper relate essentially to applications where cables or conductors are directly connected to machinery. Naturally it is to be expected that the rate of deterioration in material like rubber is somewhat different from that found in class *A* materials used in machinery, but very likely a suitable rule can be determined for rubber insulation and it is hoped that some efforts will be made in this direction.

From the data quoted from Mr. Rosch's paper it would seem that an excess of five degrees for short-time ratings of rubber insulated conductors, i.e., a total temperature of 55 degrees centigrade as compared with 50 degrees centigrade for continuous ratings, is quite conservative. Assuming that these values are reasonably correct, it would simply follow that with a continuous cable rating based on a 10 degree temperature rise and a 40 degree ambient, the temperature rise can be increased to 15 degrees for a short-time rating, and with a continuous rating based on a 20 degree rise and a 30 degree ambient, the temperature rise can be increased to 25 degrees. This is equivalent to an increase in current rating of at least 22.5 and 12 per cent respectively and therefore means worthwhile economies.

I am glad that Mr. Montsinger in his discussion on transformers has emphasized the fact that the ordinary rms method is definitely limited in its application to some load conditions. His load cycles range from two hours to 12 hours, with the load period being one-half of the total time. He finds that for his shortest load cycle the rms method gives reasonably correct results. With the application for which the methods in my paper are most useful, the rms method gives incorrect results for much shorter periods because in machines without the large heat-absorbing capacity of the oil and with other factors reducing the time constant, the temperatures follow load changes much faster. Mr. Montsinger is correct in his assumption that the eight degree rule has been used for the temperature curves in my paper; the method can, however, be applied for any other value.

Mr. McAuley's discussion gives some very valuable test data on motors. He is entirely correct in stating that the method of my present paper cannot be applied to some enclosed motor ratings. His figures further indicate that the ratio between the rate of temperature drop with the motor running and the rate with the motor standing still is influenced appreciably by such minor design changes as variations in the field strength of the motor. I therefore believe that, in general, the method given in a previous paper prepared jointly with Mr. McAuley will, with some slight modifications, be more suitable for all those load cases where the ventilation or core-loss conditions during the idle periods are considerably different from those during the load periods. The method in this paper was worked out chiefly for use by those who prefer a modified rms method for applications where it will give satisfactory results.

Mr. Alger is correct in stating that part of my paper relates to the application of apparatus rather than to methods of rating. However, my main purpose in going into the methods of application was to point the way toward a rating structure which would permit of simple and correct application of apparatus and conductors. In any intermittent service with wide load fluctuations, the heat-absorbing ability of apparatus is a factor of utmost importance, because without it every load change would mean an instantaneous change in temperature. This is the reason why I have suggested a short-time rating giving an indication of the heat-absorbing ability combined with a continuous rating expressed by a load factor, and also why I have subsequently demonstrated methods for applying such a rating structure. A simple rating structure is of little value if it does not permit of simple methods of application. Unfortunately the present method is not as generally applicable as the one given in the previous paper; however, it has the advantage of being very similar to the conventional rms method and of covering a much broader field than the latter.

Large Electric-Arc Furnaces—Performance and Power Supply

Discussion and authors' closure of paper 41-40 by B. M. Jones and C. M. Stearns, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (July section), pages 763–9.

N. R. Stansel (General Electric Company, Schenectady, N. Y.): The term *large* in the title of the paper is relative with reference to power systems. These vary widely in sizes and methods of service. A large furnace for one system may be a small furnace for another system.

The two functions of reactance in an arc-furnace circuit are: (*a*) circuit stability, and (*b*) limitation of current surges. The first relates to furnace performance; the second, to the voltage regulation of the power system.

As regards furnace performance, the desirable value of reactance is that which gives a satisfactory degree of stability after the initial erratic period of operation, that is, after a certain amount of molten metal is obtained, which means temperature and gas conditions in the chamber which are favorable to the maintenance of the arc. This value of reactance usually corresponds to an average power-factor within the range of 80 to 90 per cent, that is, 60 to 45 per cent reactive voltage drop with the normal current of the arc for a given voltage.

The circuit of an arc-furnace is defined by counting all the reactance and resistance in the conductors from the point in the power system at which the voltage is held constant. The maximum power in this type of circuit occurs at 0.707 power factor. The i^2r loss in the circuit for a given current, subtracted from the power in the circuit, gives the value of the power in the arc. The maximum power in the arc is obtained with a value of current less than the current value which gives maximum power in the circuit.

The value of current, for a given applied voltage, for maximum power in the arc is:

$$i_{\text{opt.}}=\frac{e}{\sqrt{2}x}\sqrt{1-\frac{r}{z}}\ \text{line amperes} \tag{1}$$

e, γ, x, and z phase to neutral values.

The corresponding power-factor of the circuit is obtained from the expression,

$$\tan\phi=\frac{x}{z+r} \tag{2}$$

The value of maximum power is,

$$p_{\text{max.}}=\frac{3e^2}{2(z+r)}\ \text{watts} \tag{3}$$

The resistance of the circuit is, or should be, small in comparison with the reactance. Hence, we can write

$$p_{\text{max.}}\approx\frac{1.5e^2}{x}\ \text{watts} \tag{3a}$$

This approximate expression emphasizes the importance of the value of the reactance of the circuit of an arc-furnace installation.

An analysis of the power system at the point of a proposed furnace installation gives the maximum permissible value of current surges at that point. An analysis of the circuit of the proposed furnace, as outlined by equations 1, 2, and 3 shows the performance of the furnace circuit. These two analyses can be correlated to predetermine the operating results from a proposed installation. The exception is the effect of the frequency of current surges—which can not be predicted—with reference to the class of customers affected, as discussed by L. W. Clark in a paper entitled, "Power Company Service to Arc Furnaces," AIEE TRANSACTIONS, volume 54, 1935 (November section) pages 1173–8.

O. B. Falls, Jr. (General Electric Company, Schenectady, N. Y.): This paper is very timely due to the marked increase in the use of arc furnaces during the past two to three years. Messrs. Jones and Stearns present a study which should be carefully reviewed by all utilities interested in this class of service, with a view towards handling such loads with the least possible delay and at a reasonable cost, when called upon to do so.

The authors point out the multiplicity of data and calculations required to determine the effects of arc furnace loads on power systems. Would not the following be a simple and conservative basis on which to start?

Assume the system connections on which the furnace will be operated most of the time. Then, determine the maximum allowable change in current to give a voltage change which is within the specified limits for the system in question. This step should be quite simple since the necessary information has usually already been prepared for system short circuit studies. The total reactance in the circuit of arc furnaces, below approximately 5,000 kva, is of the order of 50 per cent at the nominal current of the furnace. This means that the maximum current under a short circuit (of the furnace electrodes which may occur during the cold-melt period) will be twice the full load current of the furnace. With these two facts, the full load current rating of the furnace is determined. The maximum power input of the furnace circuit corresponding to this current is at 70.7 per cent power factor. Deducting the I^2R loss in the furnace transformer and connections from this value of maximum power gives the maximum rate of heat development in the furnace. Thus, it is possible to determine the maximum individual furnace load which can be supplied at a given point in the power system.

This method, from one viewpoint, will indicate a furnace load smaller and from other viewpoints a furnace load larger than could actually be tolerated.

The results obtained from the use of this method will depend a great deal on the discretion of those using it in properly taking into account the various factors involved. Its use, however, will help to indicate the order of magnitude of furnace load allowable at any one point in a system. If results obtained are favorable, then a more detailed study, as indicated by the authors, may be justified.

With regard to corrective means, the authors have mentioned only synchronous condensers. This is probably due to the fact that the present conditions of operation indicate that no correction will be required, and further detailed study of this problem was not necessary. It would be interesting to know if any other methods of correction, such as the use of series capacitors, has been considered in connection with this problem. A series capacitor will "balance out" a part of the reactance of the circuit, or can be made large enough to maintain practically constant voltage at any given point in the system, such, for example, as the furnace bus. The series capacitor is a *lumped* reactance, and as such, produces all the voltage rise at its location. Thus, the voltage on the *load* side of the series capacitor is all that is effected. Therefore, the series capacitor would necessarily have to be placed far enough back in the circuit to be at a point where the voltage fluctuations without a series capacitor would not be objectionable.

Since these furnaces are fed by a line tapped in on a 66-kv ring, two series capacitors would very likely be necessary to eliminate voltage flicker at both Valley and Ambridge substations. One would be placed at each substation on the side opposite the source of trouble. The economics, and probably the operating results obtained would quite likely not justify the application of series capacitors in this case. However, it would be interesting to know how the calculated results and costs would compare to other methods of correction.

Along this same line of thought, I would like to point out that a series capacitor has been installed in Chile, South America for just this type of application. The installation, which has been in successful operation for approximately three years, consists of three single-phase units, each rated 115 line amperes, 264 kva, 2,300 volts. The equipment is installed at the present time in a 33-kv three-phase circuit which will ultimately be changed over to 66-kv.

The units are installed at the receiving end of a single transmission line just ahead of the step-down transformer bank. This bank furnishes power for normal city distribution, as well as an arc furnace load. This series capacitor has proven itself quite effective in eliminating voltage flicker on the low voltage side of the step-down bank.

I would like to describe briefly a similar problem in connection with arc furnaces which I have had the opportunity of analyzing.

A certain southern utility served power to a three-phase electric arc furnace by means of a separate feeder direct from the generating plant in order to segregate the voltage flicker caused by the arc furnace load. It was the desire to eliminate this special feeder at the same time that certain other changes were being made in the system.

The problem involved was one of determining from tests made with existing system connections, voltage flicker conditions which might result under future system connections.

Using calculated characteristics of the system, as well as test data, it was found that there were four possible system connections which would result in less than 1.35 per cent voltage variation, with a minimum of approximately 0.9 per cent variation. Since the furnace was operated only at times when one of the four allowable system connections would normally be used, the utility proceeded with work on the changes with the assurance that when these changes were made, and the furnace load changed over to the distribution bus, the results would be satisfactory insofar as light flicker was concerned.

One other interesting result obtained from the study conducted by Messrs. Jones and Stearns is that the diversified operation of the two furnaces results in load swings only 20 per cent greater than obtained by one furnace, and that the frequency of fluctuation of load swings was actually reduced when the second furnace was installed. This would suggest the possibility, from an engineering standpoint, of using two or more smaller furnaces, rather than one larger furnace to meet a given production demand.

S. B. Griscom (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors have performed an outstanding service for power supply companies and electric furnace operators in presenting the co-ordinated data on furnace power loads. Several problems in connection with electric furnace loads have come to the writer's attention recently, and in those cases where the installation was not already in operation there was much indecision as to the proper loads on which equipment application should be made. The authors by presenting graphic charts and oscillograms at sampling intervals throughout a heat have presented a very clear picture of the nature of an electric arc furnace load in all its phases. In addition figures of 15 minute demands, maximum instantaneous three phase swing with power factor change are established for one furnace installation and corresponding figures for simultaneous operation of two furnaces. These figures, of course, apply definitely only to the particular installation, and in using them on projected jobs, intelligent modifications must be made to allow for different ratings, methods of operation, and type of scrap metal.

The writer's principal contact with power supply to electric furnace has been in connection with synchronous condensers for power factor correction or reduction of voltage flicker. For power factor correction the principle item of interest with the usual form of demand billing is the power factor at the peak interval demand. In one case coming to attention, this was 82 per cent as compared to the 85 per cent given by the authors.

For flicker determinations, strictly speaking, the maximum single phase *change* in load with its attendant power factor is of chief importance, since lighting is done at single phase. The authors evidently base their flicker calculations on the three phase load change. This leads to a lower calculated value of flicker voltage than if based on single phase quantities. For example, points 5 and 6, table I show a three phase change of 8,600 kva or 450 amperes per phase. However, phases *A* and *C* each drop about 660 amperes. Considering that the voltage change is 1.15 times as great for a given current from line to line as for line to neutral, the change in voltage based on single phase quantities would be $\frac{660}{450}\times 1.15$ or 1.42 times that based on a load swing of 8,600 kva three phase.

I would be interested in the authors' reasons for adopting the three phase basis. There would appear to be some justification for this procedure following the reasoning given in paragraph 5 under "Results." That is, if the worst swings are to be eliminated because of their infrequency, the use of three phase quantities may be a satisfactory way of doing this. Another factor is the difficulty in obtaining instantaneous single phase currents and power factors as a watt-element oscillograph is about the only available means, and this would require an excessive amount of film.

B. M. Jones and **C. M. Stearns:** Answering Mr. O. B. Falls, Jr., series capacitors were considered but not to the extent of obtaining cost estimates. Service for each furnace was required in so short a time that very little time was allowed for exhaustive engineering research and estimates. In the case of each furnace certain restrictions were required; viz., separate reactance for the first furnace and staggered operation for the second. Fortunately no corrective equipment was required for the first furnace or for the first two. Had corrective equipment been required, we have two 7,500-kva synchronous condensers which could have been "borrowed."

The amount of furnace swing, that the system can stand at the point of connection, has been increased slightly since the first furnace was placed in operation. It will further increase a small amount this summer (1941) when an additional 60,000-kw unit is placed in operation at the Reed station and will increase quite materially in 1942 when the new 60,000-kw unit, near Ambridge substation, is placed in operation. For this reason, and for others, we wished to avoid the installation of corrective equipment if possible.

As has been mentioned, we are to supply service to two more (a total of four) furnaces at this location in the summer of 1941. Our experience with the first two furnaces leads us to believe that voltage flicker will not be too severe with four furnaces. Voltage regulation of course will be worse and voltage regulation, rather than flicker, may require us to install corrective equipment.

For capacity reasons for two more furnaces we are cutting the tap to Pittsburgh Crucible off from the line between Ambridge and St. Joseph lead substation, extending it back to a point across the river from Ambridge and connecting it to the second line between Brunot Island and Ambridge. (See figure 1 in original paper.) This will connect the furnace load at a point nearer the center of the system and allow a greater furnace swing than at the present.

In 1942 a new power station with a 60,000-kw unit will be located across the river from Ambridge substation and the line to Pittsburgh Crucible Steel will be connected to the station bus through an oil circuit breaker.

Answering Mr. S. B. Griscom; we did not stress the single phase change, particularly because there seemed to be considerable discrepancy between the instantaneous current readings obtained from the graphic ammeters and the current calculated from the 3ϕ-kw and *R*-kva readings. For instance, at point 5 on table I (main paper), the average amperes per phase, calculated from the kw and *R*-kva readings was 630, while the average of the ammeter readings was 824.

The observed values of voltage change at the nearest attended substations are not as great as Mr. Griscom indicated they might be, based upon single phase furnace load swings. This leads us to believe that there might be overswinging or some peculiar reaction of the ammeters to rapidly changing loads which differs from that of the kw and *R*-kva meters.

As pointed out by Mr. Griscom, the oscillograph is the only way to get one-phase amperes and power factors. However, as he agreed it is necessary to use a very large amount of film in order to assure obtaining the maximum values which occur during the heat. In addition, without special connections, the one-phase wattmeter element will ordinarily not record true watts because of the incorrect phase angle relation between line amperes and line voltages.

Mr. L. W. Clark presented a very interesting slide showing the maximum size of a three-phase arc furnace which could be connected to the Detroit Edison Company system at locations with varying amounts of short circuit kva. This slide showed a family of curves for various values of allowable voltage flicker. We do not have such curves, but actually apply the principle of the curves for new furnace applications. The short circuit kva at the point where the tap to the Pittsburgh Crucible Steel connects to the system is approximately 500,000 kva. This value was believed too low for connection of a 10,000 kva furnace. We allowed the furnace to be connected with the restrictions mentioned before. The load swings of a furnace are of varying magnitude, the maximum values occurring only a few times during a heat, and as a result the voltage flicker has in no way been objectionable.

In closing we would like to say that we are by no means afraid of electric furnaces and believe that the power companies should encourage this business, but of course feel that the proper method of connecting furnaces to their system should be determined so as to prevent interference with other customers, making necessary reinforcements as required.

We are in hopes that the data presented in the original article and these additional comments might be of some use to others in their furnace application problems.

Rotor-Bar Currents in Squirrel-Cage Induction Motors

Discussion and author's closure of paper 41-1 by J. S. Gault, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941 (July section), pages 784–91.

M. M. Liwschitz (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The paper by J. S. Gault gives a very interesting and valuable picture about the currents in the rotor bars of a squirrel cage motor; it shows the shape of these currents as well as their distribution. The author tries to draw from his tests conclusions on the stray load losses. Unfortunately, the present state of our knowledge does not permit such conclusions.

The currents and the corresponding losses in the rotor bars are due:

1. To the slot openings of the stator.
2. To the step harmonics of the stator.
3. To the phase belt (= band) harmonics.

While the first losses depend on the flux density, the second losses depend on the current. While the first losses increase with increasing slot opening, the second losses decrease with increasing slot opening. The first losses appear at no load, the second and third at load.

In most modern machines these losses are low. The losses under (1) equal 10 to 20 per cent from the total no-load losses and the losses under (2) and (3) are about the same percentage of the total stray load losses. The main part of the stray load losses consists of:

(*a*). The eddy current and hysteresis losses at the surfaces of the tooth crowns.

(*b*). The eddy current and hysteresis losses in the tooth bodies.

Due to the additional currents on the rotor bars very little losses will be in the bodies of the rotor teeth of the squirrel cage motor, but higher losses than in the wound rotor motor will occur in the tooth bodies of the stator. It is well known that the no-load losses of a squirrel cage motor remain about the same when the motor runs with squirrel cage or without squirrel cage. The high frequency currents on the rotor bars force the superimposed flux wave due to the stator out of the rotor teeth and produce additional iron losses in the stator teeth.

In two-pole motors the losses due to the phase-belt harmonics can become considerably high. The influence of these harmonics on a 20-horsepower two-pole motor I have shown in the discussion of the paper by T. H. Morgan, W. E. Brown, and A. J. Schumer (AIEE TRANSACTIONS, volume 59, 1940, pages 1208–09).

R. E. Hellmund (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): In connection with the problem discussed in Mr. Gault's paper, an article which I wrote in 1906 on the subject, "Magnetizing Currents in Polyphase Induction Motors," (*Electrical World*, volume 48, page 329) may be of interest inasmuch as it outlines some of the basic considerations for determining primary and secondary current wave shapes and their higher harmonics caused by the fact that the stator distribution of magnetomotive force is not sinusoidal under the usual assumption that the primary magnetizing current is sinusoidal. Data relating to current wave shapes and higher harmonics in both stator and rotor of single-phase machines are also given in my paper "No-Load Conditions of Single-Phase Induction Motors and Phase-Converters" (AIEE TRANSACTIONS, volume 37, 1918, pages 539–626). Actual test data given in a discussion of the latter paper by A. M. Dudley and C. A. M. Weber may also be of interest. Unfortunately the analytical methods above referred to, as well as those of Mr. Gault's paper, are too complicated to be used in everyday work for determining corresponding losses; nevertheless they are valuable, as are also the tests, in that they indicate to the designer the most favorable arrangements.

In his paper Mr. Gault emphasizes the practical importance of the band-frequency currents and leaves the impression that the tooth-frequency components are of secondary importance. This is correct for the particular motor tested because its primary chording gives a high value to the band-frequency currents, and its slot arrangements minimize the tooth-frequency currents. However, in actual practice very few three-phase motors are designed with the unfavorable two-third or full pitch chording, the majority of them being built with an intermediate value, which, as mentioned in the paper, very materially reduces the band-frequency currents. As a consequence the losses caused by them are in the majority of motors of less importance than in the particular motor tested. Furthermore, many motors, particularly some of the older designs, differ from the one tested in that they are designed with an appreciably greater number of secondary slots than of primary slots. This, together with the fact that the slot bridges of entirely closed slots or tooth tips often become saturated under load and thus bring about a condition approaching that of open slots, tends to materially increase the variations in air-gap reluctance and to increase the tooth-frequency currents. I am therefore confident that the tooth-frequency currents are of greater importance than the band-frequency losses in many designs. I fully agree with Mr. Gault that under some of the conditions indicated above, appreciable losses are caused by high-frequency currents in the rotor.

P. L. Alger (General Electric Company, Schenectady, N. Y.): The test methods and results presented in this paper must be of great interest to every designer of induction motors, because of the clear picture they give of stray load loss phenomena. Although the conclusions reached have been qualitatively known for some time, the quantitative results appear more precise than those heretofore published.

Modern three-phase induction motors normally have windings with a pitch in the neighborhood of $^5/_6$, selected to minimize the belt leakage (or band) harmonics. As the author points out, in reference to figure 20 of the paper, the band frequency losses in this case are much less than for the $^2/_3$ pitch winding used in the test motor. Considering the fifth and seventh harmonics only, the ratio of flux densities is only 27 per cent as great in the former case, for the same value of fundamental flux wave, giving an expected loss ratio of only seven per cent. The test motor also had a slot ratio of 45/48, unusually close to unity, which greatly reduces the tooth frequency losses (at the expense of increased magnetic noise).

In usual motors, therefore, the load losses are due chiefly to the tooth frequency fluxes and associated rotor currents rather than the band frequency currents. At these higher frequencies, the iron losses are relatively greater as compared to the copper losses. Also, the higher flux leakage between rotor and stator windings makes the assumption of a sinusoidal total flux wave highly inaccurate. Hence, considerably more test information is needed for a thorough analysis of the problem.

An important aid in studying these effects is to take oscillographic records of the flux pulsations in a stator tooth, that are produced by the high-frequency rotor currents. Very useful data can undoubtedly be obtained by the author's methods, if they are applied to motors of more usual winding distribution and slot ratios.

J. S. Gault: The discussions submitted indicate careful study of the paper by recognized authorities in this field. For this and the helpful nature of their criticisms I am deeply grateful.

The primary object of the paper was to present oscillographic records of rotor bar current under various conditions, together with a theoretical study of methods for computing the different components. The division of losses found in the case analyzed showed a band-frequency rotor current loss which was about 25 per cent of the total stray load loss at full load. It was not intended that this would indicate a probable average value for other motors, as Mr. Liwschitz implies. It was stated in the "conclusions" paragraph of the paper that this loss was high due to the two-thirds pitch winding employed; and that a change in pitch to five-sixths would reduce this loss to about one-third. This would be in closer agreement with the figures Mr. Liwschitz presented as representative average values. It should also be noted that, for motors with wider phase bands, this component of the stray load loss becomes more important; for example, two-phase and consequent pole windings and many single phase windings.

Mr. Hellmund's remarks concerning the importance of tooth-frequency rotor harmonics are extremely helpful and pertinent. The greater emphasis on band-frequency eddy-current loss in the paper was due to an academic interest in this portion of the subject rather than the study of stray load losses as such. Also the band-frequency effects in the rotor have received less attention in the literature. When the paper was written I had not read the papers referred to by Mr. Hellmund, which contain a masterly theoretical treatment of the subject, especially his paper in the 1918 TRANSACTIONS. I apologize sincerely for the omission from my bibliography of his important contribution.

Mr. Alger's comments are in general agreement with the other discussion. His constructive suggestions concerning the need for additional tests are very helpful in connection with a program along this line which is already under way. Mr. Coho also contributed to the discussion, at the meeting in Philadelphia, some remarks concerning the effect of skew, which indicate the need for further work along this line in order to get a more complete picture.

Overvoltages in Polyphase Induction Motors During Single-Phase Operation

Discussion and authors' closure of paper 41-83 by C. Macmillan and G. K. Carter, presented at the North Eastern District meeting, Rochester, N. Y., April 30–May 2, 1941, and published in AIEE TRANSACTIONS, 1941 (August section), pages 819–23.

L. M. Nowacki (General Electric Company, Schenectady, N. Y.): A number of the mathematical expressions for the stator and rotor voltages given in the paper can be obtained by the use of symmetrical components and equivalent circuit. The main advantage of this method is that it gives a rigorous solution for certain cases, taking into account resistances as well as reactances. The solutions in the paper were based on the assumption that the motor resistances were negligible. The validity of this assumption may be questioned. Therefore a particular motor has been taken and the various voltages calculated both by the formulas and by symmetrical components.

As a result, assurance has been obtained that the assumption of zero motor resistances is justified. The largest error occurred in the calculations of appendix *A*, in the special case of single-phase rotor in a three-phase stator. The error here was less than three per cent. In appendix *B*, in the case of single-phase locked rotor in a single-phase stator, the error was of the magnitude of one-half of one per cent, that is within the accuracy of slide-rule calculation.

The case of the revolving single-phase rotor in a single-phase stator does not adapt itself to the ordinary method of symmetrical components. It has been repeatedly stated by qualified mathematicians that this case has no rigorous solution. However, it is believed that this problem can be solved by the extension of symmetrical components using ladder networks. As the time for the submission of the discussion is limited, it will not be possible to complete the study at present. All that can be offered is a voltage formula arrived at by analogy. This is not exactly a correct technical procedure.

For the purpose of calculation we have taken a wound rotor motor with a one-to-one turn ratio between the rotor and stator. The motor was rated eight-pole, 30-horsepower, 900-rpm, three-phase, 60-cycle, 440-volt.

The following are the motor constants all referred to the stator at line frequency of 60 cycles and are given in ohms per phase *Y*:

Stator resistance	r_1	0.17 ohm
Rotor resistance	r_2	0.22 ohm
Stator leakage reactance	x_1	0.63 ohm
Rotor leakage reactance	x_2	0.63 ohm
Magnetizing reactance	x_m	10.0 ohms
Total external resistance between the two rotor rings	R	ohms
Ratio of turns between rotor and stator	n	1:1
Ratio of rotor frequency to stator frequency	s	
Stator line-to-line voltage	E	440 volts rms
Stator frequency	f	60 cycles
Open-circuit impedance	Z_m	$0.17+j10.63$ ohms

APPENDIX A. SINGLE-PHASE ROTOR IN A THREE-PHASE STATOR

Case I

$r_1 = r_2 = R = 0$

$s = 2$

No external resistance in rotor circuit

The equivalent circuit for a single-phase rotor in a three-phase stator is given in figure 1.

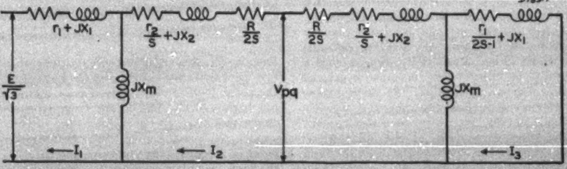

Figure 1

The rms voltage between rings, as obtained from the circuit of figure 1, is

$$E_R = 3sV_{pq} + j\sqrt{3}I_2R/2 \qquad (1)$$

For case I, as stated above, the rms ring voltage is

$$E_R = sV_{pq} = 2\times 358 = 716 \text{ volts (rms)}$$

This corresponds to the formula in the paper for this case

$$E_R = \sqrt{3}B(M_0/L_0) \qquad (2)$$
$$M_0 = x_m/2\pi f = x_m/377$$
$$L_0 = (x_1+x_m)/377$$

Thus

$$M_0/L_0 = 10.0/10.63 = 0.940$$

and

$$E_R = 716 \text{ volts (rms)}$$

Case II

$r_1 = r_2 = 0$
$R = 6.72$ ohms
$s = 2$

External resistance in rotor circuit

This corresponds to $r/X_e = 1.33$ in the paper, the condition for maximum ring-to-ring voltage.

$r = R/2 = 3.36$ ohms
$X_e = (x_1+x_2)s = (1.26)(2) = 2.52$ ohms
$r/X_e = 3.36/2.52 = 1.33$

According to the paper, the rms ring voltage for this case is

$$E_R = (0.940)(440)(2.30) = 950 \text{ volts (rms)}$$

Solving the circuit of figure 1 for this case, $I_2 = 57.2$ amperes and

$$E_R = (3)(2)(1.68+j1.22)(57.2) + j\sqrt{3}(57.2)(3.36) = 950 \text{ volts (rms)}$$

Case III. Same as case I except the value of primary resistance is not neglected. $r_1 = 0.17$ ohm.

Solving the circuit of figure 1, $I_2 = 55.4$ amperes and

$$E_R = (3)(2)(1.73+j1.22)(55.4) + j\sqrt{3}(55.4)(3.36) = 928 \text{ volts (rms)}$$

The difference between the 950 volts of case II and the 928 volts of case III represents the error in neglecting the value of primary resistance. In per cent, the error is

$$\text{per cent error} = 100(950-928)/928 = 2.37 \text{ per cent}$$

APPENDIX B. LOCKED SINGLE-PHASE ROTOR IN A SINGLE-PHASE STATOR

The following are the voltage expressions derived by symmetrical components. Stator phase terminal rms volts:

$$e_a = \frac{E}{\sqrt{3}}\left[\frac{\sin 2\theta}{\dfrac{Z_m+Z_0}{Z_m-Z_0} - \cos 2\theta}\right] \text{rms volts} \qquad (3)$$

Rotor phase terminal rms volts:

$$e_1 = \frac{2E}{\sqrt{3}}\left[\frac{x_m}{Z_m-Z_0}\right]\left[\frac{\sin \theta}{\dfrac{Z_m+Z_0}{Z_m-Z_0} - \cos 2\theta}\right] \text{rms volts} \qquad (4)$$

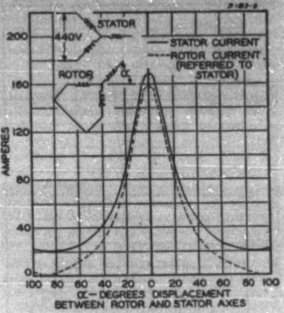

Figure 2. Locked rotor currents

MR444 8-pole, 30-horsepower, 900-rpm, 400-volt induction motor. Three-phase wound stator; three-phase wound rotor. 440 volts—single phase applied to stator. Two rings of rotor short-circuited; third ring left open

The above formulas in terms of the motor constants are:

$$e_a = 254\left[\frac{\sin 2\theta}{1.27-\cos 2\theta}\right] \text{rms volts} \qquad (5)$$

$$e_1 = 508\left[\frac{\sin \theta}{1.27-\cos 2\theta}\right]\times 1.067 \text{ rms volts} \qquad (6)$$

The corresponding equations in the paper can be simplified and put in the following form:

$$e_a = \frac{E}{\sqrt{3}}\left[\frac{\sin 2\theta}{\dfrac{2L_0l_0-M_0^2}{M_0^2} - \cos 2\theta}\right] \text{rms volts} \qquad (7)$$

$$e_1 = \frac{2E}{\sqrt{3}}\,\frac{l_0}{M_0}\left[\frac{\sin \theta}{\dfrac{2L_0l_0-M_0^2}{M_0^2} - \cos 2\theta}\right] \text{rms volts} \qquad (8)$$

where

$$L_0 = (x_1+x_m)/377$$
$$l_0 = (x_2+x_m)/377$$
$$M_0 = x_m/377$$

$$\frac{2L_0l_0}{M_0^2} = \frac{(2)(10.63)(10.63)}{(10.0)(10.0)} = 2.26$$

$$\frac{l_0}{M_0} = 10.63/10.0 = 1.063$$

Thus equations 7 and 8 become:

$$e_a = 254\left[\frac{\sin 2\theta}{1.26-\cos 2\theta}\right] \text{rms volts} \qquad (9)$$

$$e_b = 508\left[\frac{\sin \theta}{1.26-\cos 2\theta}\right]\times 1.063 \text{ rms volts} \qquad (10)$$

Equations 7 and 9 are identical for all purposes; so are 8 and 10. It must be borne in mind that the constant 1.27 in equations 7 and 8, and the constant 1.067 are vectors and should carry an angle. This angle for 1.27 is −3.2 degrees and for 1.067 is −0.5 degree. It is evident from inspection that introducing the angles would in no way change the results calculated on a slide rule.

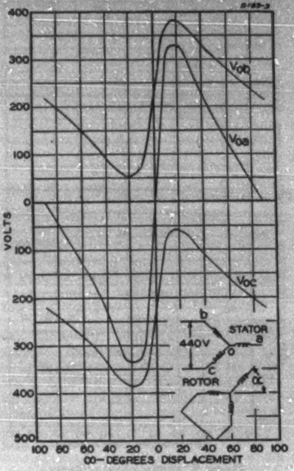

Figure 3. Stator phase voltages

Locked rotor. MR444 8-pole, 30-horsepower, 900-rpm, 440-volt induction motor

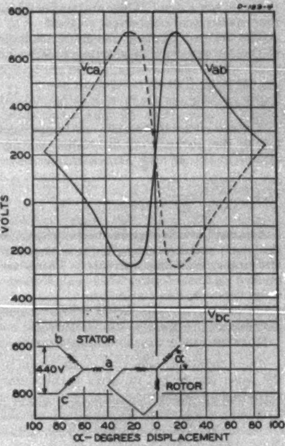

Figure 4. Stator line voltages

Locked rotor. MR444 8-pole, 30-horsepower, 900-rpm, 440-volt induction motor

In the paper the respective maxima for

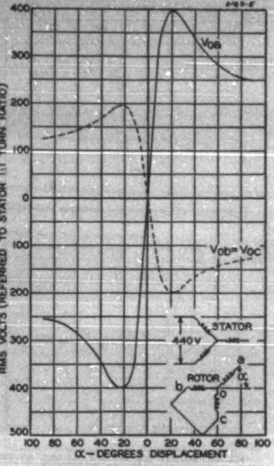

Figure 5. Rotor phase voltages

Locked rotor. MR444 8-pole, 30-horsepower, 900-rpm, 440-volt induction motor

this case are given. They are confirmed by the symmetrical component method.

The rms ring-to-ring maximum voltage to the normal rms ring-to-ring voltage is:

$$\frac{\sqrt{3}Z_m}{4\sqrt{Z_0(Z_m-Z_0)}} \tag{11}$$

The rms stator line-to-line maximum voltage to the normal rms line-to-line voltage is:

$$^1/_2+\frac{\sqrt{3}(Z_m-Z_0)}{4\sqrt{Z_mZ_0}}$$

Attached are five curve sheets, giving all the phase and line voltages, for both stator and rotor, and the currents. These are plotted against degrees electrical displacement between stator and rotor.

Appendix C. Single-Phase Rotor Rotating in a Single-Phase Stator

The maximum value for e_R as given in the paper can be put in terms of the motor constants as follows:

$$eR_{\max}=\frac{\dfrac{\sqrt{3}X_m}{2(Z_m-Z_0)}E}{\dfrac{Z_m}{Z_m-Z_0}-1} \tag{12}$$

Similarly, the stator line-to-line voltage:

$$e_{S\max}=\frac{\dfrac{\sqrt{3}}{2}E}{\dfrac{Z_m}{Z_m-Z_0}-1} \tag{13}$$

From the above, we deduce that the maximum peak ring-to-ring rotor voltage

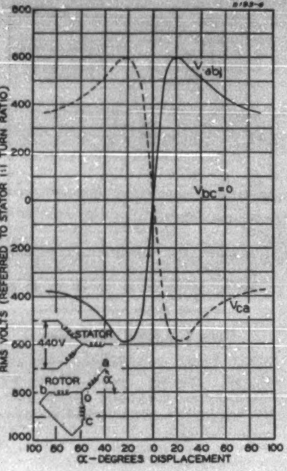

Figure 6. Rotor line voltages

Locked rotor. MR444 8-pole, 30-horsepower, 900-rpm, 440-volt induction motor

to the normal peak ring-to-ring voltage is

$$0.866Z_m/Z_0 \tag{14}$$

And, the maximum peak line-to-line stator voltage to the normal peak line-to-line stator voltage is

$$0.866(Z_m-Z_0)/Z_0 \tag{15}$$

Note that equations 12 and 13 were not derived. They were deduced from the expressions given in the paper for the maximum voltages. They are given as probable solutions.

C. Macmillan and **G. K. Carter:** Mr. Nowacki has presented a discussion which is both welcome and helpful. It is, of course, pleasing to have the numerical checks which he has given, particularly because they were arrived at by a method different from that used in the paper. As was expected, he finds that resistance plays a relatively minor part in those cases in which it could be conveniently taken into account.

An important contribution of the discussion is the presentation of the various equations in terms of the more familiar notation. It is felt that, for practical purposes, this form will be quite valuable. It must be emphasized, however, that the results quoted in appendix *C* of the discussion were not derived by the method of symmetrical components, and so are open to the same objections with regard to resistance as the corresponding expressions in the paper. The remarks made in the paper concerning the effects of the source impedance also apply equally to the method used in the discussion.

In conclusion, the authors wish to point out once more the possibility, under certain circumstances, of dangerous overvoltages on ordinary wound-rotor induction motors and the desirability of avoiding those circumstances if possible.

Photographic Study of A-C Arcs in Flowing Liquids

Discussion and authors' closure of paper 41-92 by Joseph Slepian and T. E. Browne, Jr., presented at the North Eastern District meeting, Rochester, N. Y., April 30–May 2, 1941, and published in AIEE TRANSACTIONS, 1941 (August section), pages 823–8.

H. E. Strang (General Electric Company, Philadelphia, Pa.): We agree with Dr. Slepian and Dr. Browne that information collected in this manner, if properly interpreted, can be of substantial value in the design of circuit interrupters. One would naturally be more impressed if the photographs of power arcs were taken in actual breaker interrupting chambers, although certain fundamental phenomena can no doubt be determined from still pictures of arcs in miniature structures.

No one will venture the prediction that liquid types of circuit breakers have reached the ultimate in perfection. However, in view of the growing interest in air blast types of interrupters, it has been felt that this field offered the greatest promise of substantial results from photographic studies.

An entirely new type of camera[1] was developed expressly for this purpose, capable of taking pictures at the rate of 120,000 per second. One thousand frames are recorded on a film about 4 by 30 inches, and are capable of being enlarged for study, but not arranged for sequential projection. In order to get the greatest benefit from these pictures and to be able to accurately follow the formation and decay of the a-c arc, a transposition camera was developed for transferring these results to a standard 16 millimeter film.

We will exhibit a portion of a film on this subject, showing two typical operations of a cross air blast breaker interrupting about 4,000 amperes at 14,500 volts, and photographed at the rate of 60,000 frames per second. Projected in this way, the time ratio is such that events taking place in one second would require over one hour to show. One side of the arc chute of this breaker is of transparent material, and the outline of the barriers around which the arc is blown is visible. Pictures projected in this ultra slow motion sequence, show clearly the phenomenon occurring at current zero, and have been of great assistance in the development of high capacity station types of cross blast air circuit breakers.

J. Slepian and **T. E. Browne, Jr.:** We wish to thank Mr. Strang for showing the moving pictures of an arc in a circuit interrupter taken at the extraordinarily high speed of 60,000 frames per second. This is a most remarkable achievement, and we can hope that study of these pictures near current zero will help to establish a sound theory of a-c arc interruption.

The rapid gas bubble oscillations which we have found in oil flow interrupters we believe to be of considerable importance in affecting arc interruption performance. We failed to note in our paper that such oscillations in pressure have also been observed in a breaker not of the flow type (R. Rüdenberg, "Wiss. Veröff. d. Siemens-Konzern," volume 2, 1922, page 249). It is possible that in this case due to unbalanced magnetic or other forces, a relative velocity of arc to oil was produced which had the same effect as the oil flow in our case.

The Dielectric Strength of Glass—an Engineering Viewpoint

Discussion and author's closure of paper 41-91 by E. B. Shand, presented at the AIEE North Eastern District meeting, Rochester, N. Y., April 30–May 2, 1941, and published in AIEE TRANSACTIONS, 1941 (August section), pages 814–18.

C. L. Dawes (Harvard University, Cambridge, Mass.): In his paper Mr. Shand has compiled and coordinated a large number of data relating to the dielectric strength of glass and porcelain under different methods of testing and at different rates of application of voltage. He divides breakdown into two general classes, disruptive breakdown when there is no perceptible internal temperature rise, and thermal breakdown when the voltage gradient becomes sufficiently high to cause the temperature of the insulation to rise cumulatively, without further increase in the gradient. Although the phenomena causing breakdown probably cannot be simplified to these two effects exclusively, there is ample evidence that both exist and that in general very short-time or impulse tests are disruptive in their nature and long-time tests to a considerable extent are thermal. The author implies that with thin glass sections disruptive breakdown only occurs since little temperature difference between the interior and the surface can exist. However, Wagner (AIEE TRANSACTIONS, volume 41, 1922, page 290, figure 2) has shown that under proper conditions thermal breakdown can occur in thin sections of glass. In his experiments, thermal breakdown occurred in sections of glass as thin as 0.062 and 0.075-millimeter thickness.

It would be interesting if the fundamental phenomena causing breakdown in glass were better known. There is no doubt that with disruptive breakdown there are intramolecular forces which produce electronic collisions and disintegration of the molecular structure, which is stated in the paper as being "electronic ionization by collision within the molecular structure of the material."

Within solids such as glass it is possible to break the electronic-molecular bonds with field intensities of no greater magnitude than are developed during the usual dielectric-breakdown test. These field intensities are far below those necessary to break the electronic-molecular bonds with isolated molecules. This is due to the fact that in solids, adjacent molecules develop *intramolecular* forces which assist in removing the electrons from adjacent molecules, thus increasing the free electrons. This increases the electrical conductivity as well as making available greater numbers of free electrons to produce ionization by collision. With the isolated molecule the electronic bonds are due to *intermolecular* forces only, and these are so great that they cannot be broken by the field intensities that are obtainable in the ordinary dielectric-breakdown test.

In view of Wagner having obtained thermal breakdown with very thin specimens of glass as well as with other substances, it would be interesting if more data, giving the relation of conductivity of glass to temperature, were available. At molten temperatures glass has sufficient electrical conductivity to conduct currents of power magnitude at moderate voltage. At the temperatures which would be attained during a breakdown test, with the body of the glass relatively cool, to the writer, the degree of electrical conducting that would be attained, together with the relatively short time available, hardly seems sufficient to develop sufficient joule heating to account for thermal breakdown.

There are other phenomena which frequently accompany the dielectric rupture of glass and porcelain, chipping, cracking, and mechanical fracture. These phenomena have been observed by Peaslee (AIEE TRANSACTIONS, volume 35, 1916, page 1187), by Hoover (AIEE TRANSACTIONS, volume 45, 1926, page 983), by Schumacher (*Journal* of the American Chemical Society, volume 46, number 8, 1924). Hoover found that chipping of the walls within the bore of a glass tube was due to corona formation in the oil which surrounded the center electrode. The writer has also observed chipping at the edges of glass specimens when streamers were sufficiently powerful to jump around the edges. The chipping action seems to be in a large measure mechanical, apparently being caused by heavy ions being hurled against the material by the electric field. The effect is quite pronounced when sheets of bonded mica plate are tested. These streamers literally tear or rip the edges of the individual films and ultimately the films themselves away from the plate.

In the paper, edge effect and its influence on breakdown voltage are discussed. Rogowski, by means of conformal mapping, has developed a contour for the edge of the electrode which presumably prevents any increase in field strength due to edge effect (Theory of Functions, R. Rothe, F. Ollendorff and K. Pohlhausen, page 139, Technology Press, Cambridge, Mass.). However, in order that this contour should conform to the theoretical conditions, the electrodes should be immersed in a medium having the same permittivity as the test sample.

J. J. Torok (Corning Glass Works, Corning, N. Y.): Mr. Shand's paper presents a comprehensive picture of the dielectric strength of glass as determined under various conditions and immersed in liquids and gaseous materials. We have found that these values fall pretty well within the limits set up by practical applications. However, in applying glass we very seldom approach the dielectric strength limits. Usually other considerations enter in which demand dielectric thicknesses much greater than the minimum set by the dielectric strength of the media (the glass). A power line insulator application is a very good example. A suspension insulator usually must withstand a working stress of about 10 kv and a flashover stress of 80 to 90 kv rms. Glass, in accordance with the curve in Mr. Shand's paper, would show that thickness of $^1/_{16}$ inch or even less would suffice to withstand this voltage, but an insulator having such a small cross section would be inadequate to meet the service conditions from a mechanical standpoint. Actually, the minimum thickness in suspension insulators is of the order of $^1/_4$ inch or more, and in the skirt, where unforeseen mechanical stresses may be incurred through handling and flying missiles, these sections may be an inch or more. Because of these thicknesses, very high dielectric strengths result. This is substantiated by our service records which show no evidence of a pure dielectric failure. Some insulator failures have occurred, but these have always been preceded by a mechanical breakage, which after it has occurred permits an electrical discharge to take place through the resultant crack in the glass.

Mr. Shand's paper clearly presents the detrimental effect of the presence of oil at high dielectric stresses on glass. The dielectric strength of glass appears to be very much lower in oil than in air. The dielectric strength of a material that is nonporous and chemically inert, such as glass, should not be affected by the media in which it is immersed. The decrease in dielectric strength must then be due to an action occurring within the oil rather than in the dielectric under test. Consideration of some of the fundamentals involved in breakdown shows that the reduction in apparent dielectric strength of the glass is indeed due to an action occurring in oil. Investigators on the dielectric breakdown of materials have pretty well established that the spark formation under oil may take place at speeds of the order of 10^8 centimeters per second. Photographs taken of the spark formation by so-called suppressed discharge means show this discharge to be needle-like formations with quite sharp points, a very small fraction of a millimeter in radius. A streamer of this nature progressing through the oil would be accompanied by the following conditions.

The speed of propagation of this streamer is so great and the viscosity of oil is so great that little or no space charge can be set up in front of the streamers, such as occurs in air. As a net result, the dielectric stress at the tip of the streamer will be of the order of 10,000,000 to 20,000,000 volts per centimeter. A streamer of this nature progressing through a gas such as air would be preceded by a discharge of quite large radius, which would reduce the dielectric stresses well below 100 kv per centimeter. A streamer of this type progressing through oil and suddenly impinging upon a solid dielectric such

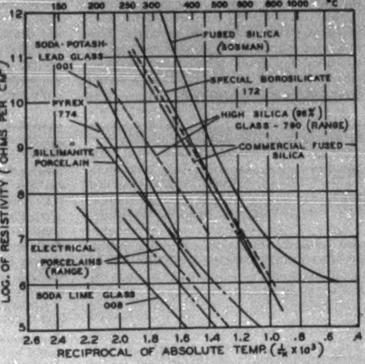

Figure 1. Electrical resistivity of glasses and porcelains at various temperatures

as glass, porcelain, or mica, would set up a dielectric stress within the material of 10,000,000 volts or more per centimeter. This stress is considerably above the dielectric strength of these materials and a puncture or failure in the immediate region where the streamer has struck the solid dielectric is bound to occur. Furthermore, the puncture voltage in this case would be dependent upon the voltage at which the streamer would form in the oil and not upon the dielectric strength of the material.

A few laboratory experiments have shown this to be the case. For example, immersing a suspension insulator in a dry oil, streamer formation started at 115 kv, and as the voltage increased the violence of the streamer action increased and puncture occurred a few seconds later. Moving picture photographs and observations of this streamer action have shown that the streamer gradually bored through the glass and a complete arc was established between the terminals. The puncture itself did not take place at the thinnest portions of the glass where the stress was highest, but in regions where the streamer conditions form first in the oil and then impinge upon the glass.

Treatment of the oil with ionizing liquids, such as some chlorides, permits the applied voltage to be raised to approximately 200 kv without streamer formation and no breakdown of the insulator resulted. However, if the voltage was raised to 220 kv the streamers formed in the oil and the insulator promptly punctured.

The detrimental effects of oil were again clearly demonstrated in the following tests:

> The head of a pin type insulator is cut down and the surface ground and polished so that the thickness of the dielectric between the top of the insulator and the pin hole is only $^1/_{16}$ inch. Another insulator having a dielectric thickness of over one inch is placed in oil. The two insulators are then connected in parallel and the voltage applied. The oil around the insulator started to show signs of distress at 100 kv and the insulator in the oil punctured at 130 kv. The thickness of the dielectric at the puncture point was of the order of one inch. That insulator was then disconnected and the other unit which had only $^1/_{16}$ inch dielectric thickness was raised on up to 175 kv where it flashed over. In this experiment the insulator having a dielectric thickness of only $^1/_{16}$ inch withstood 50 per cent more voltage than did a similar insulator having a one inch dielectric thickness but immersed in oil.

I am emphasizing the detrimental effects of oil in dielectric tests because there are still a number of specifications in use and in the process of formulation which call for testing the dielectric under oil. One such specification is the AIEE 41-A. If the results are used in a proper light they are informative in that they show that the material under test has a dielectric strength that lies above a certain level. The tests cannot say how much better the dielectric strength is than that value because another phenomenon has stepped in and prevented the stressing of the dielectric above that value. Therefore, comparisons between different dielectrics when the samples are immersed in oil should be made with only the greatest care and reservation.

E. B. Shand: Professor Dawes states his opinion to be that dielectric breakdown may be considerably more complex than is indicated by its simple division into the classification of disruptive and thermal failure. The author agrees with this opinion. It is believed that Rogowski first added the hypothesis that disruptive and thermal effects might combine to produce failure, and although recent investigations by Inge and Walther, von Hippel and others seem to discount this hypothesis in favor of the theory that these effects occur singly, the author feels that breakdown data from tests of thicker sections of glass and porcelain tend to give substantial support to the conception of Rogowski; and the paper has been written from this standpoint. Furthermore, the usual type of breakdown of glass and porcelain occurring under oil cannot be considered as either disruptive or thermal under the definitions given in my paper.

Professor Dawes believes that the breakdown of glass, under long-time conditions of test, is to a considerable extent thermal. Various opinions have been expressed on this point (for instance, see J. B. Whitehead, AIEE TRANSACTIONS, volume 55, 1936 (November section), page 1180) and the author feels that available information is not adequate for any precise clarification on this point. It is known, for instance, that the breakdown voltage of a piece of glass tested in vacuo tends to be materially lower than when tested in air—under some circumstances, much lower. Without doubt, this effect is caused by the reduction of heat dissipation from the test sample under vacuum conditions, and would mean that the failure would be largely thermal in character. In air, on the other hand, the corresponding failure might well be essentially disruptive. In the case of the work of Wagner, referred to by Professor Dawes, the conditions of test were widely different from those ordinarily met with in practice, and it is probable that the high-resistance electrodes, instead of dissipating heat from the test sample, actually supplied considerable quantities of heat to it. The values of dielectric strength of glasses as given by Wagner are from one-third to one-half those obtained by various other experimenters for long-time tests which may indicate that the conditions were somewhat comparable to those of tests in vacuo.

Recent tests on the dielectric strength of soda-lime glass reported by von Hippel and Maurer (*Physical Review*, May 1941, page 820), were made on specimens of the same order of thickness as those of Wagner. Thermal breakdown was observed for all temperatures above −50 degrees centigrade. The values given for dielectric strength at room temperature were considerably lower than those of Wagner. This may suggest that here also there was some unusual condition tending to reduce the thermal breakdown strength below that ordinarily obtained, although this is not readily apparent from the description given of the test arrangements.

In answer to the question regarding the conductivity of glass at various temperatures, figure 1 gives the resistivities of glasses over a range of temperatures. The high negative coefficient of resistivity with temperature of insulating materials is readily apparent. Various types of Corning glasses are identified by number. The data on porcelains, both sillimanite and electrical types, have been taken from Riddle ("Ceramic Insulators for Spark Plugs," S.A.E. convention, Detroit, 1940).

The author is indebted to Mr. Torok for his description of the action involved in the breakdown of glass and porcelain under oil. Mr. Torok gives estimates of the magnitude of the intense voltage gradients existing at the surface of the insulation at the point of impingement of the streamers in the oil. Such gradients are greater than the dielectric strength of any known material. The initial failure may occur across only an extremely thin surface layer of the insulation, while complete failure occurs only after a succession of many such surface failures, which becomes observable in the gradual progress of the arc through transparent glass.

Professor Dawes describes this action in terms of a bombardment of the insulation by heavy ions of the oil. He also describes the mechanically destructive effect of this bombardment.

Both Mr. Torok and Professor Dawes concur in the conception that this type of failure represents a breakdown of the ambient oil rather than an overstress of the insulation itself. This is further emphasis on the fact that oil-puncture tests of insulation should be used only with the greatest discrimination, and only with a full appreciation of their true significance. The author voices the hope that standard insulation test specifications will eventually be modified to recognize this condition.

The Determination of Magnitude and Phase Angle of Electrical Quantities

Discussion and author's closure of paper 41-89 by E. A. Walker, presented at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941, and published in AIEE TRANSACTIONS, 1941 (August section), pages 837–9.

C. L. Dawes (Harvard University, Cambridge, Mass.): In this paper Dr. Walker states that unavoidable variation in circuit parameters during a test makes it difficult to obtain a balance with a bridge. This is of course true, but frequently with a little skill a momentary balance may be obtained and the data are those prevailing at the instant of balance. However, the three-voltmeter method described by Dr. Walker is also subject to errors when the parameters vary with time. In order to determine correctly the instantaneous circuit conditions the three voltages must be determined simultaneously. This requires three voltmeters and three observers, who must make simultaneous readings with the fluctuating instruments. When the method is applied as described in the paper to measure the ratio and phase angles of current transformers, three different readings with a single instrument together with the accompanying resistance adjustments are necessary. Obviously, under these conditions, steady conditions in the circuit during the entire measuring interval are necessary for precise results.

The method shown in figure 2, in which a voltage E_2', 180 degrees out of phase with E_1 is used to close the polygon of voltages, is inherently inaccurate. For example, E_2' must exceed E_2 in magnitude and in figure 2 its value is about twice that of E_2. A study of the figure shows that if E_2' departs by a very small angle even from the 180 degree relation with E_1, a considerable percentage error in E_3 and in the supplement of the angle between E_1 and E_3 will occur. This same large error will therefore occur in the angle θ. A precise 180 degree relation obtained by using windings on the same transformer core, connected oppositely, is difficult to obtain without some precise compensating means. The author recognizes this difficulty and states that it will be discussed later in the article. I do not find this discussion.

The same difficulty in the matter of precision occurs in figure 3. A small departure of E_1 and E_2 from the 180 degree relation will introduce a substantial error in the angle δ, the angle of defect. Also a study of figure 3 shows that the method of balance is far from being critical. That is, I_1 can be changed considerably in magnitude without changing very much the value of I_D. However, since I_D is measured directly by the instrument D, the fact that the balance is not critical affects only the value of I_1, and not the value of the angle of defect δ, since I_1 does not enter directly in the computations.

As Dr. Walker states, however, the methods which he describes are quick and simple and under suitable conditions results sufficiently precise for many purposes can be obtained.

Eric A. Walker: Professor Dawes states that it is possible to make a momentary balance on a bridge if the device being tested is not stable. He infers that since there are three instruments to read, the same problem would be very much more difficult by the method described. This is not true.

Consider the three readings necessary for the determination of the capacitance and power factor of a condenser. The first reading is the line voltage which is maintained at a constant value. The second is the in-phase component of current which might vary from two per cent to four per cent. This variation of the in-phase component will not change the total current appreciably since the two add vectorially. So it can be said that in the practical application of the method only one reading will fluctuate and the balance is relatively easy.

Furthermore, if one is merely checking the power factor of a lot of standardized parts it is only necessary to vary C through the balancing range and make certain that I_D falls below the tolerance limit.

To check the angle between the two voltages E_1 and E_2 it is desirable to replace the unknown condenser C_x by a no-loss air condenser. If the two voltages are not exactly 180 degrees out of phase a zero reading cannot be obtained on the detector. There are two methods of overcoming this difficulty. One is to draw a correction curve of residual current I_D as a function of the total current I_1 and subtract this from the actual reading. A second method is to put a corrective network in the standard condenser circuit. This solution is not entirely satisfactory because no single network will serve for all currents and all voltages.

The fact that the balance is not a critical one is an advantage rather than a disadvantage. It must be remembered that the position of the dial on C_s is not important. The quantity to be measured is the smallest attainable value of current I_D and because the balance is not sharp this value is easily read which considerably reduces the possibility of making an error. Such a quality is of considerable importance in a field instrument.

Surge Characteristics of Two-Winding Transformers

Discussion and author's closure of paper 41-85 by Reinhold Rüdenberg, presented at the AIEE North Eastern District meeting, Rochester, N. Y., April 30–May 2, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1136–44.

L. V. Bewley (Lehigh University, Bethlehem, Pa.): In this very interesting paper Dr. Rüdenberg has introduced a number of simplifying assumptions which have allowed him to reduce the problem of transformer surges to that of a pair of no-loss transmission lines, of which his four differential equations 17 and 19 are the specifications. I must take exception to his method of solution of these equations, which leads to erroneous results. His equation 29 was arrived at by utilizing only two of the four differential equations, and he then states, "Since this relation is valid for any value of i_1 and i_2, both the sides must disappear independently of each other." This, I think, is the crux of the matter—i_1 and i_2 are *not* independent, they are very definitely related in this mutually coupled circuit, and to find this relationship all *four* differential equations must be invoked.

Before proceeding to do so, let us consider an exactly analogous case of the lumped circuit shown in figure 1. The differential equations of this circuit, corresponding to Dr. Rüdenberg's equations 17 and 19, are:

$$e_1 = L_1\frac{di_1}{dt} + M\frac{di_2}{dt}$$

$$e_2 = L_2\frac{di_2}{dt} + M\frac{di_1}{dt}$$

$$\frac{de_1}{dt} = P_1 i_1 + G i_2$$

$$\frac{de_2}{dt} = P_2 i_2 + G i_1$$

where

$$\begin{aligned} P_1 &= (C_2 + C_3)/(C_1C_2 + C_2C_3 + C_3C_1) \\ P_2 &= (C_1 + C_3)/(C_1C_2 + C_2C_3 + C_3C_1) \\ G &= C_3/(C_1C_2 + C_2C_3 + C_3C_1) \end{aligned}$$

Now if we disregard the second equation in each line—as Dr. Rüdenberg did in arriving at his (29)— we can differentiate the first, equate the second, and rearrange as follows:

$$L_1\frac{d^2i_1}{dt^2} - P_1 i_1 = -M\frac{d^2i_2}{dt^2} + G i_2$$

and this corresponds exactly to (29) of the paper. Applying the same argument—that i_1 and i_2 are independent, etc.—we would arrive at solutions for the natural frequencies of

$$\omega_1 = \sqrt{\frac{P_1}{L_1}} \qquad \omega_2 = \sqrt{\frac{G}{M}}$$

But these are *not* the true solutions for this circuit! Solving this circuit by utilizing all *four* differential equations (for example, by using three of them to eliminate e_1, e_2, i_2 and then writing the solution for i_1) we find for the actual natural frequencies

$$\omega^2 = \frac{(L_1P_2 + L_2P_1 - 2MG) \pm \sqrt{(L_1P_2 + L_2P_1 - 2MG)^2 - 4(L_1L_2 - M^2)(P_1P_2 - G^2)}}{2(L_1L_2 - M^2)}$$

The two frequencies represented by this equation reduce to ω_1 and ω_2 given above for the special case $P_1/L_1 = P_2/L_2 = G/M$, but this certainly is not the general solution, and results only by a special selection of circuit constants.

Let us now obtain the actual solution of Dr. Rüdenberg's problem. Instead of in-

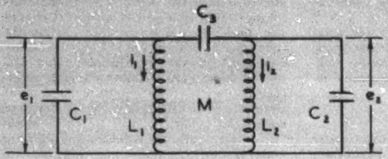

Figure 1

troducing two space parameters x_1 and x_2 along the high voltage and low voltage windings respectively, it is simpler and more straightforward to use but a single space variable x as the axial distance along the winding stack. Then instead of equations 17 and 19 of the paper we have:

$$-\frac{\partial e_1}{\partial x}=l_1\frac{\partial i_1}{\partial t}+m\frac{\partial i_2}{\partial t}$$

$$-\frac{\partial e_1}{\partial t}=p_1\frac{\partial i_1}{\partial x}+g\frac{\partial i_2}{\partial x}$$

$$-\frac{\partial e_2}{\partial x}=l_2\frac{\partial i_2}{\partial t}+m\frac{\partial i_1}{\partial t}$$

$$-\frac{\partial e_2}{\partial t}=p_2\frac{\partial i_2}{\partial x}+g\frac{\partial i_1}{\partial x}$$

in which now (not the same as given in the paper) $l_1=L_1/h$, $l_2=L_2/h$, $m=M/h$, $p_1=hP_1$, $p_2=hP_2$, $g=hG$, while L_1, L_2, M, P_1, P_2, G have the same meaning as in the paper; that is, are the constants for the entire winding. If we use y to represent any one of the four quantities e_1, e_2, i_1, i_2, then upon eliminating the other three between the four differential equations given above, there results:

$$\frac{\partial^4 y}{\partial x^4}-\left(\frac{l_1p_2+l_2p_1-2mg}{p_1p_2-g^2}\right)\frac{\partial^4 y}{\partial x^2\partial t^2}+\left(\frac{l_1l_2-m^2}{p_1p_2-g^2}\right)\frac{\partial^4 y}{\partial t^4}=0$$

This equation is satisfied by the wave functions $f(x+vt)$, if

$$v^2=\frac{(l_1p_2+l_2p_1-2mg)\pm\sqrt{(l_1p_2+l_2p_1-2mg)^2-4(l_1l_2-m^2)(p_1p_2-g^2)}}{2(l_1l_2-m^2)}$$

which has exactly the same form as the frequency equation given previously for the simple lumped circuit of figure 1. If the values of L_1, L_2, M, P_1, P_2, G, be those given in the paper of Dr. Rüdenberg by his equations 33, 35, 37, 39; then the velocity equation as given above, after some algebraic manipulation, takes the form

$$v^2=\frac{v_0^2}{\mu\epsilon}h^2\times\left[\frac{(a_1^2+a_2^2)-2a_1a_2(b_2d_1/b_1d_2)\pm(a_1-a_2)\sqrt{(a_1+a_2)^2-4a_1a_2(b_2d_1/b_1d_2)}}{2a_1^2a_2^2(1-b_2d_1/b_1d_2)}\right]$$

If the ratio $(b_2d_1/b_1d_2)<1$ may be neglected, the axial velocities become

$$v_a=\frac{v_0}{\sqrt{\mu\epsilon}}\,\frac{h}{a_1}\text{ and }v_b=\frac{v_0}{\sqrt{\mu\epsilon}}\,\frac{h}{a_2}$$

agreeing with equations 32 and 41 of Dr. Rüdenberg's paper; but now appearing in their proper light as approximations of the true axial velocities. If the proportions of the transformer are such as to permit this approximation, then the rates at which the multi-velocity electromagnetic field sweeps the conductors of the high voltage and low voltage windings are:

$$v_1\cong\frac{a_1}{h}\quad v_a=\frac{v_0}{\sqrt{\mu\epsilon}}$$

$$v_1'\cong\frac{a_1}{h}\quad v_b=\frac{v_0}{\sqrt{\mu\epsilon}}\,\frac{a_1}{a_2}\text{ for the high voltage}$$

$$v_2'\cong\frac{a_2}{h}\quad v_a=\frac{v_0}{\sqrt{\mu\epsilon}}\,\frac{a_2}{a_1}$$

$$v_2\cong\frac{a_2}{h}\quad v_b=\frac{v_0}{\sqrt{\mu\epsilon}}\text{ for the low voltage}$$

The expression v' is not to be construed as a velocity exceeding the velocity of light; it is merely the velocity of shear of the axial field as it cuts the conductors of the high voltage winding.

It will be observed that the above method of analysis gives all the results directly, and the limits within which approximations are permissible are defined. The analysis of section 4 of Dr. Rüdenberg's paper would lead one to suppose that there are two mathematical velocities in each winding and that all four of these are physically equal. Later on, in section 6, he admits an interaction between windings, discusses the physics of it, and concludes after all that each winding has one wave traveling at the velocity of light, and another induced wave following the axial field set up by the other winding. This concept appears as an approximation in the light of the analysis given in this discussion.

It should also be remarked that each wave has its own surge impedance, rather than the simple "single-conductor" surge impedances given in the paper.

I wish also to point out an error in the table comparing calculated and measured results. The calculated voltages are values of

$$\frac{e}{E}=\frac{\text{transmitted voltage}}{\text{traveling wave voltage}}$$

and as seen by equation 51 of the paper the line terminal voltage is taken as $2E$, due to the doubling by reflection. But in the case of the oscillograms shown in the closing discussion of the paper by Palueff and Hagenguth, the low voltage terminal voltage was 30 per cent of the high voltage *terminal* voltage, or only 15 per cent of the traveling wave voltage. Thus, there is in this case a 2:1 discrepancy between calculated and measured values.

R. Rüdenberg: Professor Bewley suggests in his discussion another kind of analysis than that of the paper, namely the well-known d'Alembert method, and he applies this analysis to another problem, as shown by his differential equations and his definitions of constants, both deviating from those of the paper. I doubt if for the problem treated in my paper this is the simplest method of arriving at a practical solution in a straightforward manner, particularly in view of the fact that Mr. Bewley has omitted in the discussion all his cumbersome intermediate calculations.

The conditions 26 and 28 of the paper under which my relatively simple solution is derived, and which Mr. Bewley apparently has overlooked, are rigorously fulfilled by the constants of any transformer with homogeneous electromagnetic space, such as are derived in section 5. This is proved by the considerations leading to equation 41. For slightly heterogeneous space such as in many actual transformers these symmetry conditions are very nearly fulfilled, as can be shown by applying appropriately to the two-winding case the viewpoints of section 3 of the paper. The need for publishing a more detailed but much more complicated solution is therefore not particularly great, although I am always in favor of refining a problem—if it is once solved in principle.

In my opinion it is often not advisable to use for the first attempt at clarification of a complicated problem, such as the performance of traveling waves in two-winding transformers, highly involved mathematical methods. I personally prefer to approach such problems by simplified conceptions as a guidance to the physical understanding. In the solution of engineering problems there is always the necessity for many approximations and omissions. It is a matter of intelligent choice which of them one will make in order to secure a simple but characteristic analysis. In the present case the simplification stressed by Mr. Bewley is not by any means the only one and is not even the most important one with respect to the wave velocities.

An Improved Frequency Meter for Commercial Power Frequencies

Discussion and author's closure of paper 41-108 by K. J. Knudsen, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 866–9.

B. E. Lenehan and **L. J. Lunas** (Westinghouse Electric and Manufacturing Company, Newark, N. J.): The self-contained, low energy frequency meter developed by Mr. Knudsen is a desirable contribution to the art. We are interested in the statement regarding resistance changes of the coils being responsible for errors due to ambient temperature change. The instrument utilizes a parallel resonant circuit with the difference in current of the inductance and capacitance branches flowing through the

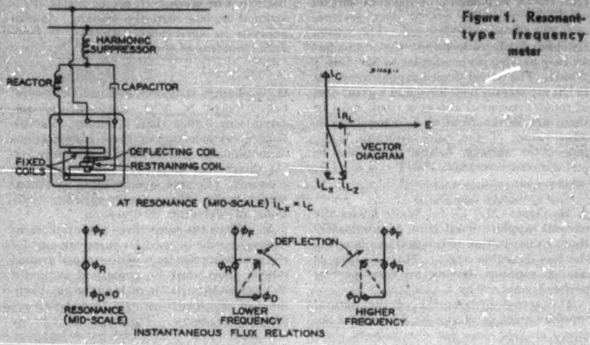

Figure 1. Resonant-type frequency meter

deflecting coil producing torque. Since the resistance component is in phase with the voltage and lags the capacitance component 90 degrees and leads the inductance component 90 degrees, no torque is set up by this component. Thus any change in resistance should produce no error in indications. The Westinghouse Company has built a frequency meter for a number of years utilizing a parallel resonant circuit with a conventional air core electrodynamic mechanism in which resistance changes produce no errors in indications. We wonder if the iron core mechanism might contribute to such errors.

The harmonic error mentioned might readily be reduced by introducing a series reactor of the proper value to suppress such higher frequencies. Such a reactor is included in the instrument shown in figure 1 of this discussion. In this way the influence of harmonics has been reduced to about one twentieth the value. For narrow frequency range instruments such suppressors are particularly effective. This suppressor might of course be omitted for the purpose of obtaining a self contained instrument.

A. J. Corson (General Electric Company, West Lynn, Mass.): It is interesting to note that, while modern frequency meters of various makes differ considerably in structural detail, they practically all operate on the same basic principle. This may be stated as a combination of an alternating current ratio meter and one or more impedance networks for obtaining the particular current-frequency relationship which this ratio meter requires. In this respect, the instrument described by Mr. Knudsen is similar to instruments now in use.

It would appear that the inductor-capacitor arrangement used in this instrument is open to serious question with respect to its susceptibility to wave form errors, due to suppression of harmonics in the inductive circuit and accentuation of the harmonics in the capacitative circuit. This is substantiated by figure 5 which shows very considerable errors given for the rather optimistic service conditions which have been assumed. It would appear that very distinct improvement could be obtained by using two parallel resonant circuits, with resonant points at say 45 and 75 cycles. The admittance of these two circuits for the third and higher harmonics of a 60-cycle fundamental will be very nearly the same with consequent elimination of the wave form error.

The paper as a whole appears to be rather general in character, lacking information as to values of torque gradient, mechanical factor of merit, damping, response time, and other criteria of the design. It is hoped that this information will be supplied by the authority, in closing the discussion.

K. J. Knudsen: As Messrs. B. E. Lenehan and L. J. Lunas point out, resistance changes in the deflecting coil will not alter the indication of the instrument. It should, however, be realized that the current in the inductive circuit does not lag behind the line current by 90 degrees due to the resistance of the field coils and the restoring moving coil; also the calibrating resistor in the capacitive circuit causes the current to lead by less than 90 degrees. This may be more clearly seen by studying figure 2 of this discussion, which is based on the formula: cos $\phi = R/Z$, ϕ being the angle of lag or lead, R is the ohmic resistance of the circuit, and Z the impedance. The magnitude of the current vector is V/Z, V being the voltage across the circuit.

The angle ϕ_1 is the resultant phase angle of the current in the deflecting moving coil, which causes no deflection, this current being 90 degrees out of phase with the magnetic field. ϕ_2 is the phase angle caused by increasing the ohmic resistance in the field coil circuit 25 per cent, and ϕ_3 is the phase angle necessary to maintain no torque relation in the deflecting moving coil. Actual tests show that by changing the resistance of the field circuit ten per cent the deflection changes 0.2 cycle, all other component parts being unchanged.

While it is true that connecting an inductance in series with the line greatly reduces the effect of wave form errors, it should be realized, that in so doing the voltage across the effective circuit is reduced by 80 per cent approximately, with a corresponding reduction in mechanical factor of merit, if third harmonic errors are to be reduced 20 times. The power factor of the complete instrument would at the same time be reduced to 20 per cent.

When a low power precision instrument is desired, it would be advisable to use a series tuned circuit in series with the line. The inductance having an impedance of 20 or more times the impedance of the frequency meter in this case, the impedance introduced would be no more than the ohmic resistance of the inductance at the reference frequency, and the power factor remain near 100 per cent.

Whenever iron core chokes are used, care should be exercised in order to prevent third harmonic distortion of the voltage wave due to high saturation of the core. The actual circuit used for calibration is shown in figure 3 of this discussion, it will be noted that an air core choke has been used. The choke has an inductance of 0.8 henry and a resistance of 15 ohms.

With respect to Mr. Corson's comments, it should be noted that the paper as far as basic principle of design is concerned does not claim a new circuit, in fact it appears to be the same as that shown in figure 1 of Messrs. Lenehan and Lunas' discussion. The new thing about it is the elimination of an external reactor in the tuned field circuit and a greatly decreased power consumption.

It is seen from figure 5 of the paper that a

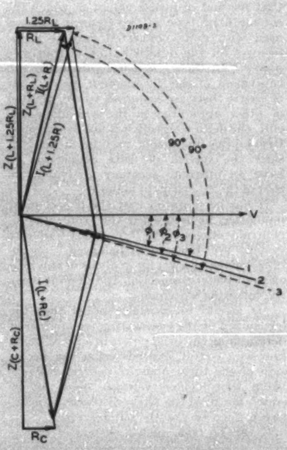

Figure 2. Vectorial diagram—current and impedance relation

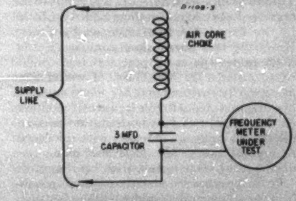

Figure 3. Diagram showing series-tuned harmonic eliminator

15 per cent third harmonic distortion is permissible before the consequent error exceeds 0.1 cycle, and as I have yet to see a commercial power circuit with a third harmonic voltage component greater than 15 per cent, I am in doubt as to the seriousness of the error. Should such a circuit be encountered, it would be a simple matter to insert a choke or a series tuned circuit in series with the line, as previously discussed. As far as a double tuned field is concerned it is possible that lower errors would be found. It would however be necessary to use two capacitors and considerably greater difficulty would be encountered in calibration, it is also possible that temperature errors would be difficult to eliminate because one circuit is operated on the high side of the peak and the other on the low side.

I am sorry that I forgot to add the vital data pertaining to criterion of design and I make amend by stating them here. On a five-inch instrument, which was at hand for tests the results were as follows:

Restoring torque at center of scale (point of lowest restoring torque): 0.01425 millimeter-gram per degree.

Weight of moving element: 1.02 gram.

Torque to weight (in $1^{1}/_{2}$ power) ratio: 1.25 for full scale deflection. Torque in this case considered uniform and same as at center of scale. Units being millimeter-grams, 90 degrees and grams.

Period: 1 second.

Damping factor: 5.2, this can be changed at will by increasing or decreasing the thickness of the damping vane.

Response time: 1.7 second.

The instrument indication changed 0.03 cycle at 60 cycles after 50 hours of vibration at 1,800 vpm. Test as described in SQ-78-A section IV-11.

It is my hope that the closure is satisfactory to the gentlemen who have shown interest by discussing the paper, for which interest I am grateful.

Effect of Sapphire-Crystal Orientation on the Wear of Watt-Hour-Meter Bearings

Discussion and author's closure of paper 41-106 by J. H. Goss, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (August section), pages 811–14.

G. G. Waite (Sangamo Company Limited, Toronto, Ontario, Can.): It is perhaps to be regretted that Mr. Goss has added so little to the knowledge first reported by Stott. However, this paper does confirm Stott's work under the more practical test conditions outlined by Mr. Goss. I would like particularly to commend Mr. Goss's use of his diagram 1. All too frequently writers on the subject of jewel orientation merely manage to confuse the reader with reference to crystal axes. Mr. Goss has made the matter very clear indeed with his diagram.

It is impossible to cut oriented jewels from small natural sapphire pebbles because of the cost of determining the optical axis for each small pebble. I think, however, the fact, that a very high proportion of natural sapphires will turn out to have θ = zero, should have been mentioned. The reason for this is easily understood. Corundum has an easy parting perpendicular to Mr. Goss's *C* axis. The barrel shaped sapphire crystals in the old stream beds have had a great deal of rough treatment and as a result most of them are in the form of hexagonal plates when found. These, quite naturally, in the process of cutting, orient themselves to give θ = zero.

J. H. Goss: Mr. G. G. Waite states the natural sapphire jewel cups predominately show a distribution of orientations favoring the less desirable angle. This, he says, is due to sapphire having an easy parting perpendicular to the *C* axis.

The actual distribution of the natural sapphire cups as shown by figure 4 for the group studied does not conclusively show this. As far as I am able to determine, sapphire has no desired plane of cleavage or parting and is listed as having a conchoidal fracture.

Relative Accuracy of Three-Phase Metering Combinations

Discussion and author's closure of paper 41-125 by C. T. Weller, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (October section), pages 925–9.

Perry A. Borden (The Bristol Company, Waterbury, Conn.): It is noted that the author of this paper makes no reference to that method of measurement in which the conventional type of two-element meter is used with delta connected current transformers for the determination of four-wire power. In theory at least this is the full equivalent of the $2^{1}/_{2}$-element meter; but of course there are instances where, because of other apparatus in the secondary circuit, the delta connection is not permissible. Beyond this limitation, does the author consider the system of delta connection to have an inherent accuracy equivalent to that of the $2^{1}/_{2}$-element meter?

It has been stated that the $2^{1}/_{2}$-element meter may be used where the "three line-to-neutral voltages of the three-phase four-wire system are fairly well balanced." Stubbings[1] gives us a vector analysis of the $2^{1}/_{2}$-element meter connection and upon it bases the following statement:

"It should be carefully noted that the legitimacy of the two-wattmeter method of determining the total power in a three-phase four-wire circuit depends upon the vector sum of the three phase-to-neutral voltages being zero. These voltages need not be equal, nor need the phase displacements between them be exactly 120 degrees."

If this be true, such a system of metering four-wire loads need not be nearly so restricted as has been the custom. Is this analysis in agreement with Mr. Weller's understanding of the problem?

G. S. Lunge (General Electric Company, Schenectady, N. Y.): Some of the considerations, other than accuracy, that influence the selection of these combinations of meters and instrument transformers are: (1) directional ground relaying needs, (2) economy, (3) safe operation of potential transformers, (4) previously existing conditions, (5) detection of diversion.

1. When the same three potential transformers are to be used for metering and for the polarizing windings of directional ground relays, they must be connected grounded Y-Y even though there may be no likelihood of any line-to-neutral loads being applied to the circuit. This may result in the selection of cases 5 or 6, with potential transformer primary neutral grounded in each case. The relay windings would be connected in the corner of the broken delta secondary winding of a grounded Y-broken delta connected assembly of three auxiliary potential transformers, connected to the secondary windings of the main potential transformers (figure 1 of this discussion).

2. In the case of high voltage circuits, economy may dictate the use of three single bushing potential transformers with primary neutral connection grounded, rather than two potential transformers, each with two bushings and designed for line-to-line connection. This might result in the selection of cases 4, 5, or 6, with grounded potential transformer primary neutral.

3. Unless the potential transformers are suitable for the connection contemplated, their safety may make it impossible to use cases 4, 10, or 13, with the potential transformer primary neutral grounded in each case. For these three connections to be safely usable, the potential transformers must be designed with low flux density at line-to-neutral voltage, to the extent of being suitable for line-to-line connection permanently without damage. The turn ratio of such potential transformers would, of course, not be suitable for line-to-line connection, since for use with two and one-half-element or three-element meters the potential transformer turn ratio must be such as to give 115 volt secondary voltage when the potential transformer is connected from line-to-neutral of the primary circuit. Except in the case of high-voltage potential transformers of very recent manufacture, this condition of exceptionally low-flux density may not necessarily be met.

4. Previously existing conditions may make it logical to adopt a combination giving less than the highest grade accuracy, e.g., cases 2 or 3 on systems to which ground-fault neutralizers have been added.

5. To prevent diversion of energy, it may be advisable to select cases 8, 11, or 14 in order that there may be a current transformer in each primary lead of the circuit. Thus even when only the neutral of the source is grounded, and not that of the load, this consideration may require resorting to a two and one-half-element or three-element meter, with corresponding instrument transformer connections, in preference to the combinations of cases 2 and 5.

Circuits to be grounded via ground-fault

---

[1] COMMERCIAL A-C MEASUREMENTS, G. W. Stubbings. D. Van Nostrand Company, 1930, chapter 2, pages 38 and 39.

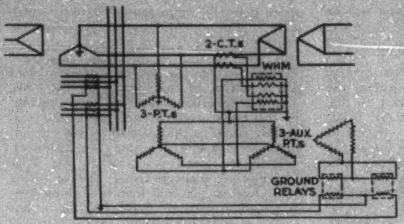

Figure 1 (Left). Joint use of Y-Y potential transformers for metering and ground relaying

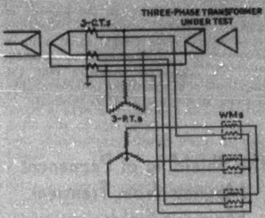

Figure 2 (Right). Proposed ASA recommended connections for measuring three-phase transformer excitation loss

neutralizers must have been: (*A*) formerly operated with isolated neutral, (*B*) formerly operated with grounded neutral, (*C*) built initially for operation with ground-fault neutralizer neutral grounding.

A. For this group, the existing metering will undoubtedly be on a three-phase three-wire basis, using either two-element or, in rare instances, three-element meters, depending on the degree of accuracy required when very low power factor loads are to be metered. No change in meter equipment or performance should be involved.

B. Solidly or low impedance grounded neutral circuits may have been metered as case 2, i.e., three-phase three-wire metering. If so, no change will be necessary. If, however, the circuit was metered as a three-phase four-wire circuit, a two and one-half-element or three-element meter will have been used. For important loads, undoubtedly the three-element meter would have been used originally (case 14), and no change will be necessary. If two and one-half-element meters were used, these should be changed to the three-element type.

C. For this situation, this paper rightly advocates the use of three-element meters, with three potential and three current transformers, though, except for very low power factor loads, comparable accuracy can be obtained with two-element meters connected to two potential transformers and two current transformers. Energy diversion detection need not be considered, for line-to-neutral single phase loading is not feasible when neutral impedance as high as that of a ground-fault neutralizer is involved.

In applying information in this paper to cases involving indicating or recording wattmeters, it should be borne in mind that they are not available in three-element types, so that the choice lies between two-element and two and one-half-element instruments.

Special considerations may outweigh other factors governing the selection of an appropriate metering combination. Case 10, with isolated potential transformer primary neutral (figure 2 of the discussion), is generally considered preferable for low power factor circuits such as are encountered in the measurement of transformer excitation losses (see clause 10.088 of proposed ASA transformer test code C57.2). Were the potential transformer secondary and instrument potential circuit neutrals to be interconnected, the instrument potential coils would be subjected to voltages containing a prominent third harmonic voltage which is not necessarily present in the system line-to-neutral voltage but is impressed upon the meter simply due to the instrument transformer connections. Case 7 could be used with equal accuracy instead.

It is only very rarely that the same set of potential transformers will be used both for ground detection purposes and for metering. However, as in cases 4, 5, and 6, it is possible to use the line-to-line secondary voltages of three such line-to-line voltage rated Y-Y connected potential transformers for two-element meters.

C. T. Weller: The subject of metering accuracy is a broad one, so much so that a paper on but one phase of it must omit much interesting and pertinent material if a reasonable length is to be achieved. That such is the case with the present paper is evident from the discussions of it since it was first proposed. It might be in order, therefore, to outline briefly some of the underlying ideas.

In a paper presented in 1930 (reference 1), the author dealt with the Y-connection of potential transformers from the operating standpoint; metering problems were not discussed. The need for a supplementary paper written from the standpoint of metering accuracy was not recognized until recently, when it became apparent that some effects of the Y-connection on the metering accuracy were not fully appreciated. A similar lack of appreciation has long been evident with respect to some of the so-called "secondary interconnections" of instrument transformers and watthour meters. This accounts for the emphasis in the paper upon potential-transformer connections and upon secondary interconnections. However, no such need was apparent with respect to current transformers, so these are dealt with only in their simplest form.

The primary object was to summarize in one table appraisals of several three-phase metering combinations under various conditions from the accuracy standpoint. In order to present a general picture, the appraisals are in general terms, for which relative accuracy was chosen, using the best metering practice as a standard of reference. The table nominally contains 17 cases, but six of these are double while two are appraised in the accompanying text, thus making a total of 25 cases; these should be sufficient to illustrate the basis of grading used and thus make possible its extension to other cases not included in the paper. The impracticability of estimating the metering accuracy to be expected in the 25 cases will be appreciated by those who have attempted to make such estimates for actual installations, where it is often difficult to obtain sufficient information for the purpose; some apparently minor details may considerably affect the result. Paraphrasing an old saying, it might well be pointed out that "Too many hedges spoil the summary."

Explanations of the purposes for which the several combinations are used or proposed and of the theories underlying some of the phenomena mentioned were deliberately omitted from the text to emphasize the subject of metering accuracy as well as to conserve space. The schematic diagrams in figure 1 of the paper represent an attempt to combine voltage-vector diagrams with straight-forward connection diagrams having no conductor cross-overs.

In his discussion, Mr. P. A. Borden mentioned the omission from the paper of the metering combination consisting of a two-element meter and three delta-connected current transformers for a three-phase, four-wire system; the omission has been explained. This combination must be assigned relative-accuracy grade C, because of the current-transformer interconnections, thus bringing it definitely below the two and one-half-element combination, which shares with it the uncertainty as to the one unmeasured phase voltage but is otherwise more straightforward. This unmeasured phase voltage will, of course, be correctly represented whenever the vector sum of the three line-to-neutral voltages is zero as Stubbings has pointed out. However, what assurance is there that this will always be so, even next to a power-transformer bank, particularly when large single-phase loads may be applied without warning? In metering, no possibilities of error can safely be overlooked and this includes erroneous tap connections of the power units.

Mr. G. R. Lunge mentioned various reasons for choosing some of the metering combinations in preference to others, such as relaying, economy, safety, previous condition of servitude, and protection against diversion. These are both interesting and pertinent but outside the scope of the paper. He did, however, discuss some cases where either a two- or three-element metering combination could be used, so the choice might depend upon the relative accuracy obtainable. As to this, it should be clear from the paper that the 3-element metering combination has a slight edge over the 2-element combination for such three-phase, three-wire systems. Since the 3-element meter also is suitable for three phase-four-wire systems, it is the most generally applicable of the watthour meters considered.

In conclusion, it might be stated that a secondary object of the paper was to stimulate thought in metering problems with the hope that an increase in the number of grade A metering installations ultimately would result. The thought so far inspired as shown by the discussions is encouraging. However, experience indicates that the magnitude of any resulting improvement in metering accuracy will be indeterminate.

The Shielding of Permanent Magnets From Transient Magnetic Fields

Discussion and author's closure of paper 41-112 by G. J. Wey, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 875–7.

A. M. Opsahl (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): 1. The development of a watthour meter damping magnet that is shielded against change due to lightning surge currents was the best way of solving the problem. Lightning discharges seek the best path to ground. For safety reasons, each secondary service is required to have an effective ground on one service conductor, preferably a connection to a water pipe system. A severe lightning discharge on either the primary or secondary circuit cannot be prevented from discharging surge current through this grounded service conductor which passes close enough to the meter to be a source of demagnetizing flux.

2. Any means of bypassing the lightning current around the meter would require quite major changes in standard practice of house wiring and code requirements. The best inherent protection against failure of meter coils due to voltage surges is obtained by the present practice of closely coupling grounded and ungrounded service conductors, not separating them.

H. L. Thomson (The Hartford Electric Light Company, Hartford, Conn.): Mr. Wey, in introducing the subject of a very ingenious method of shielding permanent magnets from transient magnetic fields by rapid yet effective copper plating on steel, has referred to the broader subject—the effect of lightning on watthour meters in the field. The principal object of this discussion is to try to prevent those in the field from accepting wrong impressions of conditions in the field.

Mention was made of isolated instances of weakened watthour meter magnets having been found by electric utility companies. Instances where watthour meters have been found in excess of four per cent fast may be spoken of as somewhat isolated. Four per cent was the original figure chosen in 1931 because it eliminated practically all other known causes of fast meters and, therefore, was considered as a good indication of lightning surge demagnetization. This is probably what Mr. Wey refers to. From our later studies, it is apparent that lightning surge demagnetization has caused slow meters, also correct and fast meters, to run faster. Those meters speeded up from one per cent to four per cent must not be spoken of or considered as isolated instances.

Mr. Wey, in quoting McEachron and McMorris on magnitude of current surges in the ground lead of distribution system primary lightning arresters, considers the use of these figures when applied to distribution secondaries as extremely pessimistic. In the absence of an extensive study, that may be true, but as far as the watthour meter is concerned, evidence from the field indicates a large percentage of demagnetizing strokes directly to the building housing the meter or to nearby objects. In this way, one meter and its permanent magnets may be subjected to the demagnetizing effect of the total current of the surge before it reaches the secondary system where it may then divide to a multiplicity of grounds or arresters.

Meter engineers are not as familiar as others with the nomenclature of lightning arrester current magnitude probability data and may accept and act on a wrong impression. Although admittedly pessimistic, if the data may, for example, be applied directly to watthour meters, three and one-third per cent of rural meters may be subjected to a ten thousand ampere surge each year, or twenty per cent of the meters during a normal six-year test period.

Now that we have found reasonably satisfactory and inexpensive solutions to the problem of weakened magnets, it would be foolish not to protect new meters and substitute them for older meters in the most exposed areas. However, to rebuild and similarly protect meters in service in exposed locations on any grand scale would be extremely pessimistic. First, we should know more about lightning exposure itself, and we also should know more about the other possible measures which may be taken to alleviate the fast meter difficulty as far as the customer is concerned.

Mr. Wey has selected certain wave shapes for his test surge currents. Due to the inherent nature of copper shielding, the shielding effect changes profoundly with different wave shapes. Those currents rising to crest more rapidly produce more shielding effect and vice versa. This effect, although far from extreme in this particular case, is demonstrated in the reverse curve effects noted in Mr. Wey's curves 4 and 5, figure 1 of the paper, where the wave shape is changed as the current magnitude is increased. It might also be said that, if it were necessary, Alnico magnets could also be copper plated, improving them still farther against surges. This, and the effect of change in wave shape, are shown very clearly in "Braking Magnets for Watthour Meters" by I. F. Kinnard and J. H. Goss, paper 40-128, presented at the AIEE Pacific Coast convention, August 1940 (AIEE TRANSACTIONS, volume 60, 1941, pages 431–9).

Speaking of wave shapes, it is my understanding that in the initial unsuccessful laboratory tests, an attempt was made to pass surge currents through the current coils of a meter, but, due to the wave shape and the high impedance of the coils, the current flashed across the terminals and only a small portion actually went through the coils. Surge currents through the service wiring seemed, therefore, to be more effective. Perhaps this is the experience Mr. Wey refers to. Later, however, when more powerful surge generators were available, it was possible to generate surge currents with a wave form whose rise to crest was slow enough so that the impedance drop across the coils was insufficient to cause any shunting of the current by the coils. The demagnetizing effect of surge current in the meter coils proved to be approximately equal to that caused by the current in the service wire, doubling the total effect.

From the meter design angle, Mr. Wey has plotted demagnetizing and shielding effect against per cent loss in working flux. When these data are applied to loss in accuracy of watthour meters, one per cent loss in working flux can be considered as equal to approximately two per cent loss in meter accuracy.

Mr. Wey should be complimented very highly for having brought to light a very ingenious method of applying copper shielding, making possible its use in connection with watthour meter permanent magnets, against the common enemy—lightning surges. He should be complimented even more highly perhaps for contributing to the discussion of the broader subject of lightning damage to watthour meters, and it is hoped that the study and discussion will broaden and continue.

A. L. Nylander (General Electric Company, West Lynn, Mass.): In connection with surge demagnetization, the following experiment is of interest. A length of chrome meter magnet bar stock was subjected to a uniform surge field in a direction opposite to the magnet flux. A 15–45-microsecond surge was used and measurements of total flux of the bar magnet made by means of a coil and ballistic galvanometer before and after each surge application. With the particular test set-up, it was found that after the sixth surge, the total flux of the bar magnet was zero. Taking precautions not to disturb the magnetic condition of the sample, thin layers of the magnet material were successively ground off the surface and following each grinding, the total flux was measured as above. After correcting the total flux to compensate for the change in the ratio of length to cross section of the bar magnet, a curve was plotted showing the maximum flux density of the magnet versus the distance in from the sample surface. This plot showed that following this application of the six surges, the outer skin of the magnet was actually saturated in the direction of the surge field while at the center of the magnet the flux was in the direction of the original magnetization and still at more than half of its original value. This is evidence that the magnetic state of the sample depends upon the extent to which the field is able to penetrate into the material.

By making use of the fact that the penetration of the field into the magnet is a function directly of the square root of the resistivity and inversely as the square root of the product of the permeability and the disturbing field frequency, Transient Electric Phenomena and Oscillations (C. P. Steinmetz, page 365), it has been possible to predict approximately the behavior of a given material with respect to any other material under a given surge. Also, if the direct current demagnetization curve of the material and both the surge and d-c demagnetization of the reference material are known, surge demagnetization of the material under question can be determined. Since the permeability varies between wide limits according to position on the hysteresis loop, this value must be judiciously chosen in the operating region. The following shows the results of such calculations as compared with actual test values. The figures given are the ratios of the peak-surge field strength to the d-c field strength required to reduce the total flux of a bar magnet—designed to give maximum useful flux per unit volume of material to zero. (Magnet Steels and Permanent Magnets, K. L. Scott. AIEE TRANSACTIONS, volume 51, 1932, page 412).

	Chromium Steel	Cobalt Steel	Alnico II	Sintered Oxide
Ratio of 15–45 microsecond surge to d-c				
Calculated (reference)	15.5	6.9	3.7	1.00
Test	15.5	5.3	3.2	1.0
Ratio of 28–86 microsecond surge to d-c				
Calculated (reference)	7.1	3.16	1.70	1.00
Test	7.1	3.25	1.52	1.0
Ratio of 84–215 microsecond surge to d-c				
Calculated (reference)	4.19	1.87	1.02	1.00
Test	4.19	2.23	1.25	1.0

Use of this method in cases where only approximate values are desired saves considerable time and expense in surge testing.

The author shows an interesting curve on the increased demagnetization due to repeated surges. In tests under comparable conditions, these results check very closely with other tests made, giving a ratio of ultimate to single surge demagnetization of approximately 3.5 to 1. Further tests on the same material without copper plating and on several other materials give different results. The same material without copper plating has a lower ratio of ultimate to single surge demagnetization of approximately 2.3 to 1, while cobalt steel and Alnico have similar ratios respectively of 1.9 to 1 and 1.7 to 1. These ratios are true only under specific test conditions and any change in surge duration will change these ratios and the shape of the curve of demagnetization versus number of surges. For unplated chromium steel, for instance, in going from a 20–50 to a 90–220 microsecond surge, the ratio drops from 2.3 to 1.7 approximately. This change in ratio may be attributed to increased penetration of the field into the magnet at longer durations resulting in a lower inter-layer magnetic gradient and consequently, less magnetomotive force available to cause magnetic redistribution.

George J. Wey: The experiment described by Mr. Nylander is particularly interesting in that it explains how a transient field can reduce the external flux of a bar magnet to zero without penetrating to the inner layers of the magnet material. The action of the transient field, therefore, is to short circuit the external flux path of the bar magnet by reversing the magnetism of the outer layers.

The table of ratios of peak surge field strength to direct current field strength required to reduce to zero the external fields of bar magnets of various materials is of interest in emphasizing that chrome steel, due to its higher permeability and lower resistivity, offers more resistance to demagnetization by transient fields than a comparison of its coercive force (H_c) with other magnet materials would indicate.

It is quite true, as Mr. Nylander points out, that longer surge durations will tend to lower the ratio of ultimate to single surge demagnetization and thus change the shape of the curve in figure 7 of the paper.

Mr. Thomson, in correcting the impression gained from the paper, that the number of meters speeded up by lightning discharges is negligible, creates the impression that twenty percent of the meters in a rural area may be subjected to a 10,000 ampere surge in the course of a six year testing period. If this were the case, twenty percent of the meters in rural areas would be found from six to eight per cent fast during a six year period and protection on a "grand scale" would be justified, which conclusion Mr. Thomson denies. In stating that it was desirable to protect meters in service as well as new meters, I merely want to point out that in order to reduce *materially* the number of damaged meters found on a system, a large percentage of the installations must be protected. Therefore, when protecting a large number of installations, it is desirable to protect existing meters without having to buy new ones.

Mr. Thomson is quite correct in pointing out that Alnico magnets can also be copper plated. Such a solution could hardly be justified economically, since it is much easier to copper plate the existing chrome magnets and avoid the additional expense incident to developing and tooling a new magnet.

The effect of the field from the current winding of a five ampere meter is approximately one-half that from the service wires. For a 15-ampere meter the effect is from twelve to fifteen percent of that from the service wiring.

Among the first solutions proposed to the problem of demagnetization was one in which the meter was offset about 16 inches from the vertical run of service conduit, thus putting the meter out of reach of the field from the service wires. As Mr. Opsahl points out, this practice requires major changes in house wiring practice, is unsightly, and expensive.

Impulse Strength as a Measure of Cable Quality

Discussion and author's closure of paper 41-131 by L. I. Komives, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (October section), pages 929–34.

T. F. Peterson (American Steel and Wire Company, Worcester, Mass.): I admire the courage shown by Mr. Komives and his associates in embarking on a test program which might possibly yield data that could be used as a measure of cable quality. Impulse strength seems to provide a means for the instantaneous integration of many cable characteristics which, in one manner or another, determine cable serviceability. These include such elements as mechanical uniformity of application of paper, perfection of saturation, characteristics of electrodes, etc. However, the tests give no further indications as to the ability of the cable to stand prolonged application of voltage, temperature load cycles, mechanical handling, etc.

Dr. Whitehead has suggested that only one characteristic should be studied at a time, and that all other variables should be held fixed during such studies. While this would be the correct approach to the problem of measuring cable quality, it is submitted that we would never reach an end point because of the long time necessary for testing and because the cable art would change at a rate more rapid than such test procedure could follow.

In view of the fact that the authors have obtained test data integrating many cable characteristics, perhaps we can obtain rather rapid over-all results by following the change in impulse strength of cable with testing designed to bring out other cable characteristics. For example, if impulse strength tests were made at intervals during high voltage load cycle tests on cable or over a period of cable operation, the trend in the impulse tests for a given set of conditions simulating operation might be a very valuable indicator of cable quality. I am wondering if the author contemplates any such studies. Perhaps they have been made. In this event, a discussion of results would be appreciated.

Wm. A. Del Mar (Phelps Dodge Copper Products Corporation, Yonkers, N. Y.):

SIGNIFICANT STRESS

Mr. Komives has given us valuable data on twenty-six impulse breakdown tests of paper cables which may be divided into the following groups—

Solid type	11
Ionization free types	9
Low gas pressure	6
	26

It we average the maximum stresses (as given by Mr. Komives) for all of the cables of each type and find the mean divergencies from these averages and then do the same thing for average stress we obtain the following results:

	G Max	G Avg
Solid type	917	13.0
Ionization free types	8.5	13.0

We may eliminate the low gas pressure type from this comparison as only one size was tested, so that the *G* maximum and *G* average were necessarily in the same ratio.

This comparison gives another indication that maximum stress is a more important factor in impulse tests than average stress for both types of cable. This conclusion is not materially affected by any corrections in the stresses that I may offer later.

TAPING

In table I of the paper the taping for cable *G* is described as very irregular. However, the Mildner diagram for this cable shows greater regularity than for cable *H* which is described as very good. The mean divergence from the mean overlay is 60 per cent for cable *G* and 67 per cent for cable *H*. The trouble with cable *G* appears to be registrations due to too short an overlay.

STRESS WITH STRANDED CONDUCTORS

The basis of the formula for stress at the surface of stranded conductors is not given and would be an interesting contribution as the only theoretical treatment of this subject that I have seen is that of Levi-Civita, summarized by Jona in his International Electrical Congress paper of 1904, as a formula which is exceedingly cumbersome and impracticable.

The formula used by Mr. Komives may be converted into one for ratio of stresses with and without stranding by dividing by—

$$\frac{E}{2.3r \log_{10} R/r}$$

We then obtain the following formula for the ratio—

$$\frac{\text{stress with stranding}}{\text{stress with smooth conductor}} = \frac{1}{\dfrac{0.0904}{n \log_{10} R/r} + 0.759}$$

Taking $n = \infty$, the ratio will be 1.32. Obviously, it should be 1.00. The Levi-Civita formula suffers from the same defects of being wrong at the limits.

Neither the formula given by Mr. Komives nor that of Levi-Civita checks with Atkinson's experimental data of 1919, the ratio of stresses for stranded to solid being, in both cases, greater than Atkinson's.

The comparative figures are as follows for the specific cables described, the "Atkinson" figures being derived by interpolation from the data given on page 1008 of AIEE TRANSACTIONS, volume 38, 1919:

n	W/2r	Komives	Atkinson
7	0.54	1.25	1.19
18 or 19	0.65	1.30	1.19
24 or 25	0.44	1.30	
37	0.36	1.30	

It is interesting to note that Atkinson's experimental ratio for 19 strands was the same as for seven strands although Levi-Civita's formula, like that used by Mr. Komives, indicates a rising ratio with increasing number of strands. As the ratio for $n = \infty$ must be one, it is probable that the ratio for more than 19 strands will be not greater than for 19. Indeed, it is the general experience that cables with a larger number of strands are not inferior in dielectric strength to those with a small number. It would seem that a ratio of 1.19 should be about right for all practical strandings.

If we apply this factor to the figures in table I of the paper we obtain the average values shown in table I of the discussion for cables *A*, *E*, *F*, *G*, *H*, *I*, and *J*.

STRESS IN SECTOR CABLES

The use of shoulder radius for computing maximum stresses in shielded sector cables is of doubtful accuracy. We made a large scale (30 to 1) model of a smooth faced sector and determined the stresses by the electrolytic method. The results were as shown in figure 1 of the discussion and compare as follows with calculations from shoulder radius:

	Experimental Sample	
	Meas'd	Calculated
r (radius of shoulder)	154	154
w (insulation wall)	313	313
Ratio $G_{max.}/G_{avg.}$	1.70	1.83

$G_{avg.}$ here means E/w and not the average from the curve of figure 1.

This shows that the calculated value using *r* makes the stress about eight per cent high in this case, so that if this ratio be assumed to hold generally, the average values for cables *B*, *C*, and *D* would be reduced as shown in table I.

RECALCULATED MAXIMUM STRESSES

The maximum stresses recalculated as indicated above would be as shown in table I, which gives the average for each cable.

Table I

Cable	Komives	Recalculated Values
A	2,690	2,560
B	2,070	1,900
C	2,450	2,250
D	3,110	2,860
E	3,120	2,620
F	3,350	2,810
G	2,540	2,130
H	3,290	2,770
I	2,770	2,260
J	2,980	2,500

These new values do not invalidate any of Mr. Komives' conclusions except that they cast doubt on the high "ceiling" of 3,300 volts/mil which he suggests.

The discussion is offered merely to save us from pitfalls in future work of the same character, as the laws governing impulse strength will not be fully understood until many more data are available. In the meanwhile we owe a debt of gratitude to Mr. Komives and his associates for giving us the latest information as it becomes available.

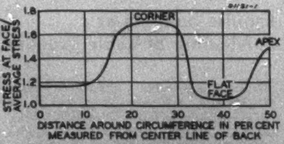

Figure 1. Ratio of stress at conductor face to average stress, shielded conductor, type H, sector cable, 350,000 cir mils, 20/64-inch paper

By average stress is meant voltage from conductor to ground divided by insulation thickness

J. A. Scott (General Electric Company, Schenectady, N. Y.): Mr. Komives' paper is a most welcome and valuable contribution to the only too scarce literature and accumulation of data on the impulse strength of cable insulation.

I am interested in several aspects of this.

1. He presents a large number of values of calculated maximum stress at breakdown. These range from 1,900 volts per mil to 3,500 volts per mil. The interval between 2,600–2,900 volts per mil contains a greater number of these values than any other similar interval. This interval, too, is near the center of the range presented; it contains the average value (2,830), so why is this not the most significant value rather than the 3,200–3,400 selected by the author? Variation is caused by many factors; combinations of unfavorable factors produce values below the average, and combinations of favorable factors produce values above average. Where the property measured varies 2 to 1 as it does in the data presented by Mr. Komives, many values are needed to produce reliable averages. The 66 cases cited are only too small.

2. Most of Mr. Komives' discussion of the influence of such factors as taping, degree of impregnation, and smoothness of electrode is supported, as he points out, by selected instances involving three or at most four test values. I would prefer to consider from such meager data that inferences only may be drawn. These inferences are most important, and we especially need more such data particularly with respect to the performance of cable after years of service. The Utilities are to be encouraged whenever possible to take more such data, and to correlate it with their experience with cable failures caused by lightning. To my knowledge we have no reliable data on the number of such failures.

3. The maximum stress argument crops up again, this time with more logic because impulse failure seems to be more of a disruptive thing than does our ordinary long time 60-cycle endurance or load cycle test. Short time 60-cycle breakdown values have never been highly considered as criterion of cable quality. They are in the nature of necessary conditions but are by no means regarded as sufficient proof of quality. Average stresses, cylindric maximum stresses, and strand maximum stresses are all geometrically related. Since our service stresses are determined empirically by experience, when we use one of these stresses to the exclusion of the other, we neglect only the variation of the geometric ratios existing between these stresses over the commercial range of cable sizes and insulations. The variation in the ratio of cylindric maximum stress to average stress amounts to something like 40 per cent over the commercial range of sizes, which is considerably less than the 100 per cent range of breakdown values given in Mr. Komives' tabulation. Commercial thickness ratings sometimes call for increased insulation when unusually small conductors are used. On the other hand, large conductors being bulky and unwieldy, are given more insulation than stresses would seem to require, for mechanical reasons alone. The ratio of the strand maximum stress to cylindric maximum stress using the formula cited by Mr. Komives[1] is practically constant in the neighborhood of 30 per cent for the usual number of strands in the outer layer. This

automatically becomes absorbed in our empirical design constants. Furthermore, the effect of stranding stresses exists only in the region near the conductor.

4. In the light of the viewpoints brought out above, it seems scarcely logical to use impulse breakdown tests as a rigid criterion of cable quality as Mr. Komives suggests. It is a most variable property as his tabulation shows. It would seem wiser to seek other more direct measures of those causes of variation (taping uniformity, registration, and saturation) mentioned by him. There are, of course, other factors causing variations; the purity and characteristics of the basic materials used in manufacturing cables are probably more important than those listed.

If operating stresses are low in cables as now used, it is because the art has advanced cautiously and at the same time surely. I cite the rapid increase in cable system voltages to 130 and 220 kv as proof of daring and a not too great unwillingness to pioneer. If we trim our thicknesses further in the future, it will be because we have made improvements in quality and reduced variations in manufacture so that the step is warranted.

REFERENCE

1. *ETZ* Formula 2, W. Deutsch. November 23, 1911, page 1175.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): Mr. Komives and his company have made a substantial contribution to our knowledge on underground cables through their extensive series of impulse tests.

As to the author's point on the impulse tests indicating the degree of impregnation, it strikes me that ionization tests and visual examinations also give the same information. As to impulse tests indicating the quality of the taping, it seems that they should give no more information than 60-cycle breakdown tests and visual examinations of the cable or styrene wafers. In this regard it seems that surge tests should show freedom from wrinkling, registrations, and an excessive amount of gap spaces in any radial path, but it should be expected that otherwise the lay, i.e., the length of the leakage path, has little effect as surge failures seem to be in general radial punctures. In other words, these two cable characteristics, that is, impregnation and taping, can be observed by using methods and tools available in all cable factories. The additional check method, that is, using the impulse tests, which require special apparatus and complicated potheads, is desirable to fill out our knowledge, but it does not seem to me to be desirable as a procedure for every cable factory. Such data are of particular interest in connection with operating and design problems involving switching and lightning surges, and therefore I hope that The Detroit Edison Company and a few others will continue to make impulse tests as needs dictate.

For predicting the serviceability of a cable, accelerated aging tests, together with supplementary tests and inspection of small pieces of cable before and after aging, seem to be of first importance.

The paper shows that a number of variables have an appreciable effect on the surge strength of cable. This fact emphasizes the need not only of a careful study of all variables involved, but also of the accumulation of a large amount of general data because comparison and interpretation of the data presented by various authors are made difficult as they show the composite effect of several variables, some of which were not well controlled.

It is gratifying that recently considerable information has become available. When the breakdown voltages presented recently by eight laboratories are plotted versus insulation thickness, a surprisingly small amount of scattering is obtained considering the many variables involved. These data indicate an average impulse breakdown stress of 1,600 volts per mil.

Mr. Komives has presented data which indicate that the maximum rather than the average stress may be the controlling factor. If this is true, breakdown voltages plotted versus *r* log$_e$ *R*/*r* should give more nearly a straight-line relation than when plotted versus insulation thickness. While there is an indication that this may be so, the difference in the results of the two methods of plotting is not sufficient to decide definitely between maximum and average stress as a controlling factor.

While Mr. Komives' evidence for the effect of maximum stress is impressive and agrees with the results of visual examinations of surge failures, it appears that under some conditions neither the maximum nor the average stress may be exclusively the controlling factor. It seems reasonable that for two cables with the same insulation thickness but with different conductor sizes the one with the larger conductor would have the higher breakdown voltage. On the other hand, it may be assumed that if the maximum stresses for a given voltage are the same for two cables, i.e., if *r* log *R*/*r* is the same, then the insulation thickness or the average stress would be the controlling factor, the cable with the thicker insulation having the higher breakdown voltage. These arguments seem to be supported by some of the test results, as shown in tables II and III of this discussion. However, there are some data that do not check this theory, possibly due to the disturbing effect of other variables.

One important variable showing considerable variations between the various laboratories is the method of testing with regard to wave shape, polarity, and type of breakdown. Mr. Komives made single-shot tests with most or all breakdowns presumably on the front of the wave. Most other investigators made step-by-step tests with probably in most cases full-wave breakdowns. The limited data on time lag curves by Held and Leichsenring show that front wave breakdowns at very short times can be as much as twice the full wave breakdown values, while beyond one microsecond the time lag curve appears to become flat. For proper co-ordination of results, the time lag curves, or at least reporting of breakdown time with breakdown voltage, would be desirable, especially for co-ordination of the impulse strength of cables with that of terminal equipment. The time lag curves for cables and potheads may intersect with the result that the surge strength may be higher for cables than for potheads with long durations but lower with short durations.

Table II

Investigators	Insulation Thickness—Mils	r× log R/r	Breakdown Voltage—Kv	
Komives	386	245	578–630

	945	547	1,300	
	945	580	1,400	

Table III

Investigators	r× log$_e$ R/r	Insulation Thickness —Mils	Breakdown Voltage —Kv
Foust and Scott	H402	500	792
	H397	600	972

It is of interest that the *F* samples were subjected for eight years not only to aging tests in Chicago but also to lightning and switching surges, as the cable was connected to a commercial overhead line. The maximum recorded surge strength during the eight years was roughly 690-kv crest, which compares to breakdown voltages of 730 and 775 kv obtained by Mr. Komives for this cable.

J. B. Whitehead (The Johns Hopkins University, Baltimore, Md.): The question of the relative importance of the maximum stress and the average stress in cable breakdown is an old one, which has been quiescent for some time. This is probably because in a very copious amount of experimental data in recent years, there is nothing to suggest a special significance of the average or overall stress.

The hypothesis that the average stress is the determining value in cable breakdown is apparently based on the assumption that the stronger portions of a path through the insulation wall in some way help out or support the weaker portions. This picture implies the further assumption that breakdown is an instantaneous phenomenon and that all elements of the breakdown path let go at the same instant. It assumes, in fact, that "pure electrical breakdown strength" is a property of cable insulation.

There are two good reasons why this picture is not correct. The first is the well-known fact that in all types of insulation the value of breakdown voltage is a function of the duration of time of the application. For example, the present paper indicates that under impulse tests breakdown stresses are some seven or eight times normal 60-cycle values. The second fact, not so well known, is that breakdown in cable insulation is a progressive phenomenon involving the passage of time and that it has recently become possible to interrupt the over-all process of breakdown before it is complete. Partial failures of various stages of advance may now be studied and reveal that during the process of complete failure, certain parts of the insulation wall are at first affected, others remaining apparently intact.

Now it is well known that cable insulation is not uniform in structure and has regions or spots which are weaker than others. The spread of the experimental values easily shows this. This fact, taken in conjunction with the fact that we have local failure before complete failure, points very definitely to the importance of maximum stress. If the weak spot is in a region of maximum stress, it will obviously let go first. If the weak spot is in the region of minimum stress, it may or may not let go before another region in the region of maximum stress, but would only have the effect of giving a higher value of breakdown voltage than when the weak spot were located in the region of maximum stress. The essential thing is that the weak spot has a definite breakdown stress. Whatever the location of the spot, the stress, when it is reached, will have a definite relation to the maximum stress. Failure is progressive in time and the behavior under impulse tests simply indicates that with shorter and shorter durations of time, higher and higher values of stress are needed for the failure to progress from the initial weak spot through the entire wall.

It will thus be seen that I am in agreement with the author's hypothesis of the importance of maximum stress rather than the average stress. However, I do not feel that his paper has added very much in the way of a direct proof. The chief grounds he offers are that there is less spread in the experimental results if they are plotted in terms of the maximum stress than if they are plotted in terms of the average stress. The contention would be more convincing if all of his experimental samples were of the same type. However, they differ so widely and involve so many different conditions that the conclusion looks rather more like a possibility than a certainty. This unfortunately is a necessary characteristic of experimental results on completed cables. It would be highly desirable if cable manufacturers and users could join in a concerted effort to conduct a series of experiments on laboratory-controlled samples in which the various elements entering the cable stability could be studied separately, and subsequently, conjointly.

E. W. Greenfield (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): Of particular interest are the test results on cables *C* and *D*. These are solid-type cables with sector-shaped, "compack" strand conductors, and differ only in that cable *D* is of so-called type *CB* design. That is, the conductors are covered with several layers of a special semi-conducting, highly adsorptive, colloidal carbon-filled tape.

Since the test involves only a pure electric type of failure, it is assumed by the author that the 30 per cent higher impulse strength of the *D* cable is entirely ascribed to the effective smoothing, or shielding, of the conductor strands by the use of semi-conducting tapes. It is agreed that complete conductor shielding is actually effected by the carbon-black tapes. It is also agreed that the adsorbing and oil-purifying action of these tapes is unimportant in impulse tests since the failures are too rapid and not ionic in nature. However, it should be pointed out that strand shielding may play only one part in producing the *D* cable's observed high impulse strength. Two other effects exist which have a significant bearing on the test results:

1. Series damping due to the semi-conducting tapes.
2. Discharging electrode shifted from metallic to nonmetallic (carbonaceous) material.

The series damping effect is due to the effective presence of a longitudinally-distributed, non-reactive, resistance in series between the conductor and the insulation. For applied impulse voltages, this series resistance modifies both the steepness and magnitude of the wave front to an appreciable extent and thus affords the cable an automatic, built-in measure of protection.

The fact that the high-voltage electrode is shifted from copper to carbon-filled paper is important since the character of the discharge is thereby modified. Discharges from metallic electrodes are more disruptive and severe than discharges from non-metallic electrodes. The relation of work functions between copper and carbon and carbon and paper causes a real difference in barrier potentials over that existing between copper and paper as in the standard cable construction. The work function between carbon and paper is probably only about one-fifth that of the copper-paper interface.

By virtue of the above, it is believed that the excellent impulse strength obtained for the *D* cable cannot be duplicated by a cable with the ordinary metallic-tape form of conductor shielding, or even by a cable with a smooth, solid-copper conductor.

L. F. Roehmann (Anaconda Wire and Cable Company, Hastings-on-Hudson, N. Y.): Physicists distinguish between two forms of breakdown of a dielectric; namely, pyroelectric and electric. When a cable dielectric is subjected to impulses with a steep wave front, the breakdown is of a purely electric nature. Hence, it is reasonable to assume that there is a relation between impulse strength, and electrical stress at the moment of breakdown.

It is not surprising that there is no simple relation between breakdown strength and *average* dielectric stress. This latter quantity, while widely used for rule-of-thumb calculations, has no physical significance. As in structural calculations, it is the *maximum* stress which is the determining factor.

Some time ago, the idea was conceived that impulse breakdown for a given material always occurs at the same *maximum* stress.

Davis and Eddy's paper[1] permitted, for the first time, a check of this hypothesis. These authors published breakdown stresses obtained on samples of a single, round, solid conductor (number 6 American wire gauge) insulated with a rubber compound of 5, 10, 15, and 20/64 inches wall thickness, respectively. They reported *average* electrical stresses and concluded that the unit impulse strength decreases with increasing wall thickness. However, when one recalculates their values on the basis of *maximum* stress, one finds the following values: 2,000, 2,060, 2,060, and 1,950 volts per mil; that is, practically constant within the range of measuring accuracy.

It is gratifying to see this theory is confirmed again by the data reported by the author. Calculations involving stranded, compacted sector conductors are much more complex than for a single round wire. Hence not the same accuracy can be expected when testing such types of cable.

There are three cables designated by the author as inherently, or accidentally, inferior with respect to impulse strength, namely *B* (low gas-pressure cable), *C* (ordinary solid-type cable), and *G* (oil-filled cable with very irregular taping). When these three cables are eliminated, one finds that the breakdown strength, or more accurately the maximum electrical stress at breakdown, is *constant;* namely, 3,050 volts per mil ±12 per cent, *independent of design and of insulation thickness.*

Additional confirmation is contained in an English investigation.[2] The authors made puncture tests on paper-insulated cables rated from 10 to 66-kv three-phase. They used an 0.5 microsecond wave front, and report puncture stresses of 2,670 volts per mil for positive and 2,440 volts per mil for negative polarity. These values, as they state, do not consider stress concentration due to stranding. If one takes this into account by adding 20 per cent, one arrives again at a value in the neighborhood of 3,000 volts per mil.

The practical consequences of this result are twofold:

> First, if one is willing to consider, with the author, impulse strength as a measure of cable quality, it follows that a cable not living up to approximately 3,000 volts per mil maximum impulse stress is "not acceptable."
>
> Second, if one has to select a cable with respect to its impulse strength (for example, a connection between an overhead line and a station), one should choose the type which combines highest impulse strength with simplest design and lowest cost. This is, obviously, the conductor-shielded, solid type; or more specifically, type *D*, where the conductor is shielded with semi-conducting tapes.

In figure 5 of the paper, it seems rather confusing to plot maximum stress versus breakdown voltage. Increasing voltage, for the same type of cable, necessarily means increasing stress; hence, all points for the same type necessarily lay on straight lines. This question only is of interest: At which stress did breakdown occur? When type and breakdown stress are known, any impulse voltage can be obtained for purposes of insulation coordination by varying the conductor diameter and insulation thickness.

It is interesting to note that the formula for maximum strand stress derived by Mr. Serguis Vesselowsky, of the Detroit Edison Company, confirms that obtained by W Deutsch in 1911,[3] and reprinted in Schwaiger-Sorensen's textbook on Dielectrics.[4]

K. S. Wyatt (Phelps-Dodge Copper Products Corp., Yonkers, N. Y.): Mr. Komives' development of the impulse breakdown test as a measure of cable quality will be welcomed by all who are working to improve cable. His paper is particularly valuable in comparing different cable constructions, solid, gas-filled, oil-filled, compression, and oilostatic; and in studying the effect of conductor shielding, and of pressure, in addition to the effects of thorough impregnation and of uniform and well designed taping.

It should be made quite clear that the significance of these results lies in the relative values of impulse strength and not in the absolute values given. Beyond the question of wave-form and similar variables, there is that of pre-excitation. This should be important, particularly in cables containing appreciable gas spaces in the insulation as in used solid cable, or gas-filled cable. In such a cable, during service operation, there may be ionization taking place in the gas spaces as a result of normal voltage, perhaps assisted by a high frequency component which is often present in operating cables. When an impulse is impressed on such a cable, it is believed that breakdown will occur at an appreciably lower voltage than on a cable which has not been energized and in which pre-excitation is absent. Impulse tests on energized cables have not been carried out because of the difficulty of sufficiently insulating the transformer equipment. Thus it appears that absolute values for impulse breakdown on cables, particularly gas cables, should not be taken too seriously if the cable is not under operating voltage when tested.

A warning note should also be sounded for those who may be tempted to use impulse strength as the sole criterion of cable quality, and in this I feel sure Mr. Komives will agree. Impulse strength is not only a function of mechanical uniformity and of degree of impregnation, but of paper density. It is believed quite feasible to raise the impulse strength of a cable by employing super dense super calendered paper throughout the insulation wall. Such a cable would prove unstable on a severe load-cycle test because cavitation (voids) would occur, and this would result in ionization. In other words, it would be a bad cable from the operating man's point of view, yet the impulse strength would be high. Hence, the impulse strength of a cable should be used in judging cable quality only when complete details of the cable construction are available, and sufficient test data to permit reasonable interpretation of the results.

The author refers to judging the degree of impregnation of his cable samples by visual inspection. While I am quite agreed that this is roughly satisfactory in practice, nevertheless, it would seem desirable to have a more quantitative test, particularly for solid cables. Actually, it is simple to determine the degree of impregnation quantitatively by taking a few feet of cable, fresh cut at ambient of 20 degrees centigrade or below, sealing up the ends with polystyrene or paraffin wax, and immersing in a pipe of thin oil. Liquid pressure is applied by steps up to 200 pounds per square inch—the decrease of volume of the cable sample being measured by the amount of oil fed in. Knowing the initial displacement of the sample, the void volume is readily calculated. It is surprising to find that modern cable carefully impregnated has an appreciable void volume. The range at 200 pounds per square inch is probably from one-half to three per cent. It would give support to the author's conclusions if he could give exact figures for void volume.

The variations in impulse strength of the various constructions described in this paper have been convincingly interpreted, but there is one exception. Consider the two solid cables *E*4 and *D*2, figure 5 of the paper. Cable *E*4, without conductor shielding, breaks down at a maximum stress of more than 3,300 v/mil., whereas *D*2, about an average of *D*1 and *D*3, with semi-conducting strand shielding, breaks down at a stress of less than 3,100 v/mil. The hasty conclusion might be drawn from these data that conductor shielding was harmful and lowered the impulse strength. In just the same way might it not be hasty to generalize from the data on the *D* and *C* samples that conductor shielding (including the semi-conducting type) raises the impulse strength? Would it not probably be nearer the truth to say that, if the stranding of the conductor is poor, or the insulation makes poor contact with the conductor, a uniformly applied and satisfactory conductor shielding will raise the impulse strength appreciably? On the other hand, if the outer surface of the stranded conductor is smooth, and the insulation everywhere makes close contact with it, then conductor shielding probably will not improve the impulse strength, and in fact may decrease it slightly.

To the writer the discussion of the last paragraph is largely theoretical, since it applies chiefly to new cable which has been subjected to little reeling and re-reeling. Wafer studies have shown quite clearly that three-conductor cable which is subjected to severe installation, conditions of reeling and re-reeling and pulling under winter conditions when compound is viscous, may suffer a deformation of the insulation resulting in a separation of the insulation from the conductor. Under such conditions of rough or repeated handling of the cable under winter conditions, conductor shielding of a satisfactory type, if it can be uniformly applied, may be expected to improve considerably the cable performance under severe test conditions.

Aside from these points, the paper is important in that it opens up the possibility of quickly evaluating the excellence of the mechanical uniformity of paper cables. Had there been some sure test in the past, greater progress would have been made in good design and precision application of taping. As it was there were so many obscuring factors that mechanical characteristics have not received the attention they have deserved. The importance on impulse strength of a good design overlay, and the precision application of taping following that design, is brought out very clearly by the Scott-Mildner diagrams of figure 6 (cable *E* 3,300 volts per mil) and of figure 8 of the paper (cable *G* 2,500 volts per mil). The weakness of the taping of cable *G* (figure 8) is twofold: a poor choice of overlay, namely, 20 to 25 per cent, and second, a high percentage of registrations or near registrations. The poor overlay means a comparatively *short leakage path* from conductor to sheath. The registrations mean a *radial alignment of butt-spaces,* some without any separating paper layer to break up the continuity of the oil-spaces. Wafer studies made several years ago in conjunction with load cycle aging of cable made clear the rudiments of the arrangement of the layer structure of the insulation and its effect on cable characteristics. These rudiments are as follows: On the severe load cycle with over-voltage of two to three and one-half times rated voltage, a long leakage path was probably more important than registration or radial alignment of butt-spaces, particularly if the cable length under test included a minimum diameter bend so that the layers at the outside of the bend opened up. Gaseous ionization soon searched out and penetrated along short leakage paths on the cooling cycle. The "step" leakage path equals the "Zig-zag" path at about 45 per cent overlay for tapes of the usual width and thickness. On the other hand, radial alignment of butt spaces across the insulation wall results in a weakness on short-time dielectric strength tests, probably because the field is very badly distorted around such butt-spaces[1] giving rise to appreciable tangential stresses even when filled with oil, and partly because such butt-spaces tend, at high points along a cable route, to drain clear of oil leaving gas spaces. These, of course, constitute a serious dielectric weakness. For instance, it was at that time pointed out that a 50 per cent overlay resulted in a butt-space super-imposed every two layers along a radius, 33 per cent in a butt-space every three layers, 25 per cent every four layers, and 20 per cent every five layers. Radial alignment of such butt-spaces means also that "hinges" or slip zones have been built into the cable wall so that the bending of the cable does not take place uniformly but is concentrated at such hinges with bad effect on dielectric strength.

To obtain high values of leakage path with absence of "hinges" due to radial butt-space alignment, it has been customary to use an overlay from 35 to 45 per cent, depending on the degree of precision of the machinery available.

There are two surprising features to the impulse values obtained in connection with figures 6, 7, and 8. Why should an impulse breakdown, which is a straight-through radial puncture, be so much influenced by the short leakage path of figure 8? And why should the cable presented by figure 7, which has an almost random overlay, have such a high impulse strength?

Other factors of importance in determining impulse strength, it would appear, are degree of compactness of the insulation cross-section as measured by a Cenco tester, and the presence or absence of a thick oil-film or void between conductor and insulation.[2] Unfortunately, these data are not available in the present paper.

Impulse breakdown tests should also be capable of searching out weak mechanical spots of other kinds. For example, in much paper cable there are often periodic "surge" effects of different kinds. In a joint paper[3] by Mr. Komives and the writer in 1936 the beneficial effect of using caterpillar grips in place of capstans was indicated. In another paper in 1938, it was shown that periodic crushing could be avoided by pre-spiralling.[4] Beyond these influences, there are undoubtedly still periodic mechanical effects which limit the stresses at which cable insulation can be safely worked. It is, of course, hardly necessary to point out that the older taping machinery, lacking in precision, led with certainty to periodic effects of the most serious kind.

It would appear probable that if the author of this paper should measure the impulse breakdown of a solid cable built on the best taping principles and employing a carefully made conductor shielding, at the same time avoiding the periodic effects referred to above, he would obtain higher values of breakdown stress than those recorded in this paper.

It is believed that the short-time d-c breakdown strength may be used as a rough guide to the relative impulse strength of various constructions. If this is so, the work done by Shimizu[5] should be of interest. He points out that the breakdown voltage is the the sum of the breakdown voltages of the paper layers and of the oil layers. Accordingly, for a given insulation thickness, a "juicy" cable, with thick interlayer oil film, would have lower breakdown strength. He also points out the effect of gaps or butt-spaces in reducing the breakdown strength. A bad arrangement is to have an oil layer in contact with the electrode instead of a paper layer. The mechanism of breakdown for d-c is quite different from that of a-c: where butt-spaces are only slightly off-set along a radius, the a-c breakdown will follow the path connecting the gaps whereas d-c will puncture the paper along a direct path rather than deflect even a short distance to one side. A-c breakdown involves surface discharge and creepage between fibre and oil, whereas surface effects are absent with d-c (D. M. Robinson also points out such differences between a-c and d-c breakdown).[6] D-c breakdown is increased by increasing impermeability of the paper, and by increase in viscosity of the impregnating oil; whereas gas dissolved in the oil lowers the a-c breakdown, it has little effect on the d-c breakdown.

If impulse breakdown does not follow the alignment of butt-spaces along a radius, but prefers to puncture straight-through the paper, how is it that it is affected by uniformity of taping? The author, perhaps, wisely refrains from proposing a theory.

It would be very helpful to confidence in the impulse test as a measure of taping quality to develop some rational explanation of the dependence of the impulse breakdown mechanism on taping.

L. I. Komives: 1. Mr. J. A. Scott is still not convinced that maximum voltage gradient rather than average stress determines the impulse strength of a cable. The author readily agrees with Mr. Scott that the data available are perhaps not sufficient to accept this theory without reservations. However, if a choice is to be made as to which of the two, maximum or average stress, should be used as a criterion, the available data strongly favor the maximum stress theory. In establishing impulse strength as a criterion of the quality of the insulation, it was necessary for the author to make this choice.

2. Professor Whitehead in his very helpful discussion goes a step farther and considers the maximum voltage gradient theory as an old story. Decidedly the probability lies between these two viewpoints, strongly favoring Professor Whitehead.

3. Mr. Wm. A. Del Mar's discussion in regard to maximum stress calculations is very helpful. It is exceedingly difficult to measure minimum radii on sector-shaped copper conductors at the point of breakdown. The author used theoretical values throughout the paper and deviations from theoretical figures, as Mr. Del Mar points out, are quite possible and will upset calculations in a considerable degree. In regard to the effect of stranding in the calculation of maximum stresses, it is proposed that we agree on one of the several theories available and use it throughout the industry when tests of such a nature are performed.

4. The author heartily agrees with Mr. Halperin's discussion. Perhaps the paper did not bring it out quite clearly but it was the author's idea that when sufficient data are available we can use the visual examination method with occasional checks on the impulse generator. It is not necessary that every cable manufacturer should have impulse testing equipment.

5. Messrs. Roehmann and Greenfield in their discussions, bring out a few points more clearly than the author. For this they should be given credit. Mr. Greenfield's theory in regard to the effect of the carbon electrode versus copper electrode on impulse strength is interesting. However, subsequent tests made by the author's company indicate that perhaps this effect is less pronounced than Mr. Greenfield indicates.

6. As to Mr. Wyatt's discussion the author agrees with him heartily that a surge super imposed on an a-c potential would have different effects on different types of cable. The author's company is not in a position to conduct such tests and perhaps the General Electric Company would be the only one in this country who could do it at the present time with the available equipment.

7. In regard to Mr. Peterson's discussion it is certainly desirable to eliminate variables in cable testing such as the effect of handling, service or load cycle aging etc. As such a program would be very costly it is believed that the industry will have to be patient and build up data slowly as they are accumulated.

The author wishes to thank all those who discussed this paper in such a fair and straight forward manner.

Bushing Tests

Discussion and authors' closure of paper 41-120 by A. L. Brownlee and W. H. Wickham, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (October section), pages 940–2.

L. Wetherill (General Electric Company, Pittsfield, Mass.): The construction of a large bushing is sufficiently complicated that a measurement of one overall electrical characteristic can hardly be expected to give all pertinent information regarding the condition of the internal dielectric. However, a considerable body of experience with power factor measurements made on bushings at voltages up to ten kilovolts has shown that such data are very useful. The authors have discussed the usefulness of the additional information which can be obtained by making power factor measurements at voltages exceeding ten kilovolts up to and above the rated operating voltage. Such usefulness consists, of course, in the ability to detect the presence and nature of undesirable conditions which would not have been indicated by power factor readings taken at a voltage of ten kilovolts or less.

Of four cases of power factor data taken at voltages exceeding ten kilovolts which are cited in the paper, three involve bushings using solid materials as the principal dielectric. In at least two, and probably all three, of the cases involving solid bushings it appears from the data that the power factor measured at ten kilovolts or less would have indicated no abnormal conditions, whereas power factor readings made at considerably higher voltages served to indicate abnormality which, on examination, was found to be of a serious nature.

The fourth case cited in the paper involves an oil filled bushing which had a power factor exceeding 23 per cent at ten kilovolts so that, as pointed out by the authors, the existence of an undesirable condition would have been unmistakably indicated by a power factor reading at ten kilovolts.

These data seem to suggest that the usefulness of power factor measurements made at voltages exceeding ten kilovolts in detecting the existence of undesirable conditions which would not have been disclosed by a measurement at ten kilovolts, may be considerably less on oil filled bushings than on solid bushings. Oil filled bushings are not, in general, susceptible to cumulative localized injury from repeated over-voltages, because of the fact that the recovery of oil after subjection to over-voltage is complete. Since the usefulness of power factor measurements at voltages exceeding ten kilovolts appears to be related principally to localized injury, it would reasonably follow that the usefulness of power factor measurements at voltages exceeding ten kilovolts will be considerably less on oil filled bushings in which the occurrence of such a condition is unlikely. Thus an examination of the nature of the phenomena appears to confirm a conclusion drawn from the data presented in the paper. Doubtless the authors have additional data not included in the paper which would further illuminate this point.

In many cases radio influence voltage measurement has been used for the detection of localized injury or defect in a solid insulating structure, and of course in such cases voltages of the order of operating voltage are applied. If the localized condition consists of a void leading to ionization the measurement of radio influence voltage should indicate its presence at least as definitely as a power factor measurement at the same test voltage. If on the other hand the localized condition consists of a partly conducting region of variable resistance it would appear that power factor measurement over a considerable range of voltage would be a more effective means of detection than a measurement of radio influence voltage. Of course the economic justification of field power factor testing at relatively high applied voltage is a matter which must rest on the frequency with which such tests disclose undesirable conditions which would otherwise have been undisclosed.

In figure 9 of the paper is shown a cross-section of a solid bushing core. This core was probably manufactured at the time when the inner layers of paper were impregnated with a dark compound as contrasted with the light brown compound which was used to impregnate the outer layers of paper. It is possible, therefore, that re-examination of this core will show that the dark region next to the conductor and at the upper end indicates the use of a dark impregnating compound in this region at the time of manufacture; rather than migration of the filling compound used inside of the bushing shell in contact with the core, which seems unlikely.

In table III, reference is made to surface power factor measurements. While the property of power factor has usually been associated with a volume rather than a surface it is, of course, fairly obvious that surface readings can be significant and useful. It would appear, however, that the value obtained would be dependent on the capacity of the testing circuit, as well as on the electrode arrangement. Perhaps the authors would care to give additional information regarding the method in which the surface power factor measurements were made.

I. W. Gross (American Gas and Electric Service Corporation, New York, N. Y.): The paper by Messrs. Brownlee and Wickham brings out two rather important points. The first, covered in the latter part of the paper, shows what can be done in determining the location of a fault in bushing insulation after an overall test has pronounced the bushing faulty. Prior to and during the early stages of our field testing of bushings in the field, we made similar tests on quite a few of the bushings found faulty by overall test. The defective insulation adjacent to litharge and glycerin was determined early in the testing program and, incidentally, was on a 44-kv bushing as given by the authors in their table I. At that time we not only found this defective insulation by tests on each condenser layer, but also proved by field and laboratory tests that a relatively high power factor in the order of five to eight per cent on the entire bushing indicated that the insulation had deteriorated and that the bushing would not stand up under 60-cycle overvoltage test.

The authors of this paper seem to be making a point that the ten kilovolts, which is now used very extensively for routine field testing of insulation, is not capable of showing up deterioration in some bushings which a higher test voltage would find. Unfortunately, there does not seem to be much data in the paper to bear out this contention. It would indeed be most instructive if comprehensive, comparative test data obtained at widely different test voltages were given to support this contention.

It has been frequently stated, and often repeated, that over-stressing of insulation by excess voltage will injure the insulation. This statement was often made in the past in reference to high voltage cables. It has also been made in connection with high voltage impulse tests on transformer insulation. In fact, at the start of transformer impulse testing, considerable fear was expressed that subjecting insulation to excessively high voltages might cause deterioration which would later show up as a service failure and that such failure might not occur if the high voltage tests had not been made. I think practically all of our operating experience today relegates most of this philosophy of high voltage testing to a minor factor in successfully operating modern high voltage systems. We have good reason to believe at the present time that there is much insulation in service not only in bushings but in many transformers including some power transformers and certainly a large number of distribution transformers where the insulation has undoubtedly been injured by excess lightning voltages; yet it appears that such insulation was able to give a high grade of service, although, of course, no operator would choose such insulation in preference to that which has not become deteriorated.

It is, of course, true that the opinion is prevalent that it is desirable to test under operating conditions as nearly as possible, and this means at operating voltage. However, before deciding on such a procedure, it might be well established that testing in this way will uncover a sufficiently larger number of hazardous faults than cannot be detected by the commonly used and flexible lower voltage test, if such is the case. There are a number of complications which enter the picture in practical field testing when an attempt is made to test at operating or rated voltage. First, the testing equipment becomes cumbersome, and second, Y connected transformers with graded insulation do not lend themselves at all to testing the high voltage end at operating voltage.

There is, however, one field where it would seem that this idea of testing at operating voltage, or even above, has very practical application and might prove of considerable benefit to the industry, and that is, in the testing of new equipment in the factory before it is sent out into the field. I would like to suggest as one of the practical uses to which high voltage power factor testing might be put, that of routine testing in the factory of high voltage bushings at apparatus rated voltage and perhaps some 25 per cent or so above this, to determine not only design defects but manufacturing faults as well. Overvoltage dielectric tests, as is well known, are now made on practically all completely assembled high voltage equipment. Why would it not be an excellent idea to establish the high voltage power factor test as a standard commercial test for practically all bushings, certainly in the higher voltage ranges above 15-kv rating?

Charles F. Hill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): We have recognized the value of high voltages in the measurement of power factor of bushings as proposed by Brownlee and Wickham, and have used them in development and design studies for several years.

We have not been concerned, however, about the presence of small amounts of internal corona except in that the amount of such corona losses indicates the degree of mechanical perfection. The opinion of the authors that internal corona will lead to the destruction of the insulation does not seem to agree with our experience and a theoretical analysis of the various types of corona action possible would seem to verify our observations.

Corona reacts on insulation in three possible ways; namely,

1. Thermally by heat generated.
2. By electron bombardment.
3. By chemical action.

The thermal action is due to the heat generated by the corona discharge itself and the resulting temperature rise of the insulation around the void. Bushings have a capacitance of the order of 200 μμf. At 40 kv for curve 1 of figure 1 of the Brownlee and Wickham paper the power factor increment due to corona is 0.04 per cent. The power loss is therefore

$$2\pi fCE^2 \times 0.0004 = 0.012 \text{ watts}$$

It would require energy at a rate at least 100 times greater than this to be serious if the void is of appreciable area. Even at 100 kv the loss would be only 0.25 watt.

The second type of reaction, electron bombardment of the walls of the void, can also be treated theoretically. Approximately 12 and 15 electron volts are required to ionize O_2 and N_2 with one impact. The mean electron-volt energy at one atmosphere under gradients in the void as exist for curve 1 of figure 1 at 40 kv amounts to 3.5 to 4 electron volts. It is also evident since at 40 kv corona is just starting, only enough electrons have reached the 12 to 15 electron volt value to ionize a small part of the gas. Electrons with 10 to 20 electron-volt energies should not affect solid insulation although the critical electron volt energies to affect cellulose, for example, are probably not known. We do know that in the high voltage cable where gradients are four to five times those used in bushings and where mean free paths are much greater due to reduced gas pressure in the voids, thus giving electron volt energies of approximately 10 times that possible in bushing voids, the oil is affected, but so far as I know the paper is not. Fellows and Schoepfle (*Ind. Eng. Chem.*, vol. 21, 1929, page 529) were able to deteriorate paper by electron bombardment with energies of several thousand electron volts and state that the effect could have been done at somewhat lower energies. This is the only direct information I have seen but it seems probable that the 15 to 20 electron volt energies available in the bushing are quite negligible.

The chemical type of reaction is, of course, oxidation. This occurs only if O_2 is present. With sealed voids the original oxygen would react and disappear and no further action would occur unless the void can breathe. We would expect, and have observed, discoloration as the authors mention, but I do not believe it possible for any internal void to breathe sufficiently to allow material damage, as the bushing is sealed top and bottom from the air. It would be quite interesting to dissect some old condenser bushings that have been operating 15 to 20 years as a check on these calculations, for I am sure voids could be found which have been operating with appreciable corona throughout their life.

As stated at the beginning, we have been concerned with voids as a check on mechanical structure, but in that case, only from the standpoint of design of bushing, design of winding equipment, and materials, so that high voltages have been used merely as a laboratory tool. It has been our opinion, therefore, that a ten-kilovolt power factor test is practically as valuable as a far higher test. There is no objection to the use of higher voltages and whether they are used would seem to be a question of economics and convenience.

L. R. Ludwig and H. J. Lingal (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The study which the authors have made of conditions in bushings is of considerable interest to operators and manufacturers alike, and the results disclosed with respect to condenser bushings have been before the designers of this apparatus for several years as a result of their development activities.

Ionization and voids in condenser bushings can be detected, as stated by the authors, by using high voltage power factor tests to determine the power factor as a function of voltage. High voltage power factor measuring equipment has been available to the discussers for a long time, during which it has been used for design and development tests.

Figure 1 shows typical curves of power factor plotted as a function of voltage. These curves were made on a 34.5-kv bushing with voltages from 10 to 50 kv. Curves 1 and 2 were made on production bushings and represent the present standard of quality. To show the effect of voids on the power factor voltage curves, two bushings were made in which voids were deliberately introduced. The bushing from which curve 3 was obtained was built by folding the paper over part of the bushing length. The bushing from which curve 4 was obtained had strips cut from the paper. The figure shows that bushing 3 showed a decided increase in power factor with voltage. The standard bushings 1 and 2 do not show this effect and even bushing 4 appears satisfactory, probably because the voids introduced were not sufficient in size to cause measurable corona.

Figure 2 shows typical power factor voltage curves for 115-kv and 69-kv bushings of modern design. These curves are flat and show no ionization.

It is important to eliminate voids in bushings but chiefly for mechanical reasons. Laboratory test results, field experience, and theoretical consideration all indicate that the electrical effect within the voids in reducing the bushing life is of negligible importance. Early bushings were undoubtedly manufactured in such a way that voids were generally present, but nevertheless no condenser bushings have failed in service directly as the result of ionization and corona.

In connection with studies of power factor at varying voltages, major modifications and improvements have been continuously made in winding machines and processes for constructing bushings. Elimination of voids has been accomplished by improvement in winding technique. To insure the quality of the winding in modern bushings, an air pressure test is given every bushing. Sixty-pounds air pressure is introduced at one end of the bushing for a period of 30 minutes and oil is flowed over the exposed surface of the bushing to detect the escape of air in case leakage is present.

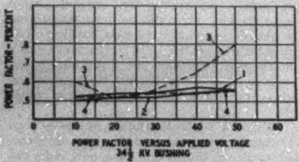

Figure 1

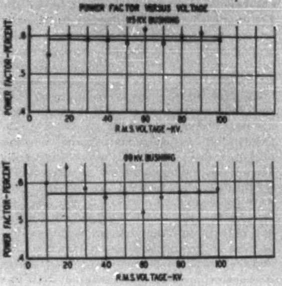

Figure 2

The authors refer specifically to ionization in two 66-kv condenser bushings. These bushings were manufactured more than two years ago and were returned to the factory for investigation. One of them was torn apart for examination and there was sufficient separation of paper layers to explain the curves in the authors' figure 1. The other bushing was returned and placed in service without modification. The degree of ionization and corona shown at 38 kv by curves 1 and 2 in the authors' figure 1 is not excessive. For example, many bushings of older manufacture have been torn down and examined after a large number of years of service. These bushings often contain voids large in comparison to the 66-kv bushings referred to, and yet there has been no effect observed on the insulation. Even discoloration has not been present and it is believed that in the case of the bushings to which the authors refer discoloration resulted from the use of abnormally high test voltage, amounting to 250 per cent of the operating voltage.

The authors refer to partial failure of an older type 34.5-kv potential bushing. The high power factor which they have measured is generally found at the outer layers only. It is one of the important advantages of the condenser type of bushing that the outer layer power factor may change without affecting the voltage distribution sufficiently to endanger the entire device. The litharge and glycerine cement undoubtedly effect the outer layer. This condition was clearly recognized by the manufacturer in 1929 and a stop foil was introduced into these bushings to prevent penetration of this material at that time. In 1934 the use of this cement was discontinued completely.

The authors' comments with respect to laboratory examinations point out the importance of adequate elimination of moisture. It is undoubtedly true that the presence of moisture has been the major reason for high power factor and failure of bushings. The situation has, of course, been well appreciated and condenser bushings have been designed for several years with adequately made seals and plastic and casing material to prevent water from coming into contact with the insulating layers of the bushing. Particular care is taken during manufacture to eliminate entrance of moisture and all bushings are power factor tested to insure that they are dry before shipment.

With respect to the authors' reference to contamination of the mixture of oil and filling compound in a 37-kv bushing, the improved winding and the leak test referred to have proven to be entirely adequate in preventing migration of the oil from the lower end through separations in the impregnated paper to the compound on the top. No difficulties of this kind have been experienced with bushings of modern design.

A. L. Brownlee and W. H. Wickham: In presenting this paper the authors' aim was to stimulate interest in high-voltage power-factor testing of bushings. It was felt that the maximum benefit to be derived from the power-factor test is not obtained when the test voltage is limited to ten kilovolts as is the common practice. This is borne out by the fact that some failures still occur on those systems where the 10-kv power-factor test is used. Extending the test voltage to, or above, operating voltage may offer a means of still further reducing bushing failures. On the system with which the authors are associated there have been no failures on the bushings included in the power-factor testing program since this testing program was inaugurated.

Mr. Gross feels that there is not enough comparative test data obtained at widely different test voltages to support the contention that higher voltages are necessary. Yet the ten-kilovolt test leaves something to be desired. In the paper, "Field Testing of Bushings and Transformer Insulation by the Power-Factor Method," AIEE Transactions, volume 57, 1938 (October section), pages 589–96 Mr. Gross, in discussing the 10-kv power-factor test, states: "Although the goal of complete elimination of all bushing, oil circuit breaker, and transformer failures in service probably never will be reached, the power-factor test method now available and in use by a large number of power companies has proved to be a useful tool in detecting faulty insulation prior to equipment failure in service." He also says: "It is unfortunate that accurate records are not available to show the decrease in bushing failures over the system before and after the test program was adopted. However, from the rather scattered records available from 1932 to 1937, it is interesting to note how closely the frequency of bushing failure and lightning storms coincide throughout the year." We must conclude that even with a program of power-factor testing at ten kilovolts bushings still fail in service, possibly due to higher than normal voltage stress. It is suggested that a power-factor test at a voltage somewhat above operating voltage might reveal some of these incipient faults and still further reduce failures in service. Only by the extensive use of higher voltages can the comprehensive data which Mr. Gross desires be obtained.

Mr. Gross is probably over-estimating the complications of field testing at operating voltage. The experience gained on our 66-kv system has shown that such testing is entirely practical on that system and could be extended still further. While it is true that because of the increased size of the testing transformer the equipment is somewhat more bulky than that required for ten-kilovolt testing it is still entirely practical and convenient to operate. In this respect it compares favorably with the equipment shown in figures 1, 2, and 3 of the paper referred to above. We fail to see the limitations in testing Y-connected transformers with graded insulation.

It has been our practice for some time to test all new bushings at voltages above their operating voltage to reveal manufacturing faults as suggested by Mr. Gross.

Messrs. Ludwig and Lingal have presented power factor vs. voltage curves (figure 1) which show the effect of voids introduced within the bushing insulation and further demonstrate the value of high-voltage power-factor testing in indicating the presence of these voids. The curves of figure 2 are characteristic of those obtained on new bushings without defects but the wide deviation of the points from the average curve is quite unusual. There still remains some question as to the effect of corona within voids on the life of the bushing. The discussers state that no condenser bushings have failed in service directly as a result of ionization and corona but we do not understand how this fact was definitely established since it is difficult to determine the original cause of failure after failure is complete. It is hardly likely that the discoloration of insulation around voids referred to in the paper was caused by the high test voltage. This voltage was applied for so short a time that it could hardly have produced that effect. Dr. Hill states in his discussion that he has observed this same discoloration and that it is to be expected.

Messrs. Ludwig and Lingal state that in modern bushings, improvements in design have been made so that some of the faults discussed in the paper have been eliminated. This fact is realized, but there are a great number of the older bushings still in service whose testing and maintenance is still a problem to the operating companies. A discussion of these faults, which have led to changes in design but were, perhaps, not generally known, should be timely for those engaged in bushing maintenance.

Mr. Wetherill's conclusion that the usefulness of high-voltage power-factor measurements is less on oil-filled bushings than on the solid type agrees with our experience thus far.

It is true that the radio influence voltage measurement will detect the presence of voids within a bushing as well as a high-voltage power-factor measurement. We have used the radio test to some extent in the past. However, a single test is preferred and since the high voltage power-factor test gives the same information on ionization and in addition reveals other types of trouble, it has been adopted in preference to the radio influence voltage measurement.

The bushing of figure 9 was re-examined in an effort to determine whether or not the center portion had been impregnated with a dark compound in manufacture as suggested by Mr. Wetherill. It is quite possible that this was the case, although it is difficult to determine. It was the mixture of this compound with the oil which traveled up through the bushing that gave rise to the high power factor.

The surface power-factor measurements referred to in table III of the paper were made between adjacent foil electrodes on the surface of the bushing parts. The value obtained is, to some extent, dependent on the size and spacing of the electrodes. The electrodes used were one inch wide and one-half inch apart. On insulation in good condition the power factor between adjacent electrodes is nearly the same as the power factor measured between electrodes on opposite surfaces as shown by the data given in table III. On insulation in poor condition the power factor measured between adjacent electrodes is usually much higher.

Dr. Hill's theoretical analysis of the effect of corona in voids within a bushing is interesting and it is unfortunate that more experimental evidence is not available on this point. He has pointed out the fact that voids are undesirable for mechanical reasons, that corona may be present within the voids, and that there is some question as to the effect of this corona upon the insulation. It would seem then that a test such as the high-voltage power-factor test which will reveal these mechanical imperfections is desirable.

The Basis for the Nondestructive Testing of Insulation

Discussion and author's closure of paper 41-118 by R. F. Field, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 890–5.

L. J. Berbarich (Westinghouse Electric and and Manufacturing Company, East Pittsburgh, Pa.): Mr. Field is proposing a new and unfamiliar method for evaluating insulation. There is a need, of course, for more informative tests than we now have. If the new method can be simplified and shown to be effective, it may be quite important in doubtful cases where present methods fail. In its present state of development, however, it still appears to be in the laboratory stage, for it is based on assumptions, implied or expressed, which have not yet been definitely established. The basic assumption appears to be that a correlation between dielectric strength and low frequency interfacial polarization ought to exist. Our experience, however, in attempting to correlate dielectric strength with other properties has not been encouraging except where moisture has diffused into the insulation.

Mr. Field also indicates that free electrons, as well as ions, contribute to interfacial polarization. All of the available evidence, however, indicates that if free electrons are present in solid and liquid insulators at normal voltage stresses, their concentration is very low. There is considerable evidence, on the other hand that practically all of the current in liquid and solid insulators is carried by electrolytic ions. It is only when breakdown gradients are approached that considerable numbers of free electrons are released, when the electrostatic coupling between the electrons and the atoms with which they are associated is ruptured. It is believed, therefore, that free electrons do not contribute appreciably to the polarization in liquids and solids below breakdown stresses.

The present non-destructive tests have been shown to be satisfactory only in determining the infiltration of electrolytically ionizable impurities, such as moisture and oxidized oils, into porous insulation. This type of deterioration, or more appropriately impurity, can be detected by 60 cycle capacitance and power factor and even dielectric absorption measurements, provided it is not too localized. It is difficult to see how any method restricted to the evaluation of the insulation as a whole can be utilized successfully in determining localized deterioration where only a very small percentage of the total insulation is involved.

The present methods have failed, except for the detection of moisture, in generators and to some extent in cables, because the types of deterioration in these cases are both different and more of a localized nature than in bushings and transformers. It is to be expected that Mr. Field's method will be somewhat more sensitive to electrolytic intrusions than other methods, because such intrusions are known to affect the polarization more at very low frequencies than at higher frequencies. Before it will be really effective, however, it must be shown that the new method will detect other types of deterioration.

The method of analyzing dispersion data proposed by the Coles may be helpful in analyzing the low frequency interfacial polarization data. It should, however, be shown that the method will represent such data accurately. The Coles have demonstrated that their procedure applies very well to the type of polarization known to be caused by dipoles, but so far not much is known as to how well it applies to other types of polarization. Mr. Field shows some rather large departures in the few cases of interfacial polarizations he has analyzed. The physical significance of the parameter α discovered by the Coles (called the storage coefficient by Mr. Field) and its relation to dielectric strength are also still unknown, which further complicates the problem.

The insulator, data for which are given in figure 8 of the paper, may be considered a representative model of a two layer dielectric. In this case the Maxwell-Wagner theory of interfacial polarization probably applies. This theory, however, has often been invoked to explain dielectric absorption in relatively pure solids. In such cases, because of the low concentration and distribution of impurities, the layer model must be reduced to molecular dimensions, and then there is no assurance that the theory applies. The existence of dielectric absorption in such a pure solid as quartz, indicates that this theory does not apply and it is believed that it has served only to obscure the true mechanism.

The further investigation of low frequency power factor and dielectric constant for various types of insulations, should prove very interesting and informative. Perhaps it can be shown that the use of two frequencies, say 15 and 60 cycles will give more information than is possible with results at the single frequency now used in field tests. Mr. Field's proposals should be paralleled with methods used at present before conclusions can be drawn as to their suitability for routine testing.

Robert F. Field: Dr. Berberich in his discussion has stated several times that I have proposed a new method for the non-destructive testing of insulation. This was not at all the object of the paper. Starting with the assumption that 60-cycle measurements have been moderately successful in such testing, the intent was to find out what electrical properties are involved. It immediately became apparent that the existing polarizations define the values of dielectric constant and loss factor at 60 cycles and at all other frequencies. Hence the parameters which define these polarizations acquire significance in non-destructive testing. It happens that the polarization mainly responsible for 60-cycle dissipation factor has a relaxation frequency well below one cycle per second and its parameters can best be determined from current-time curves. Thus it is not a new method that is advocated but an expansion of the old method, which should make possible the identification of the type of deterioration as well as its magnitude.

The point made by Dr. Berberich that much work must be done in studying the changes in the polarization parameters as deterioration progresses and in correlating these changes with decreases in dielectric strength is very well taken. The need for such studies was suggested in the paper. Not until numerical values can be assigned to the polarization parameters of all the common insulating materials and to their temperature and voltage coefficients will it be possible to interpret completely the changes in these parameters caused by deterioration.

The A-C Dielectric-Loss and Power-Factor Method for Field Investigation of Electrical Insulation

Discussion of paper 41-132 by F. C. Doble, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (October section), pages 934–9.

Eric A. Walker (The University of Connecticut, Storrs, Conn.): The reason for making a test on insulation in service is to determine if that insulation will continue to fulfill its purpose until the next test is made. Mr. Field, in his paper, points out that there are several measurable electrical quantities which might be considered as a basis for a non-destructive determination of breakdown strength. Mr. Doble, in his paper, and in the references he cites, shows that a dielectric loss and power factor test, properly conducted with 60 cycles, at ten kilovolts, approximately once a year, will greatly reduce the number of insulation failures. Mr. Brownlee, in his paper, now states that there are faults which are only revealed at operating voltage. This claim is worthy of some examination.

It is well known that there are certain types of faults which are non-linear, which only become evident at higher voltage gradients. This was conclusively demonstrated in a series of tests on more than 200 bushings in the summer of 1937. Such faults are usually ionic in nature and are the result of voids in the solid insulation. To reveal them by increased watts loss or power factor, it is necessary to increase the voltage gradient. Notice it is the voltage gradient which must be increased and not necessarily the voltage. There are two ways to increase the voltage gradient. One is to increase the total voltage and the other is to change the shape of the electrodes. Mr. Brownlee chooses the former method and Mr. Doble chooses the latter. Mr. Brownlee raises the voltage to operating voltage and in so doing may run the risk of measuring corona losses from the stud and connected apparatus. Mr. Doble continues to use ten kilovolts but he places an auxiliary electrode in a position which increases the gradient and in a position which experience has shown will reveal incipient faults.

The added complication and cost of a full voltage test can only be justified if experience shows that such a test will lower the number of failures below that attained by a properly conducted test at ten kilovolts. I do not believe Mr. Brownlee makes such a claim.

Gordon B. Tebo (Hydro-Electric Power Commission of Ontario, Toronto, Ontario, Can.): It is opportune that Mr. Doble's paper, describing one of the insulation test methods used extensively in the United States, should be presented at a convention here in Canada. The similarity of apparatus design and of service conditions existing in the two countries has naturally produced similar types of fault and usually similar maintenance methods are employed for their detection and repair. When a clear exception to this general rule occurs, it is interesting to enquire into the reasons.

Judging from the technical literature, the field testing of bushings in the United States is carried out largely by measurement of power factor and capacity. In Canada, the same types of bushings are regularly tested and the same types of faults detected, but by an entirely different method, that is, by direct measurement of potential gradient at operating voltage. This method was described in *Electrical World* for May 8, 1937. The two methods have been applied to large numbers of bushings, have been in regular use for several years, and each is apparently producing satisfactory results. It seems reasonable to assume, then, that each method has certain advantages, and that the maximum benefit will result from the use of both methods, each applied in its proper field.

Mr. Doble disposes of the potential gradient method in the statement—"The voltage distribution method was first tried, but this method failed to reveal many types of defective insulation that were responsible for costly service interruptions." I should like to ask Mr. Doble what type of measuring equipment was used to determine potential gradient in these preliminary tests. It is possible that inadequate instrumentation or interpretation of results was responsible for the negative results.

For the testing of bushings, the experience of the Hydro-Electric Power Commission of Ontario with the potential gradient method, over a period of five years, has been entirely satisfactory. The simplicity of the test equipment, the speed with which bushings, bus supports, lightning arrester stacks, and cable potheads can be tested and, above all, the freedom from interruptions to service for testing, appear to be important advantages.

For the testing of transformer and machine insulation, cables, and circuit breaker lift rods, to which gradient or other live-line tests are not applicable, several methods are being studied. These include measurements of insulation resistance, dielectric absorption, ionization voltage, power factor and dielectric constant at various voltages and frequencies. There seem to be insufficient data available correlating these various test methods with each other, and with operating experience, to support the choice of capacity and power factor at ten kilovolts, 60 cycles, as the best criterion of insulation condition.

J. B. Whitehead (Johns Hopkins University, Baltimore, Md.): Those who have had occasion to make dielectric measurements at high voltage using the Schering bridge learned very early the importance of electrostatic screening for the avoidance of errors due to the shunted capacitance of circuit connections. It is interesting to note that in the noticeable progressive improvement made by Mr. Doble in his field equipment, the same type of precaution becomes necessary in the very much older and simpler electrodynamometer method upon which his equipment is based.

An abnormal rise of power factor in high voltage equipment should undoubtedly be taken as evidence that advanced deterioration has occurred and that early trouble may be expected. Measurements of power factor on operating equipment, by the Doble or other method, should certainly therefore be useful in avoiding unforeseen trouble. However, it should be noted that for certain conclusion, some knowledge should be had of the normal loss and power factor characteristics of each particular type of equipment, and in fact of each individual piece of equipment. Different materials differ widely as to normal values of power factor and loss within the range of frequency and voltage under which they operate. Moreover, in certain types of equipment, as for example impregnated paper as found in cables, and capacitor type bushings, progressive failure due to a weak spot or incipient puncture may be well on its way before there is appreciable rise in the over-all value of the power factor. High power factor of bushings, terminals, joints, and cables, therefore, may well be accepted as a cause for early trouble, but the absence of a high value is no guarantee that trouble has not already begun.

I. W. Gross (American Gas and Electric Service Corporation, New York, N. Y.): The paper by Mr. Doble describing some of the technique used in developing the power factor test set for field use indicates quite clearly some of the difficulties which were first encountered in an attempt to produce a workable and reliable field power factor test set. The transition from measurement of volts, amperes, and watts in a circuit as carried on in the laboratory under ideal conditions, to a practical determination of these values under adverse field conditions, is one that has taken time, persistency, and a thorough understanding and follow-up of the electrical circuits and influences involved. Mr. Doble is to be complimented on not only the work which he has done in perfecting this type of instrument and adapting it for use under field conditions, but also for the development work which he is consistently carrying on to keep this test equipment ready to meet the ever increasing demands of field testing and servicing of high voltage insulation.

In our own company we are now using several of these field power factor test sets regularly throughout the year with the same certainty and dependence that we place on an ordinary voltmeter and ammeter. Since first using this set some ten years ago, our company was principally concerned with the results obtained by its use and the improvement in performance of the equipment which was periodically tested, as has been reported by several papers presented in recent years on this subject by our own organization. The results we have obtained in eliminating potential hazards to the system are a matter of record. It is indeed gratifying to find that Mr. Doble has seen fit to uncover the detailed technique which he has used in the development of his series of test sets which have been proving to the industry a valuable tool in the maintenance of high voltage insulation in the field.

E. D. Doyle (Leeds and Northrup Company, Philadelphia, Pa.): Mr. Doble's effort to distinguish his method and apparatus from others useful in the same field is to be commended. However, it is regretted that in choosing a name he did not take one more truly descriptive of his method of measurement. As power factor can only be obtained with his apparatus by calculation from the readings of volts, amperes, and watts, it would seem preferable to use the term "watt/volt-ampere method" and leave the term "power factor" for those systems in which it can be read directly.

It is surprising that, after having taken all the precautions that have been taken to eliminate effects of extraneous disturbances, it is still necessary to determine power factor by differences between two quantities as large as those in the given example.

Referring to the "example" and assuming that the 2.4 watt scale of the wattmeter was used, the two watt readings are respectively 79 and 67 percent of full scale, whereas the true value is only 6 percent of full scale. Under the circumstances a calculated power factor coming within 5 percent of the true power factor is an unusually close agreement.

Mr. Doble states that in calculating power factor from reversed readings the average of the currents may be used. Such a procedure is only justified when the test current and the current due to extraneous disturbances are substantially in phase or in opposition. While one cannot be certain from the values given in the example in which quadrants the resulting currents lie, it is a fair assumption that the current for the direct reading will lie in the first quadrant. On the other hand, the current for the reversed reading might be, so far as can be determined from the instrument readings, in either the second or third quadrants. Assuming that the current for the reversed reading is in the second quadrant, the true value of the test current is found to be 771 microamperes as compared with an average of the two currents given of 790 microamperes. This difference will make substantially no difference in the calculated power factor. On the other hand, if the current for the reversed reading lies in the third quadrant, it will be found that the true value of the test current would be 105 microamperes and the true power factor would be 14.3 percent. In the absence of other instrumental procedure, it is fortunate that the power factor could also be determined for check purposes in an environment free of extraneous disturbances.

If reactive volt-amperes had been read instead of currents, the effect of extraneous disturbances could have been properly eliminated by taking direct and reverse readings of watts and reactive volt-amperes. Such instrumentation has been already described before the Institute as long ago as 1918.

The bibliography would be more useful had it also included the patents disclosing the systems herein described, i.e., patents numbers 1,945,263, issued January 30, 1934 and 2,170,813, issued August 29, 1939.

F. C. Doble: Technically the testing method described by Mr. Tebo as representing the Canadian practice is entirely different from the watts-loss and power-factor method under discussion. His method depends upon a measurement of the potential gradient or voltage distribution with respect to ground over the outside surface of the porcelain rainshield of a given bushing. Extensive field experience has shown that many types of deterioration in the main insulation of a bushing are not reflected by a change in the external voltage distribution.

It is evident from analysis that a distributed deterioration up to a point near failure may cause no change in the external voltage distribution.

Further, as pointed out by Mr. Tebo, his live line method is not applicable to the internal insulation of circuit breakers and transformers, where many failure hazards occur.

Answering Mr. Tebo's question as to the type of measuring equipment used to determine the potential gradient in the voltage distribution tests mentioned in this paper, the apparatus referred to was developed by the author and proved reliable by several millions of tests in the field on all commercial transmission line voltages.

It was the limitations in the application of the voltage distribution method rather than inadequate instrumentation or interpretation of results that prompted the search for a testing method of wider scope.

Data from experience in the United States with the watts-loss and power-factor method, as outlined in the bibliography, have a direct bearing on the last paragraph of Mr. Tebo's discussion.

In connection with Mr. Doyle's comments on the naming of the author's test method, it should be noted that when the nomenclature was chosen there was no necessity for distinguishing this method from others useful in the same field as such "others" were non-existent until long after the "watts-loss and power-factor" terminology had become widely accepted.

The "example" given in the paper was selected to illustrate a certain point and the magnitude of the quantities measured should not be taken as an average condition encountered in the field. However, it should be borne in mind that the equipment described in the paper was specifically designed to meet special as well as average cases and that the "unusually close agreement" between calculated and true power factor is not too unusual under the circumstances.

The statement concerning the averaging of currents has been found to be true for practically all cases so far encountered in field work, since in general the magnitude of the current from induced voltages is small in comparison with the current through the specimen resulting from the test voltage. Mr. Doyle's assumption that the current for the reversed reading might lie in the third quadrant in the example given in the paper would require an induced current of 790 microamperes in a specimen with a test current of 105 microamperes, which is a condition difficult to imagine in practice.

In the event that any doubt exists as to the magnitude of the induced current, its value can be obtained directly by reading the ammeter with no test voltage applied to the specimen. Using this current and the currents obtained from the direct and reversed readings, the true value of the specimen test current, even under adverse conditions, may be determined by calculation.

Referring to the last paragraph in Mr. Doyle's discussion, the author believed that it might be more ethical to omit the patent numbers from the bibliography.

The Protection of Solid Insulation by Lightning Arresters

Discussion and authors' closure of paper 41-133 by D. D. MacCarthy and T. J. Carpenter, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (October section), pages 912–15.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): I wish to compliment the authors on their contribution to the field of knowledge of the impulse voltage characteristics of solid insulation.

As pointed out by the authors, their results differ somewhat from the results that I have obtained for larger insulation spacings in that (1) the turn-up of the volt-time curve is less; and (2) the ratio of repeated to single shot breakdown is less than I obtained. Considering the difference in the structure of the pads used by the authors and as used in my tests, I feel that the difference in results is quite logical.

The maximum thickness of their barriers

was 40 mils which is considerably less than any solid barriers that I have tested. The smaller turn-up for the pads used by the authors, I believe, is due entirely to the nearly uniform field resulting from the short spacing between the electrodes. The same difference in turn-up on the volt-time curve of rod gaps having small and large spacings has been found. In fact, for very small spacings a rod gap acts quite like a sphere gap. The same phenomenon, no doubt, applies to thin pads of insulation. The fact, as pointed out by the authors, that the breakdown voltage of the insulation as shown in figure 4 of the paper increased linearly with the thickness, is proof that the dielectric field was approximately uniform. For non-uniform fields the breakdown strength of insulation varies approximately as the thickness raised to the two-thirds power.

In reference to the repeated shot strength being 70 per cent of the single shot strength, the only condition where I found the value to be less than 80 per cent was when I used bare electrodes in which case it was as low as 60 per cent due to the appearance of corona at relatively low voltages. I have no very logical reason to offer as to why the authors obtained 70 per cent unless it was due to the absence of free oil in series with the solid. I have obtained repeated shot values as high as approximately 90 per cent of the single shot values for high voltage barriers, but the minimum and safe value appears to be approximately 80 per cent. I believe, therefore, that the authors' value lower than 80 per cent was due mostly to the fact that there was no free oil present.

P. L. Bellaschi (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): The paper by Messrs. MacCarthy and Carpenter is interesting in that it illustrates certain principles on protection. It is apparent, however, that the conclusions in the paper apply to the insulation sample (figure 1 of the paper) they have selected for their comparative tests. This insulation sample naturally has a flat volt-time characteristic as it is known from tests on similar, solid-layer insulation samples (AIEE TRANSACTIONS, volume 60, 1941, page 400, discussion by P. L. Bellaschi and W. L. Teague). This flat characteristic is not generally representative of surge-proof distribution transformers. In the modern power as well as in the present-day distribution transformer, with which the writer is familiar, the volt-time characteristic is more pronounced, attaining for a 0.25 microsecond impulse, some 150 per cent or greater the two microsecond crest value (figure 3, "Protection of Power Transformers Against Lightning Surges," AIEE Transformer Subcommittee, AIEE TRANSACTIONS, volume 60, 1941, page 568).

In regard to the ratio of the breakdown voltage for repeated and single applications, the value (0.70) cited in the paper applies specifically to the sample tested and is not necessarily the same for distribution transformers in general. This ratio depends on the "injurious corona level" of the whole insulation and on other features of design. It is well to note that the significance of the single-shot strength has long been open to much questioning. In this connection, the practice in recent years has been to consider the volt-time characteristic of insulation on the basis of repeated tests and thus do away with a factor of doubtful value.

Experience has demonstrated that dependable conclusions on transformer insulation and protection can be reached only from comprehensive tests on the complete apparatus plus field experience over a period of years. These tests should be carried well up to the steep-front, high-current surges; for the frequency of occurrence of the higher currents, particularly on rural circuits, is by no means a negligible quantity as it can be noted from reference 2 of the paper as well as from other sources of field experience.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): The interpretation of the test results in this paper, which apparently apply to some types of transformer insulation, is made somewhat difficult due to the type of the electrodes used. Some supplementary tests with well-defined electrodes would have given information of more general application. The spiral electrodes used introduce variables difficult to evaluate. The stresses are not definitely known. The fact that the spirals were tied by means of threads must result in either oil gaps between the electrode and paper pads or damage to the pads due to impressions from the threads. Actually all failures occurred at the points of threads and therefore might have been promoted by breakdown of the oil gaps or by impressions on the paper pads.

The great difference in surge strength of the paper pads and the paper wrapped upon the spiral is of interest. According to figure 4 of the paper, the one-microsecond surge strength of the paper pads is 2,660 volts per mil while the surge breakdown voltage of 20 kv for the 20 mils of wrapped insulation corresponds to only 1,000 volts per mil. Incidentally, this 2,660 value compares favorably with a surge breakdown strength of 2,000 to 3,400 volts per mil on a maximum stress basis obtained for commercial cable insulation.

The comparatively low values for the insulation wrapped on the spirals are probably caused by distortion of the field, nonuniformity of the insulation due to wrapping and due to the threads, and the fact that the wrapped insulation is not continuous as in the pads. Conversely, apparently higher overall strength may be obtained in transformer and other insulation when these disturbing factors are absent. This point is substantiated by data, e.g., in the paper by L. I. Komives at this convention.

It is extremely interesting to note the authors' conclusion that the insulation can stand safely surges up to 70 per cent of the single-shot breakdown strength.

D. D. MacCarthy and **T. J. Carpenter**: In his discussion, Montsinger has offered an explanation for the differences between the results of the present investigation and the results that he obtained in tests on high voltage insulation. It is gratifying to the authors to see that there are no irreconcilable differences between the results of their tests and those which Montsinger has obtained.

The authors agree with Mr. Bellaschi that the samples tested cannot be considered as having the same insulation strength as transformers. In the paper it was stated: "Although all of the materials in the pads are used for certain types of insulation in transformers, the pads as tested cannot be considered as representing the actual insulation strength of transformers, since in transformers steep impulse waves may result in an unequal distribution of voltage along the turns and the major insulation does not consist of paper sheets alone." Concerning the difference in the shape of the puncture voltage-time characteristic, it should be noted that the figures given by Bellaschi compare the insulation strength at 0.25 microsecond on the wave front with that at two microseconds on the tail of a 1.5x40 microsecond wave; whereas the comparison made by the authors was based on puncture at 0.25 and 1.0 microsecond, both on the front of uniformly rising voltage waves. These two sets of data differ not only because of the difference in wave shape, but there is also a difference of two to one in the range of time for which the turn up is compared.

The authors believe that the figure of 70 per cent found for the repeated shot strength of the low voltage insulation tested is in reasonable agreement with the range of 65 to 90 per cent found for high voltage insulation.

Bellaschi has mentioned the need for tests at high impulse currents. The authors did not feel the need for such tests since the effect of arrester *IR* voltage can be predicted from the volt-time puncture curve of the insulation and the arrester voltage. For example, test 9 in the tabulation in the paper was made with an *IR* voltage of 55 kilovolts across a constant resistance. To obtain the same crest *IR* voltage with the valve type arresters used in tests 2 and 3, a discharge current magnitude of 60,000 amperes would be required, providing the current wave was 10x20 microseconds. This *IR* voltage is less than 70 per cent of the single shot strength of the pads tested in parallel with gaps equivalent to a rod gap set 2 inches, see tests 10 through 21.

Mr. Halperin states that electrodes of more regular shape would have been preferable. It is true that such electrodes would give more uniform fields and would be better if the purpose of the investigation had been to determine dielectric strength of the insulation in kilovolts per mil. However, the electrodes used were chosen in the effort to simulate the insulation used in actual apparatus rather than to determine the physical properties of the insulation materials.

The explanation that Halperin gives for the relatively low strength of the paper wrapping on the line electrode and for the tendency of puncture to occur at the edge of the coils is in agreement with the authors' statement in the paper. It is of interest to note that the strength of the paper pads is of the same order as has been found for paper insulation in tests on cables.

System Short-Circuit Currents

Discussion and authors' closure of paper 41-121 by W. M. Hanna, H. A. Travers, C. F. Wagner, C. A. Woodrow, and W. F. Skeats, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 877–81.

G. C. Crossman (Consolidated Edison Company of New York, Inc., New York, N. Y.): The paper presents a simple method of calculating short circuit currents which should prove very valuable, particularly for determining circuit breaker interrupting capacity and mechanical stresses.

However, many power station busses and switch gear are of the isolated phase type of construction where it is practically impossible for faults to occur except from line to ground. While the paper appears to be based primarily on three-phase faults, it does indicate that the same method of fault current determination may be used for determining circuit breaker interrupting capacity for such ground faults. It is indicated that the same multiplying factors should be applied to the calculated instantaneous symmetrical current to obtain the maximum asymmetrical current at the time of arc interruption.

These factors appear to be based in part upon the decrement of the direct current component of three-phase fault currents. Consequently, the added resistance of the ground return will shorten the duration of this component for line to ground faults. With the usual design of station ground bus and grounding system and particularly when only one of a number of paralleled generators is grounded, the duration of this d-c component may be very materially shortened. Tests recently made at one of the generating stations of the Consolidated Edison Company indicated a reduction of approximately 50 per cent in the time constant of the d-c component for a single phase, bus short circuit as compared with the corresponding three-phase fault. A single generator unit, a 160,000-kw cross-compound machine, was used in these tests with one of the two generators of the unit solidly grounded. Had other ungrounded generators been operating in parallel with this machine during these tests, the reduction of the d-c time constant for a line to ground fault would have been still greater.

Consequently, if bus circuit breaker interrupting capacities are determined by line to ground faults, the calculation of these faults by the method given in the paper will provide an additional factor of safety. It might seem desirable in some cases not to use this additional safety factor and to buy a smaller breaker instead. However, the difficulty of determining the ground return resistance with any degree of accuracy for most power stations would probably prevent any such saving.

W. R. Brownlee (The Commonwealth & Southern Corporation, Jackson, Mich.): In view of the wide variations encountered in supply system characteristics, the authors have reached a remarkably logical method for general use in the calculation of short circuit currents. In the application of faster breakers and fuses, and in the consideration of mechanical stresses, the system d-c time constant is shown to play a major part. It has been customary for the user in applying breakers to calculate the symmetrical short circuit current and then to select a standard interrupting duty breaker with some margin of safety based on experience and judgment. System information which must be assembled for the calculation of symmetrical short circuit current will frequently include almost enough data for determining the d-c time constant with reasonable accuracy. Thus, even for users of interrupting equipment who prefer to consider specific system conditions individually, the paper is of great value in focusing attention on the relative importance of various factors such as the subtransient time constant, the d-c time constant, the effect of voltage regulators, the influence of relative phase positions of synchronous machines, and the influence of arc resistance.

Except for the case of faults at a generating station bus (which is covered by a definite exception in the paper recommending as much as 20 per cent increase in calculated current), the method outlined appears to be quite conservative. Recommendations take little account of the effect of arc drop on the d-c time constant, although the paper mentions a reduction of three to one in this time constant by means of arc voltages which may safely be considered as minimum values, particularly in the case of low voltage circuits. The method described in the paper further assumes that the fault is initiated at the point on the voltage wave which will produce a completely offset current wave. Since the interrupting duty is taken as the maximum value, this viewpoint can probably be justified for operations involving the closing of the breaker onto a fault. However, since maximum interrupting ability is expressed on a two unit basis, the first interruption will usually result from a flashover tending to produce a rather symmetrical current wave, and accordingly the assumption of complete current wave displacement for both operations may be unnecessarily conservative.

It is difficult to apply general reduction factors for equipment operated at five kilovolts and below, especially in the case of supply to station auxiliaries, which use accounts for a large number of breakers operating at 2,400 volts and 480 volts. If the supply for station auxiliaries is taken from a high capacity bus through current limiting reactors, the d-c time constant may easily approach that of a generator bus, whereas in many installations the supply is from a 5,000-kva or smaller transformer bank, with a resulting d-c time constant of around 1 cycle (or about one-third the typical value for transformers given in the paper).

While the general factors recommended in the paper are unquestionably of material value in clarifying the problem of short circuit calculations and in providing information of a general nature, it is suggested that purchasers of interrupting equipment will find it well worth while to include in their short circuit calculations enough information to determine whether the d-c time constant at the point of application is materially different from the assumed average value of nine cycles.

G. W. Hampe (Commonwealth Edison Company, Chicago, Ill.): For determining the maximum duty of circuit breakers, the short circuit calculating procedure outlined by the committee doubtless represents a distinct advance. For relays, however, its utility is considerably less for the following reasons:

1. It adds nothing to the technique of determining current values occurring appreciably after the start of the fault.
2. It takes no account of a little understood class of transient phenomena which influences high speed relays—ground relays in particular.

High speed relays for protection against interphase faults are usually pilot channel or distance types and hence require only crude determinations of fault currents, supplemented frequently by staged short circuit tests in which the combined effect of load and fault currents can be investigated.

The need for short circuit computations arises chiefly in determination of settings for back-up relays having operating times exceeding 0.5 second. This means that the difficulties ruled out by the conditions as set forth in the paper are still with us. They result from the multiplicity and wide distribution of machines, phase angles, excitations, changes of excitation, changes of saturation, and other causes.

It is true that the use of standard decrement curves is difficult and may be misleading. In the computations with which the writer is familiar such curves have not been used for a number of years. In the rare cases in which a number of relays operate sequentially at considerable intervals, the decrement (or increment) curves are evaluated and plotted for individual lines from values determined by the "internal voltage" method.

In general, however, values useful for settings on a wide range of relay types can be obtained by computing with transient voltage and impedance values for synchronous machines, with each machine impedance value adjusted to meet local conditions. The exceptions are:

1. Faults substantially at machine terminals.
2. Values specifically needed for high speed relays.

There is definite need for investigation of phenomena of the type shown on the attached oscillogram. Such phenomena are distinctly outside the scope of the present paper, and even outside the scope of the basic theory of symmetrical components, but in making settings on high speed relays they are important. Usually such transients appear as residual currents and have the greatest effect on ground relays. In many cases current transformer defects, such as remanent core magnetization cause considerable spurious residual currents, but in other instances such as that shown on the oscillogram the residual transient of about 1,400 amperes peak actually existed on the line and in the power bank neutrals. This phenomenon occurred during a staged test. A three phase fault was applied to the intermediate voltage (33 kv) winding of a wye-wye-delta bank, and the bank was made alive over a 132-kv line consisting of six miles of underground cable and 3.5 miles of overhead line with an unloaded 27-mile section of overhead line extending beyond the faulted bank. The 132-kv neutrals of the source transformers and of the faulted transformer were grounded solidly.

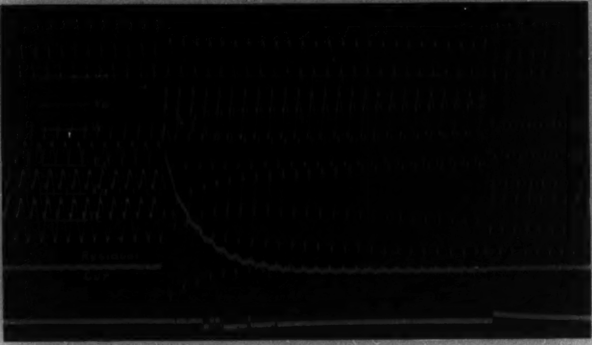

Figure 1

Similar phenomena have been obtained at other times on other equipment, but tests on circuits quite analogous to them showed a complete absence of such transient phenomena.

In view of such phenomena, too much reliance cannot be placed on computations of the type given in this paper where high speed relays are concerned. As a different class of phenomena enters in some cases, further study of the currents affecting high speed relays is needed.

W. M. Hanna, H. A. Travers, C. F. Wagner, C. A. Woodrow and W. F. Skeats: There appear to be some misunderstandings with reference to the treatment of the direct current time constant in the paper. The value of nine cycles is that used in the decrement curves of Hahn and Wagner and represented by the upper curves of figure 1 of the paper. In preparing the present paper, allowance was made for additional resistance in busses and other apparatus, so that considerably lower time constants are used, as is evident from the spread between the upper solid curves and the dotted curves of figure 1.

It should also be noted that the curves of figures 2 and 3 of the paper do include a reasonable allowance for arc drop.

Mr. Crossman's comments with respect to the decay of the d-c component in line-to-ground faults are very interesting. His data with respect to the effect of the resistance in the ground return upon the time constant are quite probably rather broadly representative. However, it should be borne in mind, as explained below, that resistance in the ground return may increase the current in one phase of a two-phase-to-ground fault, and that this condition may bring about higher currents than the single-line-to-ground case. It is not recommended, therefore, that any reduction in breaker size on this account should be considered in such an application.

The authors agree with Mr. Brownlee that short circuits in the field more frequently approach the symmetrical than the fully offset condition. Nevertheless it is felt that a high degree of offset does occur with sufficient frequency that it should be provided for in the application of interrupting devices.

Mr. Brownlee points out that a wide variation exists in circuits at five kilovolts and below as regards the resistance-reactance ratio and consequently the time constant of the d-c component. Here again the authors agree and accordingly have limited the application of any reduced multiplying factor in connection with such circuits so as to except cases where the fault current is fed predominantly by directly connected synchronous machines or through reactors.

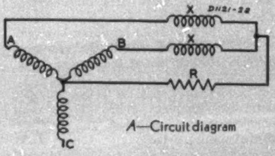
Mr. Hampe presents an interesting discussion of the determination of short-circuit currents long after the inception of short circuit for the purpose of setting back-up relays. Others faced with the same problem will undoubtedly find his suggestions helpful.

Mr. Hampe also shows an oscillogram of a three-phase-to-ground short circuit in which although there exists no normal frequency current in the neutral, there does exist there a unidirectional transient of considerable relative magnitude. This is caused by sequential closing of the circuit through the phases to ground in such a way that the d-c components from the three phases add in the neutral, or at least do not completely balance out as they would if the fault were established simultaneously in all three phases. We may assume for simplicity a circuit in which positive, negative, and zero phase sequence reactances are all equal so that a change in the current in one phase will not be reflected in the other two. Now with phase rotation *ABC*, assume phase *A* grounded at such a time as to give a fully displaced wave. This will produce both a-c and d-c components equal to the corresponding phase currents in the neutral. Now suppose that 120 degrees later phase *B* is grounded. This will also produce a fully displaced wave giving rise to both a-c and d-c components in the neutral. The a-c components from the two phases will add vectorially at an angle of 120 degrees, but the d-c components will have the same polarity and add arithmetically. If after another 120 degrees phase *C* is grounded, it also will contribute both a-c and d-c components to the neutral circuit. The three a-c components will now add vectorially in such a way as to cancel out, but the three d-c components will all have the same polarity and will add arithmetically. Thus a unidirectional surge will be obtained as shown on Mr. Hampe's oscillogram.

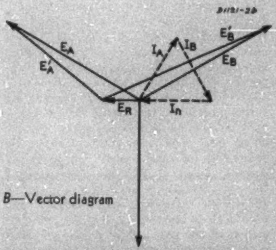
It will be readily appreciated that the same type of phenomenon can take place with other relations among the phase sequence reactances than those assumed although the magnitude of current involved may be somewhat modified.

It will also be appreciated that the magnitude of neutral current obtained in this way for a given circuit will vary from one fault to another even under apparently duplicate conditions since the amount and polarity of d-c component contributed with the faulting of each phase is dependent upon the point on the voltage wave at which the fault is completed in that phase.

Inasmuch as considerably higher neutral currents may be obtained in this way than under any normal fault conditions for a circuit of equal reactance, it is possible that it may occasionally result in false tripping of high-speed ground relays with selective operation based on the magnitude of neutral current. Relays may be obtained, however, which are sensitive only to normal frequency current and such relays will operate satisfactorily.



A—Circuit diagram



B—Vector diagram

Figure 2. Double-line-to-ground fault with resistance in ground return

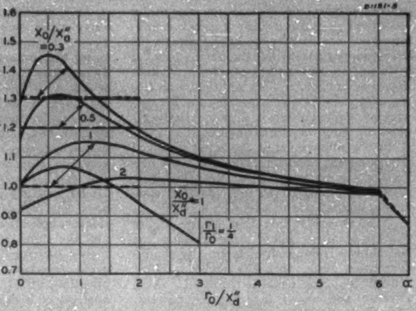
The procedure proposed in the paper calls for the determination of "the highest value of rms symmetrical current for any type of fault using subtransient reactance. . ." but gives no further instructions for the determination of this quantity. The following comments will be helpful in this respect. Let

E = leg voltage

X_d'' = circuit reactance as viewed from point of fault using direct axis subtransient reactance for generators, load machines being represented as specified in the paper

Figure 3. Maximum phase current for a double line-to-ground short circuit expressed as a ratio to E/X_d''

Dotted lines are plotted for $3E/(2X_d''+X_0)$ $X_2=X_d''$



X_2 = negative phase sequence reactance of circuit

X_0 = zero phase sequence reactance of circuit

Then the three-phase short-circuit current is $\frac{E}{X_d''}$. The line-to-line short-circuit current is $\frac{\sqrt{3}E}{X_d''+X_2}$. Since X_2 is always at least equal to X_d'', this quantity never exceeds 86% of the three-phase short-circuit current and consequently may be neglected.

The line-to-ground short-circuit current is $\frac{3E}{X_d''+X_2+X_0}$. Since X_2 is usually approximately equal to X_d'', this expression is often shortened to $\frac{3E}{2X_d''+X_0}$. It may also be noted that, as explained in more detail below, the latter expression serves reasonably well over the important range for double-line-to-ground as well as single-line-to-ground faults, whereas if there is appreciable difference between the two expressions, the former considerably underestimates the double-line-to-ground fault current. The expression $\frac{3E}{2X_d''+X_0}$ is therefore considered preferable for line-to-ground short-circuit currents on the ground of giving more useful information as well as on the ground of convenience. If X_0 is less than X_d'', the value given by this expression exceeds the three-phase short-circuit current and hence becomes the governing quantity.

Neglecting resistance, the double-line-to-ground short-circuit current is given by the expression

$$\sqrt{3}E\frac{\sqrt{X_2^2+X_2X_0+X_0^2}}{X_d''X_2+X_d''X_0+X_2X_0}$$

Except for values of X_0 less than $\frac{X_d''}{4}$, which occur very seldom in practical field circuits, the current corresponding to this formula is exceeded by one or the other of the two quantities recommended for use; that is to say, either by E/X_d''; representing three-phase fault currents, or by $\frac{3E}{(2X_d''+X_0)}$ representing single-line-to-ground fault currents. It is comparatively insensitive to negative phase sequence reactance, however, and consequently may appreciably exceed the quantity $\frac{3E}{X_d''+X_2+X_0}$ if X_2 is much greater than X_d''.

An interesting effect is produced in a double-line-to-ground fault by the existence of different resistance-reactance ratios in the three phase-sequence circuits, as when resistance occurs in the zero phase sequence circuit while it is negligible in the positive and negative phase sequence circuits. While such a resistance decreases the current in one of the faulted phases, as would be expected, it brings about an increase in the current of the other phase.

This may be understood qualitatively from the circuit and vector diagram of figure 2 of this discussion. Figure 2*A* represents a circuit in which phases *A* and *B* of a power source are connected through a reactance *X* in series with each phase and a resistance *R* in the common return to the neutral. The three phase voltages are shown as E_A, E_B, and E_C in the vector diagram, figure 2*B*. As a first approximation, the phase currents may be taken as lagging the phase voltages by 90 degrees, as do I_A and I_B. The neutral current, I_n, then closes the triangle. The voltage across the neutral resistor is in phase with this current, as shown by E_R. The voltages across the phase reactances are then E_A' and E_B', and it will be noted that while E_A' is smaller than E_A, E_B' is larger than E_B. Correspondingly the *A* phase current will be less than if the resistance were not present, but the *B* phase current will be greater.

The amount of the increase for various values of zero phase sequence resistance and reactance is shown in figure 3 of this discussion, and here it will be noted that values as much as 15 per cent higher than the corresponding single-line-to-ground current may be reached.

In connection with this increased current, however, the following facts should be considered.

1. Resistance in the other phase-sequence circuits has a mitigating effect. If $R_1=R_2=R_0/4$, the maximum increase is reduced from 15 per cent to $7^1/_2$ per cent, and the range over which any increase exists is considerably reduced.

2. Resistance of sufficient magnitude to have appreciable effect introduces a rapid initial decay of the d-c component which is great enough so that the total rms current in the first cycle will not exceed that involved in other types of fault.

3. The range of resistance in which this occurs appears to be one not frequently encountered in practical field circuits:

(*a*). Normal values of resistance deliberately inserted in the neutral lie above it.

(*b*). Transmission line tower footing resistance in general lies above it, particularly at 69 kv and below.

(*c*). The resistance introduced by a copper transmission line ground wire tied in to the station ground may bring about an increase over other types of fault at a given point on the line, but such an increase will always be less than the reduction, caused by line reactance, in short-circuit current at that point as compared with the current available at the station.

(*d*). Arc resistance may lie within the range, but is effective to increase the current only when the fault consists of a line-to-line breakdown plus a breakdown to ground from one of the two lines involved, and not in the case of breakdowns directly to ground from each of two phases.

4. From the above it will be observed that this increased current may be expected only infrequently even among double-line-to-ground faults. For the few cases in which it may occur, it is suggested that attention be given to the following:

NEMA rule SG6-84 reads as follows:

"Where on oil circuit breaker will be called on to interrupt only short circuits between line and ground of a solidly grounded system, the interrupting capacity rating in arc amperes shall be 115% of its interrupting rating in arc amperes at the corresponding line-to-line voltage."

The reason for this rule is evidently that removal of the hazard of encountering the higher recovery voltages associated with line-to-line faults and three-phase faults is assumed to enable a circuit breaker to interrupt an additional 15 per cent in current. In the case of increased current from a double-line-to-ground fault, this hazard is also absent. Consequently, it seems reasonable that a 15 per cent allowance be made here just as in rule SG6-84. Taking this allowance into account, the highest current which needs to be considered is either E/X_d'' or $3E/2X_d''+X_0$, whichever is higher. Furthermore, if R_0 is greater than $5X_d''$, as in the case of deliberately inserted neutral resistance, no consideration need be given to the latter term and the highest current may be taken as E/X_d''.

It is recommended, therefore, that the "highest value of rms symmetrical current for any type of fault" be taken as either E/X_d'' or $3E/2X_d''+X_0$, whichever is higher, except that when R_0 is greater than $5X_d''$, no consideration need be given to the latter term.

There is a discrepancy with reference to the application of low voltage air circuit breakers between the last full paragraph of the first column of page 880 and the last paragraph of the first column of page 881 of the paper. The application of these breakers should be based upon subtransient reactance for all synchronous and induction machines, and the statement on page 881 should be considered as modified accordingly.

Power-Circuit-Breaker Ratings

Discussion and author's closure of paper 41-116 by R. C. Van Sickle, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 882–4.

T. G. LeClair (Commonwealth Edison Company, Chicago, Ill.): Mr. Van Sickle's paper outlines very clearly the reason for coordinating those ratings of circuit breakers which are interdependent. However, in the final suggestion for the circuit breaker ratings, he has added the term, "rated latching current." This addition is an important one and warrants some further discussion, even though it is not entirely related to the preceding rating items.

In the preparation of the latest standard 19 for circuit breakers, there was some discussion as to whether or not this item should be added to the list. At that time it was decided not to add such a rating.

It is generally true that in the higher voltage breakers, where the strength of the mechanism is determined largely by the interrupting time, that the rated latching current is at least equal to the rated making current and rated interrupting current. However, on breakers of lower voltage and higher continuous current ratings, many of the present day breakers cannot close and latch against the maximum short time current without increasing the size of the mechanism, and consequently, the size and cost of many other related parts.

It is probably true that many, if not most, of the applications for circuit breakers are such that a breaker will not be called upon to close and latch against the maximum instantaneous current or against the rated interrupting current. The usual application is such that if a breaker is closed against a short circuit, the relays will instantly trip this same breaker so that the breaker will open and clear the short circuit without ever having reached the totally closed position. There are some applications where the breaker being closed is not the one which should be opened to clear a short circuit. In such applications, there may be damage done to the breaker if it continues to hold the circuit partially closed until the remote breaker has had time to open. For such application, the latching current should be equal to the maximum interrupting current. For the majority of applications, it would be an unfair burden on the cost of circuit breakers to make the latching current equal to the maximum interrupting current. It is possible that if full publicity were given to the discrepancy between latching current and maximum interrupting current, that it might be necessary in some cases to have a standard breaker with a relatively small mechanism and a special breaker with a heavier mechanism where the latching current must be equal to the interrupting current.

It is necessary to give the subject some additional consideration before such a rating is added to the list now in the standard for power circuit breakers.

C. A. Woodrow (General Electric Company, Schenectady, N. Y.): In at least one way, Mr. Van Sickle's contribution is a very logical extension of this working committee paper, "System Short Circuit Currents." The aim of this paper has been to provide improved and simplified methods of calculation but always within the boundaries of existing rating standards. Under AIEE definitions the interrupting rating of a power circuit breaker is based on the rms current at contact parting, regardless of the time interval between instant of short circuit and contact parting.

This variable time interval consists of relay time plus breaker contact parting time. The joint short circuit paper proposes the elimination of the relay variable. It recommends general breaker application which provides interrupting capacity for high speed relaying; this conception results in allowance for a small but essentially definite relay time interval. As Mr. Van Sickle suggests, if this approach proves acceptable, why not extend it and eliminate the contact parting time variable also? Under existing interrupting rating standards, the five cycle breaker for any particular application must have ten per cent—and the three cycle breaker 20 per cent—higher interrupting rating than the eight cycle breaker. Obviously, breaker application would be far simpler and cost analysis of higher speed fault clearing far more definite if required interrupting current rating were not dependent on interrupting time rating; i.e., if these 10 and 20 per cent factors were made design factors rather than application factors.

In order to obtain any application simplification whatsoever, the authors of "System Short Circuit Currents" have had to make approximations which violate the exact interpretation of present interrupting rating standards. For all eight-cycle breakers, four cycles for the total of relay plus contact parting time is assumed. Actually standard high current breakers may have appreciably longer contact parting time than average, whereas other eight cycle breakers may have somewhat shorter contact parting time, particularly on C-O operation. In this latter case it has been tacitly assumed that breaker design includes the technically necessary margin to allow for the higher duty possible with the shorter contact parting time.

All these problems could be eliminated if power circuit breaker interrupting current ratings were based on the current at a definite time of four cycles (60-cycle basis) after the instant of short circuit rather than on current at the instant of contact parting. Such a solution, however, means at least minor rating changes.

Mr. Van Sickle goes still further. He suggests the elimination of application factors dependent on special decrements for low voltage circuits and the possibility of interrupting rating based solely on the initial a-c component of short circuit current. It would seem that these thoughts provide important criteria for desirable future product standards and application simplification—though there may be obstacles to overcome before such rating changes can be adopted.

However, in support of the possibility of ratings based solely on a-c components of current, it is perhaps worth pointing out that, for all types of apparatus, it is highly desirable to make reasonable allowance in design for the effect of the d-c component of short circuit current and eliminate its complexity as an application investigation requirement. This goal has already been reached in determining momentary requirements of power transformers, current transformers, and reactors and in the interrupting ratings of protector tubes. No matter how simple the application rules, the occasional misapplication will continue so long as the d-c offset allowance remains an application rather than a design factor.

J. A. Elzi (Commonwealth and Southern Corporation, Jackson, Mich.): A review of the AIEE and ASA standards for oil circuit breakers indicates that clarification of some of the ratings is highly desirable. As the author has pointed out, present day breakers designed for operating voltages of 15 kv and below, usually are required to cover a broader range of operating voltage, and consequently a greater range of fault currents than the higher voltage breakers and present the greatest difficulty from the standpoint of mechanical forces and heavy maximum short-time currents. These breakers are also the ones which are most frequently used at busses with directly connected generating equipment or with current limiting reactors where the system time constants are such that the ratios of the initial current to the interrupted current proposed in this paper do not apply.

Breakers in this voltage class represent a large portion of the total number of breakers used, and it appears that the proposed method of rating breakers would be somewhat limited in its application.

A point which has not been mentioned is the fact that in many cases the ground fault current rather than the phase to phase fault current may determine the interrupting capacity required in a breaker, and the time constant for a ground fault may be considerably different from that for a phase to phase fault.

The author makes the suggestion that a further simplification could be effected by making the breaker application on the basis of the initial a-c component of fault current. It would appear that this could easily lead to a considerable misunderstanding in comparing breaker performance as demonstrated by tests. In making breaker tests, the current would usually be found to be displaced, at least by a certain amount, and it would seem rather difficult to establish the value of symmetrical current which would be comparable to an offset wave obtained from tests.

R. C. Van Sickle: Circuit breaker applications involve so many variables that there will always be exceptions to any general rule which may be formulated. The method of application proposed in the report "System Short-Circuit Currents" recognizes this by recommending factors which are modified for certain voltage classes and for special conditions.

The suggestion was made in the paper "Circuit-Breaker Ratings" that if the proposed method of application were found to be satisfactory, a new method of breaker rating could be used which would apply the factors for normal conditions in the design of the breaker. The exceptions to the general cases would still have to be taken care of by special factors. However, it would not be necessary to have two sets of factors, one for normal conditions and one for special conditions.

The industry could select and publish for various classes of breakers, the first cycle currents and the interrupting currents corresponding to the rated initial a-c. components. Breakers would be designed to make, carry, and interrupt currents having these values. If the calculated current were found to be close to the breaker rating and the decrements appeared to be unusual, the current to be interrupted could be calculated and compared with the value of published interrupted currents for the breakers in question.

Test results likewise would be compared with published values. As at present, the comparison would be on the basis of the total rms. current.

The rated latching current was included in the list of items of a circuit breaker rating because it is defined in AIEE Standards. This was not intended to imply that the rated latching current would be standardized and published along with the other items of breaker rating. As pointed out in the paper, this item bears no definite relation to the other items.

Mechanical Simplicity of Air-Blast Circuit Breakers

Discussion and authors' closure of paper 41-114 by H. W. Haberl and Otto Jensen, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 869–74.

Howard M. Wilcox (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The paper by Messrs. Haberl and Jensen marks a forward step in the accumulation of a fund of information on compressed air switching equipment which, added to as work progresses, will ultimately constitute a general practice in governing an art still young enough to display a lack of unity in the approach to fundamental problems. The authors are to be congratulated on bringing together in a single paper data covering the application of one type of air-blast operation to the complete a-c voltage range. The accumulated service experience with these structures, while still not extensive, must be accepted as the best barometer available and seems to indicate that the means used has been found adequate thus far. As a measure of progress it may, then, give rise to speculation as to how the results obtained may be interpreted in applying them to the general problems of the air-blast breaker.

Little information is offered as to the volumes of air used in breaker operation. It is noted that operating pressure for the 138-kv rating is 100 pounds (about seven atmospheres) and since the same general arrangement is used throughout it may be assumed that working pressures for the other ratings are of the same general order of magnitude, although the reservoir construction used on the lowest voltage rating might indicate a still lower pressure. The question then arises as to whether these pressures have been found best suited from the viewpoint of economical storage space as a reserve for emergency multiple breaker operations. In the United States the tendency has been toward working pressures of from 10 to 17 atmospheres even at generating voltages, with a back-up supply at still higher pressures, as a means of storing a greater reserve volume in the same reservoir space. The alternatives would seem to be to supply more reservoir space, higher capacity compressing equipment, or working the same equipment a greater proportion of the time.

Another and related question arises in connection with condensation at these lower pressures. In the United States serious consideration has been given to a compressed air supply system having a pressure about three times the normal breaker working pressure for high voltage outdoor applications as a means of moisture removal in the expansion process. The alternative would seem to be a mechanical dryer. The authors' experience on this point during the severe cold of a Canadian winter should be of particular interest.

The paper emphasizes the type of blast valve used throughout this line of breakers. While this valve undoubtedly lends itself readily to fast breaker operation, it is noted that it has been found desirable in practically all cases to install the valve almost completely within the breaker reservoir and in some cases the blast tube and contact operating rod are likewise incorporated in the reservoir. To those familiar with the rather stringent Code requirements governing the construction and use of unfired pressure vessels in the United States this would seem to present some complications. While details shown in the illustrations are not sufficiently complete to warrant forming a definite opinion, it would also seem to interpose some difficulties in the way of inspection and maintenance.

It is noted with interest that the reclosing contacts are retained in all designs down to the lowest voltage rating, necessitating use of the series isolating switch throughout. To those familiar with the limited installation space generally allowed for circuit breakers in four kilovolt service, this would seem to present a serious handicap in competition with the compact, self-contained, air-insulated circuit breakers now available for this service.

A statement by the authors as to their experience on some of these points would add materially to the value of their paper as a contribution to the art.

J. B. MacNeill (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The authors are to be congratulated on the excellent slides used in presenting their paper, which make clear to a lay observer the relationships and movements of the parts involved. The valve release mechanism is very ingenius and permits of high speed operation with a minimum of control energy.

The subject of outdoor compressed air circuit breakers is receiving intense study by several manufacturers in America and trial installations are being made. A wide commercial activity on this type must await better proof of the insulation characteristics under service conditions. There is a dearth of suitable insulating materials for outdoor interrupters that are not enclosed in oil. Research work on this subject will improve the situation over a period of time but further work is required.

The large operators have taken the position for the present that fairly definite proof of service reliability must be had before they will invest largely in dry types of outdoor switching equipment. They doubtless have in mind the limitations of interrupter insulation, the dry internal tube surfaces continuously operated between line voltage and ground, and the complication of an isolating switch which must function promptly after interruption.

The advantage of the compressed air type is its flat arcing time characteristic from no-load to full-rated when properly designed, and since this arcing time normally is very short the arc energy is small. However, any device which depends on extremely short arcing time for successful operation should be well proven by test or an extra half cycle or two of arcing may represent a destructive increase of arc energy. Little reference is made in this paper to test results, although rather liberal statements are made regarding rupturing capacity. It is hoped that the authors in their closing discussion will advise us more fully of the test results on which they base their ratings.

H. E. Strang (General Electric Company, Philadelphia, Pa.): The authors have chosen an extremely effective way of demonstrating in pictorial form the operating principles of these various types of air blast breakers. Although they all appear to have some features in common, they illustrate a healthy diversity of ideas in design to be expected at this early stage in a new field.

Presumably these different breakers have been subjected to thorough short circuit tests, either at a factory testing station or in the field before being placed in service. Although this paper was apparently intended only as a discussion of the mechanical features of such breakers, in view of the wide interest in the air blast principle, and the rather general statements contained in the paper on the subject of interrupting ratings, a discussion of such tests and a statement of the amounts of short circuit current interrupted in actual service would give added confidence in the adequacy of the interrupting ability of air blast breakers.

The one oscillogram which is shown, indicates very satisfactory performance, apparently interrupting about 20,000 amperes at 2,300 volts, or some 80,000 kva, which is well within the proven capabilities of existing simple self-contained magnetic types of breakers.

E. W. Knapp (Shawinigan Water and Power Company, Montreal, Quebec, Can.): We are indeed indebted to the authors for explaining in such an effective manner the mechanical operation of several voltage ratings of air-blast circuit breakers of one general design. A great deal of interest has been shown during the past few years in this problem of circuit breakers. As a representative of an operating company, I am not prepared at this time to discuss design problems. It might, however, be in order to discuss a number of general problems pertaining to the development and use of air-blast circuit breakers.

The Shawinigan Water and Power Company have been interested for some time in the development by various manufacturers of improved circuit breakers and have conducted a considerable number of tests on various types of oil and air-blast designs. This interest covers many phases of circuit breaker characteristics including rupturing capacity, speed of operation, amount of maintenance required, suitability for high speed automatic reclosing, possibility of adapating to single phase switching, reliability and, last but not least, freedom from fire hazard.

The air-blast circuit breaker is a comparatively new development, and as usual, with new developments, many difficulties have been experienced. Tests and operating experience have been rather encouraging and it is quite possible that in the not too distant future a complete range of this type of equipment will be available, which may be used with complete confidence.

H. W. Haberl and Otto Jensen: Referring to the comments of Mr. Howard M. Wilcox relating to air pressure: The first breaker of this general type was put into service in 1934 at the generating station of the Beauharnois Light, Heat and Power Company, where there was already available for other purposes, compressed air at 90 pounds per square inch and the breaker was built for 100 pounds per square inch. Three additional breakers installed at this station in succeeding years were built for the same pressure. The existing air pressure and compressor capacity were ample for the breaker service and there was no object in reducing the quantity of air required by the breakers by increasing the pressure, which would have required boosters. In later installations at other stations, the breakers have been built for 150 pounds per square inch for all voltages and the interrupting tests have verified the expected increase in interrupting capacity. The general design does not limit the air pressure and it may be increased above 150 in future in cases where the advantages appear to outweigh the disadvantages of a higher pressure. In regard to the use of pressure above 150 for storage with reducing valve, the advantage of such arrangement is appreciated and installations are being made along this line.

In regard to removal of moisture in air, activated alumina has been used exclusively and successfully, since 1934, and there have been no cases of trouble due to moisture or frost in the breakers since the first few months in 1934 before experience had established the minimum schedule of reactivation required, with breakers operating outdoors at temperatures down to 30 degrees Fahrenheit below zero.

In relation to blast valve, blast tube, breaker tanks, etc. this design of blast valve does not require installation *inside* of tank. In the 138- and 230-kv breakers which have been installed, the blast valve is completely outside the tank but the valve flange is approximately tangential to the tank circumference thus eliminating any pipe connection between valve and tank. In the 69-kv and lower voltage breakers the valve diaphragm is turned 90 degrees but the valve flange is still approximately tangential to tank wall. With either arrangement the entire blast valve is removed by unbolting one large flange outside the tank. Regarding the question of stringent code requirements, the internal blast tube has been incorporated in breakers built by the I-T-E Company and installed in service in the United States and therefore approved by the inspection authorities concerned. The pressure is 150 pounds. The same applied to the lowest voltage breakers built for 150 pounds in Canada.

In regard to the use of a series isolating switch in the breakers of the lowest voltage, the photograph in the paper shows a 2,000-ampere, 15-kv breaker 2 feet 6 inches wide parallel to the station bus, which appears to compare favorably with other breaker designs in the matter of minimizing required length of bus rooms and structure.

Referring to the comments of Mr. J. B. MacNeill regarding insulation, all such material which is continuously stressed is porcelain. Other materials have been used for parts which are stressed for less than six or eight cycles, the period between interruption and opening of isolating switch. No failure of insulation has occurred in the seven year period of service and the climatic conditions have been rather severe including extreme dampness and salt air. However, improvement has been made from year to year in available materials and porcelain is replacing other materials to a large extent.

Reference is made to the normally short arcing time of air blast interrupters, which is now generally recognized, but we do not follow Mr. MacNeill's apparent conclusion that "an extra half cycle or two of arcing may represent a destructive increase of arc energy," as applying to an air-blast breaker to any greater extent than to an oil breaker. In fact the contrary appears to be true. In an oil breaker the arc energy is all stored inside the tank in the form of generated gases of explosive composition; an increase in arcing time means more gas and greater pressure with less safety-factor against bursting of tank. In an air blast breaker the arc energy is not stored in the breaker; it is blown outdoors as fast as it is generated. This is true even if the breaker fails to interrupt and the back-up breaker is slow in opening, say 15 or 20 cycles. The worst that happens in tests of that nature, is excessive loss of copper from arcing contacts, excessive "erosion" of arc-chute lining, melting of edges of metal cooling sheets, etc., requiring replacement of such parts. The damage is negligible in comparison with that in an oil breaker under the same conditions.

Furthermore an air blast interrupter of suitable design shows relatively constant arcing time within its interrupting capacity. Also the shape of the arc voltage oscillogram is quite consistent as shown by a large number of shots with the same arc chute. Different shapes of arc chute naturally show different shapes of arc voltage oscillograms but the results are not generally erratic.

A large number of interrupting tests have been made in the past seven years on breakers of this general design, the tests ranging from 2.3 kv to 260 kv on large power systems and the authors or their associates will be glad to offer a brief paper on the subject at some suitable opportunity.

In response to the comments of Mr. H. E. Strang, the breakers have been thoroughly tested in the field before being placed in service. Other comments of Mr. Strang are covered in the response to Mr. MacNeill.

Mr. E. W. Knapp's comments appear to us to summarize the state of the art in a comprehensive manner. The close cooperation of Mr. Knapp, his associates, and officials of the Shawinigan Water and Power have been highly constructive throughout the development.

In reference to all of the written and oral discussion and comments on the paper, the authors wish to express appreciation of the interest shown and the open minded spirit with which the paper has been received.

Protection of Low-Voltage Circuits by Air Circuit Breakers in Cascade Arrangement

Discussion and authors' closure of paper 41-128 by A. E. Anderson and C. H. Black, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1151–60.

J. D. Wood (Cornell University, Ithaca, N. Y.): I wish to discuss the paper by Messrs. Anderson and Black on the subject of "Protection of Low-Voltage Circuits by Air Circuit Breakers in Cascade Arrangement."

While this method of operation has been used in special applications previously, we are indebted to the authors for proposing this method for the general application of air circuit breakers. The authors have also recommended cascading even though the breakers have widely varying speeds and opening times.

Your attention is directed to the set of test results shown in figure 10 which are the basis for the authors' proposal. In these results the basis for the theory that two breakers in series having different opening times in any way assist each other in opening a fault, is difficult to see.

Here is a circuit which gives an average fault current of 95,000 amperes. When this circuit is opened by a breaker having 100,000 amperes interrupting rating as in test 787-15, we find the breaker is slow because the moving element has a large mass and high inertia. This is necessarily the case as the smallest 100,000 ampere breaker is rated 4,000 amperes continuous current.

A minimum of 3.2 half cycles is required to part contacts and 5.2 half cycles to open the short.

When this breaker is used in series with a 50,000-ampere interrupting capacity breaker as in test 787-3, we find that the smaller breaker, parts contacts in a maximum of 1.2 half cycles and the short is interrupted in 1.9 half cycles—well ahead of the minimum of 6.8 half cycles required for the larger breaker to part contacts, as shown for test 787-3. The larger breaker has contributed nothing to the operation except to act as limiting impedance and to open after the interruption is over. The smaller breaker has opened a fault above its rating and has been damaged.

In tests 787-11 and 662-9 where three breakers are used in series, they each contributed impedance to further limit the current. The larger did not open, the next size opened a circuit at less than its rating, and the smallest was partially destroyed.

May I suggest that this is an expensive way to secure additional impedance. Also, impedance built into a breaker has the same effect on voltage regulation as impedance in a current limiting reactor.

A preferred method of applying breakers to low-voltage circuits is to use the smaller breakers for the distribution feeders because of their low cost where only small continuous ampere sizes are required. These breakers are provided with relays which lock the breakers in the closed position when a predetermined value of current is exceeded. In the unusual case of a severe short above the rating of these smaller breakers, the fault is passed back to the main feeder breaker which is large enough to handle it. The smaller breaker is prevented from opening and if properly designed, is not damaged. It is recognized that this can only be done where the breakers have the very important design feature of "inverted contacts," that is, contacts which do not blow open due to the magnetic forces of the short-circuit current.

All low-voltage air circuit breakers should have this type of contacts in order to handle heavy currents which they may be called upon to carry as well as open. Where the design does not incorporate this important feature, cascading would be of assistance provided the breakers have practically the same opening time.

In such applications, the normal infrequency of operation of low-voltage air circuit breakers and the possibility of maintaining the close timing of cascaded breakers over a period of time under practical service conditions, must be taken into consideration.

W. R. Brownlee (Commonwealth and Southern Corporation, Jackson, Mich.): Unquestionably the application of a group of low-voltage air circuit breakers, such that all of them are capable of interrupting the maximum short circuit current available at the bus, will frequently result in an unreasonably expensive and cumbersome arrangement. Since air circuit breakers of conventional design are incapable of withstanding the mechanical stresses associated with the heavy currents of low voltage high capacity circuits, there is no opportunity to use the familiar "lockout" scheme which has been applied with reasonable success to oil circuit breakers operating at 2,400 volts (and sometimes higher voltages). The method of "cascading" has been logically suggested, but the cascading described by the authors is quite different from that commonly understood where a protective relay or a tripping device will not initiate the tripping of a backup breaker until after a time interval equal to the total tripping and arc interrupting time of the protected breaker, plus several cycles of operating margin. It is not readily apparent how the authors have been able to secure a time coordination on the order of one-half cycle between breakers in series, particularly using "magnetic" tripping devices which have never been considered as consistent in response as standard protective relay elements. Perhaps the strongest influence on selective operation may be the current limiting effect of the inherent resistance of the feeder and backup breakers themselves (before contacts part). If so, information on these resistances would be very helpful in applying the results of the authors' investigations to anything other than the specific conditions and equipment with which their tests were made.

It is difficult to agree with the authors' interpretation of their reference 1. The tests described by Mr. Schurig showed in all cases sufficient arc voltage to have a pronounced effect on the d-c time constant. While the tests indicated that in many cases the assumption of a "bolted fault" may be made safely as far as calculation of the maximum symmetrical current is concerned, they do not justify omitting the very appreciable effect on the total rms current at the end of one-half cycle as influenced by arc drop modifying the d-c time constant.

A. E. Anderson and C. H. Black: The authors appreciate the interest shown in this method of applying air circuit breakers in cascade and believe this discussion should be both interesting and helpful. A few further comments pertaining to the questions raised during the discussion seem to be in order.

The air circuit breakers do have to be properly coordinated but do not require the extreme accuracy of "timing" referred to by Mr. Brownlee, although—when subjected to short circuit currents of relatively large magnitude—they do become remarkably consistent in their time of operation and do not exhibit the same variation in time that might be expected when magnetic tripping devices operate at currents of low or moderate magnitude. There is a great deal of test data, some of which has been shown in figure 10, to verify the sequential operation of breakers in cascade. The resistance of the breakers before the contacts part is so small as to be negligible and does not play any part in determining the sequential operation.

Mr. Brownlee's comment concerning the authors' interpretation of Mr. Schurig's test data (reference 1) is well taken. It is quite correct that the arc resistance did materially affect the d-c component, but the authors still believe it to be unsafe to assume that the "bolted fault" or equivalent thereof cannot occur. It will be further noted that the method of averaging the currents in the three phases for calculating air circuit breaker duty results in a total current, including the d-c component, which is only 25 per cent higher than the symmetrical current, hence the assumption of the "bolted fault" does not impose an unduly severe penalty upon selection of air circuit breakers.

Mr. Wood's comment concerning the ability of the larger breaker to assist smaller breakers apparently does not give sufficient consideration to the performance shown in figure 5 where it can be clearly seen that there is an appreciable interval of time during which a back-up breaker (even though it operated several cycles after the occurrence of short circuit) could have been of very material assistance to the smaller breaker. It is true that the smaller breakers are inherently more rapid in operation. This is what makes cascading effective.

Mr. Wood has suggested locking in the smaller breakers to prevent their opening under severe short circuit. The inverted contacts referred to by Mr. Wood, represent merely one possible way to design breakers to withstand the initial electromagnetic forces of high short-circuit currents. It is somewhat more difficult, however, to provide small breakers with the ability to withstand thermal effects without making them unduly large and costly. But the ability of the breaker to remain closed is not the primary question. The principal function of a circuit breaker is to protect. Protection is not achieved by locking circuit breakers closed. From the standpoint of protecting the circuit and apparatus connected thereto (which is usually far more valuable than the circuit breaker itself), the authors do not consider it good practice to prevent the inherently rapid breakers from opening at once, leaving the circuit interrupting duty to a breaker which is inherently slower. The circuit is far better protected if the smaller breakers, even though they do not actually complete interruption, are allowed to open and thereby materially reduce the short circuit currents. This current-limiting action occurs only when the breakers are opening during short-circuit, hence the cascade arrangement does not adversely affect voltage regulation during normal operating conditions.

Mr. Wood has suggested that cascading is an expensive way to secure additional impedance. When the complexity of schemes for locking in trip-free breakers is considered, together with the sacrifice of circuit protection, it becomes apparent that the use of locked-in breakers is an expensive and complicated way of avoiding a very desirable current limiting action during short circuit.

Mr. Wood has stated that the smaller breakers were partially destroyed in certain tests. The condition of these breakers was such that no unreasonable servicing would be required in order that they might perform their usual duty. While it is recommended that the smaller breakers be inspected, and possibly serviced, upon the occurrence of severe short circuits, it has been found that such severe faults occur at relatively infrequent intervals. Accordingly, most fault currents come within the ratings of the smaller breakers, which not only keeps the amount of maintenance within reasonable limits, but also eliminates the need of tripping the "back-up" breakers, so that service is maintained on the rest of the system.

Finally, the authors recognize that cascading is not the solution for *all* problems of circuit protection. The use of breakers of adequate rating throughout will certainly result in somewhat lower maintenance or, under certain conditions, the use of current-limiting means may be found desirable. It is the experience of the authors, however, that in many cases cascading provides a highly satisfactory and very economical solution, thus warranting careful consideration whenever protection of a low voltage system is being planned.

Radiobroadcasting in Canada

Discussion and author's closure of paper 41-113 by Augustin Frigon, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 896–8.

R. B. Steele (Canadian National Telegraphs, Toronto, Ontario, Can.): Dr. Frigon has given us a very interesting and instructive paper on the organization, functions, and operations of the Canadian Broadcasting Corporation and its place in network broadcasting in Canada. He has told us that while the Canadian Radio Broadcasting Commission, the predecessor of the corporation, started its network activities in 1932, the first Canadian broadcasting network was set up during the Christmas holiday season of 1923. This was, admittedly, a modest set-up, with only two radio stations interconnected by some 115 miles of telephone circuit, but it held much promise for the future for it was sponsored by the newly organized Canadian National Railway System, and Sir Henry Thornton, the speaker of the occasion, announced the establishment of the CNR radio department.

This was really also the beginning of the 1926–27 eastern Canada network mentioned by Dr. Frigon, for the CNR radio department set about the establishment of stations at Ottawa, Moncton, and Vancouver, and of a program and technical organization, and the C. N. Telegraphs set the wheels in motion to provide a wire network.

The landmark of early network broadcasting in Canada is the diamond jubilee of confederation broadcast on July 1, 1927. Months of preparation were required and all the wire companies contributed to the network, which was organized under the technical supervision of Bell Telephone Company of Canada engineers. A press release issued before the broadcast predicted the use of 21,650 miles of line and 53 repeater stations. 19 radio stations were connected to the network, including CFCT at Victoria, B. C. and CHNS at Halifax, N. S.

On December 27, 1928, the CNR radio department again pioneered by arranging a coast-to-coast broadcast program to its own and affiliated stations, this being, at the time, the largest Canadian network arranged by a private organization. The C. N. Telegraphs provided the network circuits between Montreal and Vancouver. Quebec, Halifax, and three other maritime points were included in the network by means of telephone company circuits.

The communications department of the Canadian Pacific Railway also established a coast-to-coast program transmission network and thus it came about that when Parliament, in 1932, established the Canadian Radio Broadcasting Commission there were a number of organizations equipped for and experienced in network program transmission. These were the C. N. Telegraphs, the CPR communications department, and the several telephone companies of the Dominion which are banded together as the Trans-Canada Telephone Association. These interests all participate today in the provision of the CBC's network requirements. The CNT and the CPR communications are the primary contractors, but they in turn call upon the several telephone companies to supply a number of important network sections.

In his paper Dr. Frigon mentions the operation of an FM broadcast transmitter at Montreal. It would be interesting to have some further information as to the status of this operation.

Augustin Frigon: Unhappily, under present conditions, our experiment with frequency modulation has had to be held up and we consequently have no data available concerning it.

Excitation Circuits for Ignitron Rectifiers

Discussion of paper 41-127 by H. C. Myers and J. H. Cox, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (October section), pages 943–8.

C. C. Herskind (General Electric Company, Schenectady, N. Y.): This paper provides an excellent review and discussion of the various circuits which have been developed for energizing the igniters in ignitron rectifiers. Progress has been rapid in the development of suitable igniter firing circuits because of the pressure of greatly increased business and the importance of reliable operation of the igniters. Virtually, all of the conversion equipment being supplied today for use in the electrolytic field employs mercury arc rectifiers, and a large percentage of these are of the ignitron type. Since electrolytic processes are continuous it is absolutely essential that the igniter excitation system be thoroughly reliable.

Firing circuits using thyratrons have many advantages, but the desirability of having a static-tubeless excitation circuit using dry type rectifiers, such as copper oxide rectifiers, was early recognized. The development of such a circuit became urgent with the application of a large number of ignitron rectifiers to the manufacture of aluminum.

The General Electric Company undertook the development of a tubeless circuit, and built and installed the first equipment of this type. This equipment has been in service for almost a year and has operated very successfully.

This tubeless firing circuit is shown on figure 1 of the paper. It will be noted that it makes use of dry type rectifiers for rectifying the input to the igniter, and of a combination of linear and non-linear reactors for producing the peaked current wave form. Phase shifting may be obtained by providing a saturating winding on the non-linear (saturating) reactor and adding suitable capacitors in the supply lines.

This first tubeless circuit was entirely successful and highly reliable, but further development work has resulted in circuit improvements providing substantial reductions in losses and the amount of equipment required. The improved tubeless firing equipment now available is a fully developed, efficient and reliable excitation means.

For applications where a large amount of phase control is required or losses are an important consideration, an improved capacitor thyratron type of circuit has been developed. This circuit is similar to that described in the Myers and Cox paper and is shown by figure 2 of the paper. It provides for rectifier charging and a resonant discharge controlled by a thyratron. The copper oxide or dry type rectifier charging furnishes a constant capacitor voltage regardless of phase angle. The use of the reactor in the discharge circuit eliminates the steep wave front of the direct capacitor discharge and gives uniform igniter currents of sinusoidal form. Advantages of this circuit are:

1. Low losses.
2. Accurate firing and ease of control.
3. Rapid response.
4. Suitability for half-wave circuits.
5. Large ranges of phase control.

The duration of the igniter current wave in this circuit is of the order of 8 to 12 electrical degrees. In many applications it is desirable to maintain the cathode spot for a longer period than the firing period of the igniter in order to insure reliable firing of the main anodes under all load conditions. This is readily done by the addition of an excitation anode excited from a separate low voltage winding in the excitation transformer.

It appears at present that these two types of excitation circuits, namely, (1) the saturating reactor or tubeless, and (2) the capacitor-thyratron, will be used for the majority of future installations of ignitron rectifiers.

O. W. Pike (General Electric Company, Schenectady, N. Y.): It is true, as the authors point out, that the thyratrons have a limited life due to the fact that the normal end of life occurs with the depletion of the emitting material on the cathode. However, from a practical standpoint, the life is very long. Under proper conditions of operation the average life can well be 25,000 hours with individual lives of twice this value. With lives as long as this, much of the objection to the use of thyratrons in power equipment disappears.

In an application, such as their use with igniters, where the peak currents are high but the average currents very low, thyratron cathodes can to advantage be operated at a slightly higher than rated voltage. This small additional cathode power makes up for the heat normally released by the full load anode current. Thus, peak current capabilities can be obtained with long life.

We do not wish to imply that thyratrons are, because of these factors, the logical choice in all cases, and we agree with the authors that in certain cases other systems are more suitable.

A New Transformer for Base-Load Stations

Discussion and authors' closure of paper 41-124 by Philip Sporn and H. V. Putman, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (October section), pages 916–18.

P. L. Alger (General Electric Company, Schenectady, N. Y.): The transformer described in this paper embodies several distinctive features of design, which together have enabled a marked reduction in weight and size to be obtained for a given performance. From the viewpoint of possible application to other lines of apparatus, it seems important to evaluate more carefully the respective portions of the overall gain that can be attributed to the different new features of design.

Since transformer size is normally fixed by thermal considerations, the use of forced cooling probably contributes more than any other design element to the gains reported. It will be interesting if the author can give an estimate of the size reduction that would have resulted if this forced cooling system had been used on a transformer of otherwise standard design.

The other important feature of the new design is the use of Hipersil. The data given on this material, as indicated by figure 3 of the paper, show that Hipersil has 38 per cent more flux for a given excitation at a particular point on the magnetization curve. On the assumption that the length of flux path in the core illustrated is about two feet, the point chosen for comparison is at a magnetizing force of approximately three ampere turns per inch. This figure is much lower than normally used in rotating machinery, so it is interesting to make similar comparisons at other excitation values. In table I of this discussion, the with-grain flux densities for Hipersil (obtained from data published in the *Electric Journal* for January 1936, page 40) are compared with those of two typical sheet steels, averaging with and cross grain directions. The percentage gain of Hipersil over the other steels is seen to fall markedly as the density rises, the gain at saturation being only of the order of five per cent. The value of Hipersil and other types of the modern strip steels is, usually, in the greater permeability and lower losses they possess at moderate densities, rather than in a greater capacity to carry flux under a high magnetizing force.

Table I

	At 20 Amps./In.		At 100 Amps./In.		At 400 Amps./In.	
Material	F.D. in Gausses	% Gain Of Hip.	F.D. in Gausses	% Gain of Hip.	F.D. in Gausses	% Gain of Hip.
Typical $2^{1}/_{2}$ per cent silicon motor sheet steel	13,500	28	15,500	16	17,900	3
Typical $4^{1}/_{2}$ per cent silicon transformer sheet steel	12,900	34	14,500	24	17,300	7
Hipersil	17,300		18,000		18,500	

F.D.—Flux density. Hip.—Hipersil.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): I would like to ask the authors what part or percentage of the reduction in size and weight can be attributed to (1) the use of the Hipersil iron, and (2) to the use of forced-oil cooling of the windings, etc.

It is well known that when one directs the flow of oil over the surface of a coil or coils, the loss dissipated for a given temperature rise over the oil is increased several times. This makes it possible to reduce the number of coils, the size of the core window, and size of tank. It is on account of this that it has been possible to greatly reduce the size of transformers (of a construction similar to the 40,000 kva) using standard steel for electric locomotives during the past several years. It should be possible, therefore, to state how much of the reduction in weight and size is due to the use of Hipersil.

F. J. Vogel (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): In the early days of railroad electrification, dry type air blast transformers were used. The reasons for this were that they were lighter and required less space than oil insulated transformers, and these were important advantages. They had the disadvantage of insulation troubles, from moisture and dirt, and this disadvantage led to a study of cooling methods with oil insulated transformers. The air blast transformer cooled well because air was forced through the coil ducts, and it was found that a similar benefit could be obtained by forcing oil through the coils instead of depending on natural convection. This enabled the oil-filled transformer to be laid on its side, and made the forced cooled transformer competitive with the air blast transformer so far as weights and dimensions were concerned, and with the advantages of reduced maintenance, greater insulation strength, and greater short time overload capacity.

The idea that this type of transformer might be useful in other fields presented itself, but there seemed to be many obstacles. It was introduced into the portable substation field, where the transformer must be light and small and mounted on a trailer. The idea has been prevalent that auxiliary cooling equipment is undesirable, although the use of fans was well established. The fact that this transformer apparently would have less short time overload capacity than a conventional self-cooled transformer was against its use. Also the losses increased if full advantage was taken of the cooling possibilities, and a possible decrease in cost of the unit had to be balanced against increased losses. It also represented a radical change in design, which would be approached with some reluctance ordinarily by both manufacturer and user.

The usual substation transformer may have to carry heavy overloads, and may not have attendants close by. Therefore, the forced cooled unit may not be advantageous for such service at this time, but it is by no means certain that these limitations are permanent. The central station transformer, however, seemed to be the logical first application. Mr. Sporn suggested that forced cooling would not be a disadvantage, where there were station attendants, and that overload capacity was not as important in a central station due to the limitations of generators and turbines. As stated, in the paper, the advantages of the design and its adaptability to the use of Hipersil then overcame any reluctance to use the new design. Although many modifications were suggested, it is nearly the same in general arrangement as originally conceived.

One of the advantages of forced oil cooling is that the oil is at practically the same temperature throughout the transformer. In a self cooled unit, the difference between the top and bottom oil may be as much or more than 15 degrees centigrade. This means that the hottest spot temperature in the forced cooled unit can not be greatly in excess of the average temperature. Therefore, at normal rating, the forced cooled transformer with a 60 degree centigrade rise might not have as high a hottest spot as a self cooled transformer with a 55 degree centigrade rise. Also in calculating short time overloads, it is possible that the forced cooled unit will not be at a disadvantage in comparison with the self cooled unit due to the fact that the difference between the highest and lowest oil temperature will not have to be included in estimating the safe load which can be carried. In view of this, it appears that as service experience increases, and if troubles with the forced cooling equipment are negligible, this type of design may become quite common.

Philip Sporn (American Gas and Electric Service Corporation, New York, N. Y.): It may be a rather unusual procedure for an author to discuss his own paper, but since this is a joint paper, it represents thoughts, ideas, and expressions of opinion and conclusions which are generally shared by both authors. But this paper, like a good many papers, is interesting not only for what it reveals and tells, but also for what it fails to disclose.

The paper shows pointedly how progress in new materials can be utilized with progressive ideas in design to obtain an overall result that even as recently as several years ago seemed almost too much to hope for, let alone to actually obtain. But in saying this, one has all the more regretfully to point out the failure of the authors to give any fundamental or even engineering development data on the steel and on the development and manufacture of the steel which is the very basis of the improved design.

Admitting that the progress which the paper recounts is the result of industrial research (stimulated, it is true, by certain users who are concerned with the continuation of processes leading to improved methods and improved economies in the art of electric power generation and transmission), the fact still remains, that from an engineer's viewpoint, it isn't enough to coin a new term for a fundamental steel development and hope to pass that off as an adequate presentation of the real background behind the design development discussed. The meager information given by figure 3 can hardly be considered an adequate substitute for a discussion of the physical ideas involved in the new method of rolling steel, the effect upon the magnetic characteristics of the steel that such new rolling has, the detail design changes in core construction to utilize the new steel characteristics, and the extent to which further changes and improvements can be carried and the limitations to such probable progress. All of this, it seems to me, could very well be presented today without in any way sacrificing such commercial protection as those responsible for the development are naturally entitled to. It is true that the authors state that it is hoped to present more information on the steel at a later date, but it is obvious that all of this information is available today, and as a matter of fact was available before the transformer, which is the subject of this paper, was evolved.

Again the authors stress the failure of previous transformer designs to properly take into account the altered conditions with regard to value of power energy and, therefore, of losses and the better balancing of these factors in the new design. But the meager information given with regard to the actual losses and the balancing of these losses in the case of this transformer does not quite satisfy one's curiosity with regard to how well this was worked out in this improved design.

This paper is in my opinion particularly timely and should be received with considerable welcome by that part of the engineering profession which is concerned with the broad problem of electric power supply because it indicates that as long as engineering thought is free to exercise its God-given talents and abilities, that there is no occasion for pessimism as to progress. One must, however, express regret at the failure to include the material pointed out above which I am sure would have been not only interesting but a valuable contribution to this particular branch of engineering.

H. M. Hobart (retired, General Electric Company, Schenectady, N. Y.): Messrs. Sporn and Putman's timely and practical paper describing their 40,000-kva, 138-kv transformer with forced-oil cooling and with Hipersil cores, is of particular interest to the writer because of some investigations on which he has long been working which have the object of providing power transformers of improved quality although of less size and weight and cost. On the basis of the conclusions at which the writer arrives from these studies, the introduction into their design of features which the writer will describe in this discussion, should result in decreasing the loss in their Hipersil cores by a matter of 25 per cent. This can only be made clear by considering several factors as follows:

Use of compressed gas instead of oil: The great dielectric strength of compressed gas has been called to the attention of transformer designers on various occasions by Ryan, Bölsterli, and others, and it has been considered that the substitution of compressed gas for oil could be so effected as to be accompanied by important improvements and economies. Particularly convincing was an article published by Bölsterli in 1931. The writer, at that time and since, has made repeated and very earnest efforts to interest and co-operate with transformer designers in undertaking serious comparative studies of the respective merits of oil and compressed gas. Although a few transformer specialists have become moderately interested, the general verdict continues to be quite definitely adverse.

While the original incentive to employing compressed gas was its great dielectric strength, there is soon recognized its superiority over oil as a circulating medium. An extremely small amount of power, say of the order of five one-hundredths of one per cent of the transformer's rating, suffices to circulate the compressed gas at very high speed, through the windings and then through the heat exchanger, and finally to return the cooled gas into the transformer. With some gases, for example, sulphur dioxide and carbon tetrachloride, use may be made of the latent heat to assist the cooling and circulating process, and to decrease the size of the heat exchanger.

In addition to the superior effectiveness of compressed gas as a cooling medium, there is the further advantage that it is not deteriorated in any respect by subjection to high temperature. We also have available for turn and layer insulation and for barriers and other needed insulations, many solid materials which do not suffer deterioration when subjected to quite high temperatures. Among these solid insulations may be mentioned mica, micanite, mycalex, glass-fibre products, porcelain, and asbestos.

As long as we continue to cool the windings by the oil in which the transformer is immersed, we must provide for ensuring such a low temperature as not to deteriorate the oil. Unless we employ some expensive brand of oil, the limiting temperature imposed is very low. When we design a power transformer on the basis of using compressed gas, we can go up to any temperature consistent with reasonable increase in the resistance of the windings. As regards the cores, high temperature with suitable core material will serve to greatly decrease the core loss. No particulars of Hipersil are given in the paper. But if it behaves like some other modern high permeability core materials, it will have this feature of considerably decreased core loss if operated at a temperature of the order of 200 degrees centigrade higher than the winding temperature. This may be accomplished by interposing a wrapping of asbestos or mica or other thermally suitable material between the cores and the windings. The circulation of the gas can be confined to the windings, the heat from the cores being constrained to traverse the asbestos wrapping of some $^3/_8$" to $^5/_8$" thickness (the precise thickness being a matter of simple calculation for any particular design). This characteristic of some core materials was described by MacLaren a long time ago. At that time it was the subject of considerable discussion. But its application to oil-type transformers would not have been simple.

In the pioneering days of fifty years ago, many difficulties were overcome by resort to oil. Transformer manufacturers and users in particular, owe a great debt to oil, especially for enabling them to build for higher and higher voltages to meet the increasing needs of electric transmission undertakings. However, the writer believes that this gradually left us in a rut, and we thoughtlessly accepted the use of oil in power transformers as inevitable.

The oil-transformer situation is not at all exceptional. The writer has had analogous experiences when, as has occurred a great many times, he has associated himself with taking up the cudgels for proposals to do things in "better ways." Our enthusiasm over slogans is in sharp contrast to our attitude when faced with concrete situations.

Could not the valuable gains explained by the authors as having been made possible by Hipersil cores be increased quite considerably by substituting for the forced-oil cooling, a design in which the windings are vigorously cooled by the forced circulation of compressed gas? It would appear reasonable to be able, by employing the means described, to improve the design to such an extent that the savings in copper and core materials would exceed the 10 per cent and 25 per cent respectively, which are stated in the paper. The total of all losses, instead of being increased five per cent, probably would be appreciably decreased, due to (1) the less power necessary in circulating compressed gas, and (2) the decreased core loss occasioned by maintaining the cores at a high temperature.

The need for brevity in a discussion of a paper inhibit the writer from hardly more than mere allusion to one more of the several new directions in which important progress may be made by the use of much higher temperatures than can be permitted in the *oil*-type. If we deliberately design for high temperature operation, we provide greatly increased heat flow across each unit of surface between the heated parts and the circulating medium provided for carrying off the heat.

In conclusion the writer has no hesitation in expressing his opinion that so many new possibilities are opening up that we should practically start all over again and re-design power transformers from top to bottom on the basis of fresh fundamental considerations. There will be many different ways of utilizing these modernized fundamental principles, and the writer hopes that in the near future, many "significant contributions" looking toward increased transformer and transmission economy will take their place alongside the excellent contribution reported by the authors in their valuable and interesting paper.

E. D. Treanor (General Electric Company, Pittsfield, Mass.): I have been interested particularly in the magnetic steel which is outlined in this paper, as the data and other publications indicate that it is of excellent quality. While the advantages here referred to are for a special power transformer application, it may be of interest to review the use of similar highly oriented cold-rolled strip in distribution transformers.

After considerable developmental work, the General Electric Company in 1937 placed in production small distribution transformers built on circular wound cores made from continuous cold-rolled highly oriented silicon steel strip. The introduction of this Spirakore transformer, as it was later termed, was noted in a paper presented before this Institute in June 1938 which described the use of such steel in a core structure particularly adapted to its characteristics. Its possibilities were briefly outlined in a paragraph which I quote:

> "In the practical design of transformer cores, flux density is limited by heating or magnetizing current in large transformers and usually to still lower values by magnetizing current alone in small units. The combination of a steel having high permeability and low losses in the high density range with a core structure which reduces the number and length of air gaps promises highly effective use of material, particularly in small-sized transformers."

No detailed data were presented at that time on the properties of the steel but rough comparison of permeabilities was given in figure 7 of the paper. These designs were characterized by somewhat reduced ratio of copper to core loss and resulted in considerable economies which have been widely publicized commercially.

As a report of progress since that time—some hundreds of thousands of distribution transformers for lighting and power service have since been built along these lines with flux densities materially higher than those previously used. In view of the good results obtained from this design, wound cores of other shapes have been developed by the General Electric Company which are capable of being adapted to any and all ratings in the single-phase distribution and small power transformer range. These have been introduced as rapidly as steel production facilities permitted and, as all limitations of supply should shortly be overcome, a complete and uniform line will be available. Transformers in sizes up to 1,000 kva and voltages up to 66,000 have been built so that the design requirements have been quite fully explored.

During this period, research and developmental work have continued on the steel and the optimum characteristics that this type of material can hope to show, with most effective processing, have been examined and weighed from the standpoint of application in transformers. There are some transformer characteristics which require careful consideration before taking full advantage of the best saturation, magnetizing current, loss, and magnetostriction available in the steel.

Increasing availability of magnetic steels of improved quality should, as the authors point out, have a marked effect on the design of transformers and a fairly extensive use on distribution transformers bears this out. So far the great advances in magnetic properties have been coupled only with materials produced by high reduction cold rolling and elaborate mill processing which result in material largely oriented in one direction. As suggested in the paper, it is probably more suitable for transformers designed with these characteristics in view than for other induction apparatus, although some special applications have already been made.

E. V. DeBlieux (General Electric Company, Pittsfield, Mass.): Messrs. Sporn and Putman have made a valuable contribution in setting forth so clearly these design principles which can be applied with material benefit to many other applications of transformers as well as to the special cases discussed by the author.

I believe, with the authors, that the principle of using forced cooling, and special core steel that can be operated at much higher densities than commonly used, together with proper protective and relay equipment, is a sound design principle and can result in a major reduction of the size and weight of transformers.

In particular I wish to concur with the authors' conclusion that the use of these principles "will make possible the extending of the practical size of portable transformers whether on car or trailer."

About two years ago the company with which I am associated, in considering the design of trailer-mounted mobile substations, concluded that minimum weight and dimensions were primary considerations and these could be realized to the fullest extent by:

1. Using a core steel that could be operated at much higher densities than formerly used,
2. Using forced cooling of the oil, and
3. Using forced circulation of the oil through the transformer winding.

Therefore, since the introduction of factory-built mobile substations, over a year ago, all of the mobile substations manufactured by this company have cores made of high permeability, highly oriented, cold-rolled silicon steel that operates at appreciably higher density and also employ the other design features enumerated above.

Therefore, our experience enables us to agree with the authors' conclusions, and to state that these developments have materially reduced the weight and size of trailer-mounted transformers, have increased the kilovolt-ampere rating permissible within the highway limitations and have been incorporated in a number of mobile substations that are now in service.

Philip Sporn and **H. V. Putman:** The discussers have brought out very clearly some of the various attempts which have been made to improve the overall design of transformers in recent years, and Mr. Hobart's remarks indicate that the search for further improvement has not yet been abandoned.

Mr. Montsinger brought up the question of allocation of weight reduction resulting from the use of Hipersil and the use of forced oil cooling. Since a design was not worked out on this particular 40,000-kva transformer with regular silicon steel, it is difficult to say exactly how much reduction in weight is due to forced oil cooling and how much to the use of Hipersil. However, in the redesign of small distribution transformers where direct comparisons are available and where the increase in the Hipersil core density is substantially the same as in the 40,000-kva units, the reduction in weight averaged 22 per cent. If the 40,000-kva unit were to be redesigned with similar forced oil cooling and with the regular silicon steel, it seems probable, therefore, that the weight would be about 20 per cent greater on the basis of the same electrical performance.

Methods of Determining Natural Frequencies in Coils and Windings

Discussion and authors' closure of paper 41-84 by L. V. Bewley, J. H. Hagenguth, and F. R. Jackson, Jr., presented at the AIEE North Eastern District meeting, Rochester, N. Y., April 30–May 2, 1941, and at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1145–50.

R. Rüdenberg (Harvard University, Cambridge, Mass.): I would like to draw certain conclusions from the measurements reported in the figures of this paper which may be of further interest. From the lower figure 2, we can derive the length of the winding, $a = 1{,}570m$. Estimating the effective magneto-dielectric constant of the space between the conductors of the winding and the steel core as $\epsilon\mu \cong 2.5$, the Maxwellian velocity of propagation of electric phenomena in that space would be

$$v = \frac{300}{\sqrt{\epsilon\mu}} \cong \frac{300}{\sqrt{2.5}} = 190m/\text{microseconds}$$

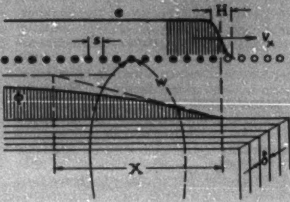


Figure 1

If we now scrutinize in figure 1 the rise of voltage over the coil in the first 10 μs, we see that after the instantaneous appearance of the initial distribution, the voltage very suddenly jumps a second time, and that the time delay of this jump depends upon the position of the tap point. For the tap point at:

$x = {}^1/_4\ {}^1/_2\ {}^3/_4$ of full length

the time until the voltage jumps is:

$\tau \cong 2.2\ 4.2\ 6.2\ \mu$ sec

Hence the wave velocity is:

$v = xa/\tau = 179\ 187\ 190\ m/\mu$ sec

These values of velocity are nearly constant and so close to the Maxwellian velocity as estimated above that it is somewhat difficult not to attach significance to these facts.

The second figure 8 shows, for the same winding, at the consecutive modes:

$m = 1\ 2\ 3\ 4\ 5\ 6$

resonance frequencies:

$f \cong 17\ 44\ 75\ 120\ 153\ 180$ kc/s

Hence the wave velocity is:

$$v = \frac{4af}{m} = 107\ 138\ 157\ 188\ 192\ 188\ m/\text{microseconds}$$

if the winding oscillates with nodes or antinodes at its ends.

Thus the three oscillations of highest frequency propagate again with the estimated Maxwellian velocity. The velocity of the oscillations of lower frequency, however, decreases, which I think is caused by a deeper penetration of their magnetic flux into the steel core. This would increase the average permeability and thereby decrease velocity and frequency.

Now the front of steep waves is always built up of the higher frequencies, while the tail is shaped by the lower frequencies, a theorem well known in Fourier analysis. Hence, we realize that both the experiments of figure 1, with steep impact waves and of figure 8a, with sustained oscillations, lead to the same conclusion, namely, that steep voltage waves in transformer coils can propagate with nearly constant Maxwellian velocity through the winding, and that their electromagnetic field is contained preponderantly in the dielectric space.

So the experiments of the authors prove very valuable not only with respect to the lower natural frequencies which they discuss in the paper, but also with respect to higher frequencies and to impact waves.

I presume that the reason for the insignificant influence of the steel core for rapidly-travelling waves is given by the effect of the time constant of penetration of a magnetic flux into steel sheets, which is represented in the accompanying figure 1. This time constant, according to a well-known formula, is for a steel thickness $\delta = 0.35$ mm, with specific resistance $\rho = 1.5 \cdot 10^4$ cm²/sec, and permeability $\mu_s \geqq 200$,

$$T = \frac{4}{\pi}\frac{\mu_s}{\rho}\delta^2 \geqq \frac{4}{\pi}\frac{200}{1.5 \cdot 10^4}0.035^2 = 20 \cdot 10^{-6} \text{ sec.} \quad \text{(a)}$$

For a ratio of pitch s to wire length w of a turn of a helical coil, such as $\frac{s}{w} = \frac{1}{1{,}000}$, the axial velocity of steep waves, as determined above, is

$$v_x = \frac{s}{w} \geqq \frac{1}{1{,}000} 190 m/\mu s = 19 \text{ cm}/\mu s \quad \text{(b)}$$

The lag in space of any magnetic steel flux behind a travelling electric wave front in the coil is therefore represented by the space constant

$$X = v_x T \geqq 19 \cdot 20 \cong 400 \text{ cm} \quad \text{(c)}$$

This means, with regard to the accompanying figure 1, that the electromagnetic field of steep voltage waves of a front length of say less than 10 per cent of the space constant, namely, $H \leqq 40$ cm in the axial direction, or $\leqq 400 m$ along the conductors, does not penetrate the magnetic core to a considerable amount.

The internal insulation between coils, layers, and turns is stressed preponderantly by these initial steep and rapid waves, which travel within the dielectric space. The slower successive oscillations, however, as those of 41 kc/s in figure 1 of the paper, may contain some steel sheet flux, in case there is no closed secondary winding to suppress it.

As to the mathematical development in the paper, I would like to ask whether the extended expression for the voltage in time and space, equation 10 of appendix I, which comprises two different infinite series, could not be condensed for all actual cases simply to

$$e = E \cdot \sin bt \cdot \sinh (\alpha + j\beta)x \quad \text{(d)}$$

a form which is more familiar to most engineers and which gives the same graphical results.

P. L. Bellaschi (Westinghouse Electric and Manufacturing Company, Sharon, Pa.): Years of research and design experience have borne out the practical and theoretical advantages of the method of free or natural oscillation for determining the performance of windings under transient conditions. These advantages are summed up by Messrs. Bewley, Hagenguth, and Jackson in their paper. To these I may add that this method, which consists in determining the natural modes of oscillation or response of windings to an impulse, also has the advantage in that the analytical process and the steps in the calculation apparently find their closely related counterpart in the experimental results. This physical relationship between the tool of analysis and the performance of the apparatus designed is an important factor for it gives the designer that physical and quantitative grasp of the problem, the importance of which I need not elaborate. Furthermore, the method fulfills an essential criterion in that it is fundamentally basic and sound. The following typical examples will serve to illustrate.

It would extend this discussion unduly to enter into a detail comparison of the extensive analytical work and the experimental results. Therefore, the comparison will be confined largely to the natural periods of symmetrical windings in the same manner as the authors have done. In the design of a 4,500-kva, 144-kv shell-type, two-group winding, the fundamental period calculated 300 microseconds—a value within seven per cent of the oscillographic record. Likewise, the initial voltage distribution of the entire winding and of the line group ($\alpha = 1.0$), the amplitude of the fundamental period, the period and amplitude of the line group, and other quantities of practical significance in the design were predetermined within about ten to twenty per cent of the actual performance. In the case of a 3,000 kva, 140 kv, shell type symmetrical winding, the fundamental period is 200 microseconds which compares within ten per cent of the calculated value. The amplitude of the fundamental oscillation developed from a long-duration, abrupt-front impulse applied to one end of the winding with the other end grounded is forty per cent. Similarly, the calculated periods and their amplitudes for the higher harmonics compare within ten to twenty per cent of the oscillograms. For instance, the natural period of the line coil group calculates 29 microseconds against an experimental value of 25 microseconds.

The method applies to core-type windings as well, in which case the distributed mutual inductance naturally must be taken into account for correct results. It is applicable to dissymmetrical windings and to other windings. It can be extended to a wide variety of conditions and problems such as inevitably are encountered in actual practice. For instance, the determination of effects resulting from transferred surges from high to low voltage windings with the latter, let us say, connected to a segment of cable, or for determining the voltage developed at the transformer terminals when an inductive element (reactor, current transformer, etc.) intervenes between the transformer and the line.

In an extensive analytical survey of the problem initiated some twelve years ago, we were able to predetermine the inherent characteristics such as the fundamental period, etc. of the various types and constructions of windings. The results were substantiated in the course of time by tests made on the transformer units built. For power transformers, it was found that the fundamental period of core-form windings from 69- to 220-kv ranges respectively from 20 to 80 microseconds and for the shell form, the corresponding periods extend from 80 to 200 microseconds and even as high as 300 microseconds as cited in preceding examples.

L. V. Bewley, J. H. Hagenguth, and F. R. Jackson, Jr.: Dr. Rüdenberg assumed a value of $\sqrt{\mu\epsilon} = \sqrt{2.5}$ for the dielectric space between the winding and core of a complete transformer. However, the tests described in the paper were made in air on a transformer, the low-voltage winding of which had been removed. Thus, the space in question was largely air, except for a supporting cylinder 0.25 inch thick and the spacing strips between the cylinder and winding. The calculated average dielectric constant for this space is less than 1.2. Accordingly, the Maxwellian velocity would be

$$v = \frac{300}{\sqrt{1.2}} = 274$$

rather than 190 as calculated by Rüdenberg.

We have measured carefully the original full-sized oscillographic tracings from which figure 1 of the paper was made. It will be seen in figure 1 that the voltage jumps are not abrupt, but start as a small fillet; and, moreover, the wave front is different at the different points along the winding. Therefore, we are not certain which instant on the oscillogram represents the time of arrival of the supposed wave at a given point. If we suppose this time to be between the start and finish of the fillet, and record these two extremes, we find corresponding to the tabulation given by Rüdenberg:

Distance from line end	1/4	1/2	3/4
Time to voltage jump	0.7	2.7–4.5	4.5–5.5
Apparent wave velocity	565	290–174	260–215

These values should be compared with those given in the second tabulation of Dr. Rüdenberg's discussion.

Dr. Rüdenberg asks if equation 10 in appendix I of the paper could not be put in the form

$$e = E \cdot \sin bt \cdot \sinh (\alpha + j\beta)x$$

The object of the particular form of equation 10 was to bring out three facts:

1. That the *dominant* term of the sustained oscillations is $EA_s \sin \frac{s\pi x}{l} \cdot \frac{b}{2\gamma_s} \cos bt$.
2. That the oscillations occur about the *initial distribution* $e(0) \cdot \sin bt$ as an axis (see figure 6).
3. That a resonant applied frequency can excite space harmonics other than those corresponding to the resonant frequency.

None of these things are indicated in the condensed form suggested by Rüdenberg. Moreover, that the suggested condensed form cannot be equivalent to our equation 10 is obvious upon noticing that our dominant term is cos bt, whereas Rüdenberg's form contains only a sin bt.

Mr. Bellaschi's test results do not entirely check the data accumulated over many years by other investigators, which indicate that the natural period of core type transformers of ordinary design varies between 25 microseconds and 160 microseconds, depending on kilovolt-ampere and kilovolt rating, and that of shell-type transformers varied between the same limits.

It is, of course, recognized that the lower the natural period of a transformer, the higher will be the amplitude of the low-frequency harmonics for a given length of applied wave. Oscillations are practically eliminated, regardless of applied wave length, in the shielded type of transformer.

Transient Torques in Squirrel-Cage Induction Motors, With Special Reference to Plugging

Discussion of paper 41-126 by E. S. Gilfillan, Jr., and Edward Kaplan, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1200–09.

W. K. Boice (General Electric Company, Schenectady, N. Y.): This paper represents a very interesting and timely contribution to the study of transient torques in induction motors. The practical significance of such torques has recently received increasing attention.

The General Electric Company is at the present time making a study including factory tests of the transient torques occasioned by switching sequences such as those involved in transferring motors to full voltage from reduced voltages used for starting. Experience has shown that very high torques are possible under unfavorable conditions. It is proposed to publish the results of this study in the near future.

New Current Transformer for Bus Differential Protection

Discussion and authors' closure of paper 41-135 by L. F. Kennedy and A. T. Sinks, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1180–7.

E. F. Bancker (General Electric Company, Schenectady, N. Y.): Some things are just too complicated for the human intellect to solve. Others can be solved but involve a lot of tedious work and since most of us are inherently lazy we use much ingenuity in devising ways to get out of such hard work. For one or the other of these reasons such things as the differential analyzer and a-c network analyzer have come into being. Another method of avoiding unpleasant work is to dodge it by getting the desired result in a totally different way that eliminates the onerous task.

Knowledge of the exact characteristics of current transformers in the saturated region is beyond the grasp of some of us and involves a lot of tiresome computation on the part of the few who know how to do it. For each bus differential application the conditions differ by just enough to require a new set of calculations. Yet high speed bus protection is deemed valuable and some way of accomplishing it is needed.

A few years ago solutions were offered in the form of relays that tried to distinguish between differential currents that should cause tripping and equally large differential currents that should not cause tripping. Last year a series of current transformer papers were presented in the hope that a better knowledge of their idiosyncracies would assist us in applying them to bus protection. This year we have two more papers based on the method of dodging the difficulty and that to me is the right approach.

The difficulties with conventional bus differential protection have been twofold. One is the non-linear exciting current of overworked current transformers. The other is the complications in secondary connection switching imposed by some primary switching arrangements. Mr. Kennedy and Mr. Sinks describe a method for circumventing the first by eliminating it. Mr. Steeb tells how to get around the second in one instance.

The development of the air gap core current transformers resulted from a facetious remark made by Mr. Sinks after he had been through the design calculations of a conventional current transformer for a specific job. He said in substance that he would have to find some iron good for a flux density of two million lines per square inch and added that in his opinion it would be better to put a gap in the core and make the a-c magnetizing current linear for all flux densities even though this current were much higher than usual. The seed thus planted took some time to germinate because at the time the discriminating relay approach looked satisfactory and it was thought that a solution using standard current transformers was advantageous. But somehow or other the calculations seemed to be just as numerous and attention returned to the advantageous features of a linear magnetizing current.

When the magnetizing current is linear the ratio of a current transformer is constant for a fixed burden. In differential applications the burden is constant for all external faults as it consists of the impedance of the secondary and leads to the paralleling point. With a constant ratio there is no secondary difference current for any external fault current regardless of its size, distribution, or amount or time constant of d-c component. This is understandable and we all prefer something we can understand. Also, it reduces computations to the simple one of determining the initial a-c short circuit current in order to select the proper rating of current transformer and a check of the sensitivity of the ground relay where the ground current is limited to a small percentage of the interphase fault current.

Thus, the development presented in this paper enables us to apply bus differential protection with assured knowledge of its operating characteristics, with a minimum of application engineering, and in an easily comprehensible manner. In other words, we have what appears to be the ideal solution to bus differential problems where the d-c effect on standard current transformers cannot be neglected.

C. D. Hayward (General Electric Co., Philadelphia, Pa.): It will be a very great relief indeed to those who have tried to calculate mathematically the performance of current transformers under short-circuit conditions to find in the air-gap core current transformer a device which does not saturate. Saturation in closed core current transformers produces variations in the self- and mutual-inductances making them functions of the applied current. Because of this the attempt to express the performance of the transformer mathematically leads to a non-linear differential equation which cannot be solved by the ordinary classical methods. One must resort to laborious approximate methods, to mechanical integrating devices such as the differential analyzer, or to actually making short-circuit tests and taking oscillograms. To cover completely any practical application problem a number of solutions must be made covering all combinations of conditions. For example, in the bus differential case solutions must be made for different combinations of fault current magnitude, distribution of fault current between the current transformers in the several circuits feeding the fault, for different degrees of wave offset, for internal and external faults, etc. Furthermore, there is always a certain amount of inaccuracy in the solutions due to variations in the saturation curves of different current transformers and due to residual magnetization. After the solutions for the current have been found there is the further problem of determining the relay performance on the distorted waveforms obtained. Altogether the problem is a very tough one indeed.

In the case of the air-gap current transformer, on the other hand, the problem is relatively simple. Since no saturation occurs the inductance of the current transformer remains substantially constant. If the secondary burden inductance also remains constant, the differential equation is a linear one which may readily be solved by the operational calculus. An analysis made in this way for the case of a single air-gap current transformer with constant burden shows that if an offset current wave:

$$i_1(t)=I\left[\sin\,(\omega t+\theta)-\sin\,\theta\epsilon^{-\frac{t}{T_1}}\right]$$

is applied to the primary, the secondary current will be:

$$i_2(t)=I\frac{M}{L_2}\left[\sin\,\phi\,\sin\left(\omega t+\theta+\frac{\pi}{2}-\phi\right)+\right.$$

$$\cos\,\phi\,\sin\,(\theta-\phi)\epsilon^{-\frac{t}{T_2}}-$$

$$\left.\sin\,\theta\,\frac{T_1\epsilon^{-\frac{t}{T_2}}-T_2\epsilon^{-\frac{t}{T_1}}}{T_1-T_2}\right]$$

where:

I = maximum value of the steady state primary current in amperes

θ = switching angle in radians

$T_1=\dfrac{L_1}{R_1}$ = time constant of primary circuit in seconds

= time constant of d-c component of primary current in seconds

$T_2=\dfrac{L_2}{R_2}$ = time constant of secondary circuit (including *CT* winding) in seconds

$\phi=\tan^{-1}\dfrac{\omega L_2}{R_2}$ = phase angle of secondary circuit (including *CT* winding) in radians

L_1 = primary circuit inductance in henries

R_1 = primary circuit resistance in ohms

L_2 = secondary circuit inductance (including inductance of *CT* secondary winding with primary open-circuited) in henries

R_2 = secondary circuit resistance (including *CT* winding) in ohms

M = mutual inductance of current transformer in henries

$\omega = 2\pi f$ (radians)

f = frequency in cycles per second

t = time variable (seconds)

The first term on the right-hand side of the expression for the secondary current is the steady-state term. Comparing this with the first or steady-state term in the expression for the primary current above, we see that the transformer ratio has the value:

$$\frac{M}{L_2}\sin\phi$$

while the phase shift angle is:

$$\frac{\pi}{2}-\phi$$

These are dependent on the secondary burden but independent of the current.

The second term in the expression for secondary current is a transient current set up due to switching the primary current at a phase angle different from the phase angle of the secondary circuit. This term will normally be quite small because of the factor cos ϕ. The secondary circuit phase angle ϕ is near $\pi/2$, and hence cos ϕ is nearly zero, because of the relatively high inductance of the current transformer secondary winding.

The third term in the expression for secondary current represents the transformation of the d-c component as given by the second term in the expression for primary current. In the usual bus differential relay application the time constant of the current transformer secondary circuit is quite small compared with the time constant of the primary circuit. If we assume T_2 may be neglected in comparison with T_1 the third term reduces to:

$$-\frac{M}{L_2}\sin\theta\epsilon^{-\frac{t}{T_2}}$$

which compared with the primary current term:

$$-\sin\theta\epsilon^{-\frac{t}{T_1}}$$

differs by the factor M/L_2, which is essentially a turn ratio factor, and by the shorter secondary time constant T_2 being substituted in place of the primary time constant T_1 in the exponential. Because of this change in time constant the d-c component in the secondary current dies away at a much more rapid rate than does the d-c in the primary. This is a proof of the assertion in the paper that the d-c component is not reproduced to any extent.

E. L. Harder (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): During the summer of 1938 a series of tests were made on air gap core current transformers for bus protection in the laboratories of the Westinghouse company. First, available designs having gaps, such as the impulse coils used on d-c circuits were tested. Then, four transformers specifically designed for bus protection were built, two having circular cores and two having rectangular cores. Each of these had four gaps instead of eight as shown in the subject paper but had four identical coils and the gaps were symmetrically disposed with respect to the coils. Based on the experience of our tests on these gapped-cores I would like to comment on the authors' paper, beginning with the necessary length of gap.

If in an iron core with gaps there was no fringing, so that the flux in the iron section crossed the gap within an area the same as the iron section, then to hold the flux density in the iron below saturation (taken as 12,000 lines per square centimeter), there must be one inch of air gap for each 24,200 ampere-turns of excitation. Considering fringing the actual gap length must be much greater. In tests of transformers with four three-eighths-inch gaps important saturation began at less than 50 per cent of the exciting current which would have been required to produce 12,000 lines per square centimeter on the basis of no fringing.

It is brought out in the paper that an air gap transformer for 100,000 amperes symmetrical will have a crest excitation current in the neighborhood of 140,000 amperes. The necessary total gap is therefore something over six inches depending on the amount of fringing. Relieving the corners by stepping back the core reduces the fringing problem. However, each of the core pieces in figure 3 of the paper is separated from its neighbor by one-eighth of the total exciting ampere-turns and the fringing flux is still very appreciable. This makes it very difficult and impractical to calculate accurately the maximum flux density at any point of the core. Reliance must be placed on tests which are subject to instrument errors as evidenced in table II. The voltmeter-ammeter method of checking linearity is simply not sufficiently accurate for this purpose as will be shown shortly. It was partly because of the difficulty of obtaining and proving pure linearity with the necessary limits and partly because a superior arrangement was in the meantime devised that the gap transformers were not offered to the industry.

The paper has stressed the energy delivering properties of the air gap design as the reason for its selection in preference to pure unadulterated air. However, the fundamental factors which determine whether a transformer can or cannot be used in a straight differential arrangement are:

1. The ratio of maximum through fault to necessary setting for internal faults.
2. The inherent errors of the transformer.

If the total errors do not cause the secondary currents to depart more than ±$2^1/_2$ per cent from primary current, divided by some constant ratio, then during a through fault the false differential current cannot be more than five per cent. If the relay is set at 10 per cent of the maximum through fault current, a 100 per cent safety factor is provided.

Thus with 100,000 amperes through fault and transformers of a constant ratio within ±$2^1/_2$ per cent (vectorial) a setting cannot be safely much less than 10,000 amperes even though the current transformer is capable of operating the relay set down to 100 amperes. This brings out the importance of the several errors; the manufacturing tolerance, the two per cent temperature error mentioned in section 6, the remnant saturation not detected by the voltmeter-ammeter method, and the remnant interference from other circuits due to not being perfectly astatic. It would be desirable to eliminate some of them altogether if possible. All of these may be cumulative in certain cases.

As long as there is ample energy to operate a reliable relay the output of the transformer is unimportant as compared with its accuracy which determines its "range," or ratio of permissible maximum through fault to setting.

L. W. Matsch (Commonwealth Edison Company, Chicago, Ill.): The authors, by means of their air-gap-core current transformer, have accomplished two noteworthy things. First, they have practically eliminated the d-c component, due to fault current, from the relay in the bus differential scheme thus making the use of a simpler relay feasible. Second, they have found a means of keeping the constants of the current transformers practically linear thus eliminating differential currents resulting from unequal current transformer saturation during faults.

The authors mentioned that a relay of the instantaneous overcurrent type could be used. A relay which is to have the same sensitivity in combination with the proposed current transformers as one in combination with conventional transformers would need to have lower impedance because of the low secondary open-circuit impedance of the current transformers described in the paper. I would like to know whether they had any special instantaneous overcurrent relay in mind.

In the last paragraph under *Application* it is stated that "good practice for the moment dictates a minimum relay setting corresponding to not less than ten per cent of the maximum fault current." This seems a rather high minimum setting since there are installations in which the maximum fault current may be as high as 70,000 amperes rms a-c and in which phase-to-ground faults of less than 2,000 amperes may occur. Apparently there must be a considerable hazard of improper operation during external faults if the relay is sensitive enough to take care of such low internal faults.

Since the ten per cent limit recommended by the authors is too high to adequately protect such a circuit I am interested in knowing what experience on the part of the manufacturer or operator led to this limit.

W. K. Sonnemann (Westinghouse Electric and Manufacturing Company, Newark, N. J.): In this paper the authors have briefly reviewed the difficulty which used to be experienced in applying bus differential relays where the d-c transient was a problem. The difficulty experienced due to current transformer saturation cannot be taken care of by conventional relays except by increasing the minimum trip setting, the time delay, or both. An analysis of the relay characteristics required to preserve both a reasonable minimum trip setting as well as reasonably high speed of operation indicated that it would be possible to build a special relay that would cope with the problem. This relay embodying "variable percentage characteristics" was developed a few years ago and a large number have been applied to bus protection with very satisfactory results. This relay was first described at the winter convention in 1939. Thorough tests, together with theoretical considerations, have shown that the relay may be applied without the laborious time-consuming calculations mentioned by Messrs. Kennedy and Sinks. All that is necessary for a proper application is to be sure that an adequate number of restraining elements are available and that the current transformers meet certain definite and well-defined requirements from an a-c standpoint.

The formulas developed in the paper are based on a four-circuit bus as shown in figure 1 of the paper. The authors neglect to mention the effect of adding additional circuits. With a given relay setting, of course, adding additional circuits will obviously decrease the sensitivity of the overall combination. The authors have concluded that the relay should not be set for less than ten per cent of the maximum fault current, and it is presumed that this is based on the four-circuit bus shown in figure 1 of the paper. Quite a number of generating station busses have large numbers of circuits up to ten or even more so that it is felt that a few words should be added explaining the effect of the additional circuits on the recommended range between minimum internal fault and maximum external fault.

It would appear that the gain obtained by using an iron-core transformer with air gaps was not all that is desirable. While it is true that the authors show that some saving in weight and dimensions has been made over the super-size current transformer design that will not saturate on d-c transients, the air gap transformer appears to be considerably larger and heavier than conventional standard current transformers. It would appear that the principle of air gaps in an iron circuit to prevent saturation is thus not readily applicable to use inside of the breaker bushings in place of bushing-type current transformers. This is considered unfortunate.

L. F. Kennedy and **A. T. Sinks:** Dr. Hayward's discussion gives a mathematical proof that there may be some d-c in the secondary of the air gap core current transformer under transient conditions but that its duration is short. Since the transient d-c in the secondary does not resemble that in the primary very closely, one might be led to suspect that there might be an unbalance of the secondary d-c components of a group of air gap current transformers connected to a bus during a through fault thus causing false relay operation. However, if the current transformers are all alike, there will still be no unbalance of either d-c or a-c because all the secondary current components bear the same relation to their respective primary currents.

Mr. Harder points out that fringing of the flux at the air gaps makes necessary a larger gap than would be necessary without such fringing. However, it should be noted that the increased length of gap together with the fringing that does occur results in a total reluctance which is the same as one would arrive at if one neglected the fringing and used the theoretically correct gap length based on a gap cross-section equal to that of the iron. Fringing, therefore, only affects the actual calculation of the shape and size of the gaps. Concerning the accuracy of calculating these gaps, it might be said in passing that for the first sample transformers of this construction made, it was necessary to alter the gaps only about ten per cent to arrive at the value of magnetizing impedance planned on.

It is quite possible that in the tests Mr. Harder mentions the stray field flux had considerable amount to do with the saturation of the core, as it has been found that at high currents, even with reasonably large conductor spacing, the amount of flux passing through the cores of current transformers due to currents in adjacent conductors is a very large per cent of the main flux. It was, of course, for this reason that the copper casing was included on the design described in the paper.

Mr. Harder indicates that the voltmeter-ammeter method of checking the linearity of exciting current is not sufficiently accurate to insure proper operation of the air gap core current transformers. For high accuracy requirements, this statement is undoubtedly true for complete air core transformers where it is almost impossible to make a transformer in a reasonable size in which the exciting current is not larger than the secondary current. In such a design, a given percentage variation in exciting current for a given voltage means a nearly equivalent percentage change in the relation between the primary and secondary current; whereas with the air gap core transformer represented in the equivalent circuit, figure 9 of the paper, a given percentage change in the exciting current for a given voltage will result in only one-sixth of this percentage change in the relation between the primary and secondary current, if the value of Z_B is less than four ohms. Consequently, the maximum spread in magnetizing impedance values of about two per cent in table II of the paper represents a difference in the phase angle of the secondary current in figure 9 which is one-third of one per cent of the secondary current and means practically no difference in ratio.

The authors' experience is that the energy delivering properties of the air gap current transformers are important because, as pointed out in the second paragraph following the mathematical analysis, in case of an internal fault, the relay impedance acts as if it were N times its actual value in affecting the accuracy of the transformers, where N is the number of transformers operating in parallel to supply the relay. This means, that even with a relatively low impedance ground relay, the effective impedance may be appreciable if there are say ten feeders connected to a bus with three transformers on each feeder, making a total of thirty transformers connected to the relay.

It is possible that the accuracy of the air gap core current transformer is not enough for the minimum ratio of ground fault to through fault current that may be encountered on some systems, although tests show that the figures given in the paper are conservative and limits could be made closer. However, if conventional transformers of reasonable size were installed on a bus having from a number of sources a through fault capacity of the 100,000 amperes Mr. Harder mentions, the transformer carrying the total fault current would saturate so badly that it is doubtful whether any relay could distinguish the condition from a fault on the protected bus. It would, therefore, seem that the air gap current transformer, even though it may not meet the most stringent requirements one can find, is a considerable improvement over conventional transformers.

In answer to Mr. Matsch's question about the sensitivity of the relay required for use with the air gap core transformer, it has been the authors' experience that no special relay is necessary but that it is usually necessary on the other hand to avoid high impedance relays.

Mr. Matsch's remarks concerning the ratio of ground fault to through fault current have been answered above.

Mr. Sonnemann indicates that the application of conventional current transformers to bus differential protection is a relatively simple matter. However, this has not been the authors' experience. Moreover, it would seem that the papers on current transformers presented at the 1940 winter convention are ample testimony to the work of calculating the accuracy of saturated current transformers.

The effect of increasing the number of circuits connected to the bus is covered for a fault in the protected area by the remarks above and by the second paragraph following the mathematical analysis in the paper. For the case of a through fault, the number of circuits connected to the bus should not affect the relay setting in per cent of the total fault current.

The air gap core current transformer designs will have to vary, of course, with different electrical and mechanical requirements of different applications and it is true that in general these designs will be larger than the so-called standard current transformers. However, enough reduction in size has been obtained by the air gap core design over the "supersized current transformers that will not saturate on d-c transients" to provide current transformers for bus differential protection that can replace the bushing transformers ordinarily used in circuit breakers.

Bus Protection Independent of Current-Transformer Characteristics

Discussion and author's closure of paper 41-99 by G. Steeb, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 859–62.

L. N. Crichton (Westinghouse Electric and Manufacturing Company, Newark, N. J.): This excellent paper by Mr. Steeb describes an installation in an unusually complex station. Using his experience as a guide, I have attempted to simplify his scheme and make it suitable for general application. Figure 1 of this discussion has the appearance, at least, of being much simpler and does not have the first two limitations listed in the paper.

In order to make the plan a general one, it should be suitable for that common case

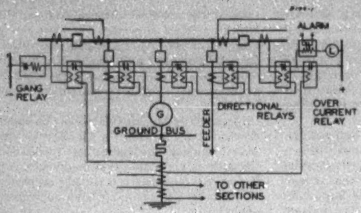

Figure 1. Bus-protection scheme using directional ground relay

where a feeder may or may not furnish fault current.

The new principle in this scheme is the use of a directional ground relay so built that its contacts are held closed by a spring when the relay is deenergized. One of these relays is connected to each feeder and to each source of power and to the bus ties. The only other relay is an overcurrent relay used as a fault detector and operated by current from the main station ground. The contacts of all the directional relays are in series as are also the normally open contacts of the fault detector.

When system conditions are normal, all the directional relay contacts are closed and upon the occurrence of a fault outside the bus section it will be necessary for at least one of these directional contacts to open before the overcurrent relay closes. There is no particular difficulty about accomplishing this and a satisfactory performance can be obtained from ordinary induction-type relays. No *B* switches are necessary, no special wires are run to the breakers, nor need system operators worry about any particular switching sequence. The only requirement is that a polarizing current must always be available, as it easily can be at all stations where there is ground connection. At substations that have no grounded neutral a polarizing potential may be used and a potential relay used on the fault detector.

The important thing about this arrangement is that all of the contacts can be supervised not only by a lamp but by an alarm relay. This, together with the comparatively small number of connective wires between different circuits should make this scheme a useful one in many locations.

E. H. Bancker (General Electric Company, Schenectady, N. Y.): Two of the difficulties encountered in bus differential protection are variation in current transformer ratio with saturation and complicated secondary switching arrangements where a set of current transformer secondaries must be in either of two bus differential systems depending upon disconnecting switch positions. Mr. Kennedy and Mr. Sinks tell of a means for overcoming the first and Mr. Steeb shows how the principles of carrier pilot relaying may be used to advantage to circumvent the second. His arrangement would be essentially the same as carrier relaying if all breakers had a circuit opening overcurrent relay and a circuit closing directional relay contact in parallel, as the tie breakers have. However, the overcurrent relays may safely be omitted from those circuits that are always sources of fault current and the directional relays from those that are never a source. In the more usual case of multiple grounded systems, the feeders would need directional as well as overcurrent relays.

Although the scheme of protection described in this paper is nearly independent of current transformer characteristics, it is not wholly so. The neutral resistor reduces the zero sequence component of two phase to ground faults but the phase to phase component is practically unaffected. The zero sequence voltage for this type of fault is 90 degrees displaced from the phase to phase voltage of the faulted phases. Since the currents are controlled by resistance in one case and chiefly by reactance in the other, they are nearly in phase so that both current transformers have primary currents that are essentially in phase but differing in size by nearly three times the zero sequence component. This difference, plus the effect of d-c. offset, may result in material changes in ratio of the two current transformers so that their secondary residual current may be considerably smaller than three times I_0. Such a reduction might prevent blocking by a feeder overcurrent relay for a two phase to ground feeder fault, but is probably not great enough to cause a directional relay to fail to operate to clear a bus fault. Consequently it would appear that this scheme has a field of utility where differential or fault bus protection would be difficult to apply.

J. H. Oliver (General Electric Company, Philadelphia, Pa.): Mr. Steeb has approached this bus-protection problem with an open mind. He has analyzed the available methods of high-speed bus protection and has recognized their economic limitations as applied to this particular job.

With true engineering spirit he did not abandon the idea of bus protection for this old station when available schemes were uneconomical to install, but went ahead and developed this scheme using standard relays. His use of oscillographic proof that the devices chosen for the job would perform in specified times and with proper contact action, combined with a year's tryout (including staged tests), shows the thoroughness of his investigation before this installation was actually put in service. Thus, others who may wish to adopt this scheme of protection for equivalent problems have the benefit of the investigation already made by Mr. Steeb.

It would seem that the limitations as outlined in the paper can be readily overcome by treating the ground-source circuits the same as the tie breaker; i.e., use one overcurrent relay in addition to the directional ground relay on each ground-source circuit, connecting the normally closed contacts on the ground-source overcurrent relays the same as on the tie breaker, and eliminating the *B* auxiliary switches now used. In addition, connect a normally open contact

on each of the ground-source overcurrent relays in parallel with a normally open contact on the bus-tie overcurrent relay and insert this set of paralleled contacts next to the overcurrent-relay-in-station-neutral contact in the gang-trip-relay-coil circuit. The connection of the supervising light can also be moved, as shown in the schematic connection diagram, Figure 2, to supervise the normally closed contacts which have been added to the circuit.

This connection avoids limitation 1 since the gang-trip-coil circuit will remain open in the case of one bus section's being fed only through a tie breaker and a bus fault taking place on one of the other bus sections, as the normally open contacts on all ground-source overcurrent relays and on the bus-tie overcurrent relays on the particular section not involved in the fault will remain open.

Limitation 2 is avoided as the normally closed contact of the overcurrent relay added to the ground-source circuit will remain closed, completing the bypass circuit around any ground-source breaker out of service for maintenance.

R. C. Silver (Gatineau Power Company, Ottawa, Ontario, Can.): Mr. Steeb's paper is particularly interesting to us since in 1935 we installed similar protection for ground faults on four 11,000-volt bus sections. Overcurrent relays were used for blocking and also for initiating the tripping. These latter were operated from the paralleled secondaries of current transformers on the two or three possible sources of ground fault current. A time delay of 0.10 second was introduced in order to insure selective operation of contacts. These four sets of relays have been in service for over five years and no faulty operations have occurred.

In 1936–37 we assisted in the design and installation of another similar protection for a 66,000-volt bus in a hydrogenerating station which involved nine generators and five 66,000-volt transmission lines. The protection was designed to respond to phase to ground and three phase faults. Impedance relays on a number of the transformers initiated the tripping while blocking was arranged through the instantaneous line and transformer protections. A time delay of 0.10 second was considered necessary in this case also.

Both types of protection were installed in older stations where it would have been very difficult and expensive to install a differential bus protection.

Mr. Steeb is to be congratulated on the high speed operation of the scheme he has described.

R. T. Henry (Buffalo, Niagara and Eastern Power Corporation, Buffalo, N. Y.): The bus relay scheme proposed in Mr. Steeb's paper was not developed as an alternative to conventional bus differential relay schemes even though it is applicable in any case where bus differential relay schemes could be used and it is true that this scheme is independent of current transformer characteristics so far as the dissimilarity of current transformers at high overloads is concerned.

This scheme was developed primarily for bus arrangements on which it is impracticable to apply the conventional bus differential relay scheme. The first application of this scheme was made on a 22 kv outdoor switching station with a double bus and selector disconnecting switches. Such an arrangement does not lend itself to bus differential relay schemes.

This scheme may be easier to visualize if it is considered as consisting essentially of directional relays on each circuit with the tripping contacts all in series, so arranged that if all of the directional relays "face in" towards the bus, the gang trip relay will operate, but if any one "faces out" from the bus it prevents the gang trip relay from operating. Actually, the relays on circuits which never supply current towards the bus can be simple current relays without any directional characteristics.

While this scheme has been applied for ground faults only, it is equally applicable for phase to phase faults.

L. F. Kennedy (General Electric Company, Schenectady, N. Y.): Mr. Steeb has used his knowledge of line protective methods to develop a method of bus protection which is essentially free of dependence upon current transformer performance. The arrangement, which he has described, is in reality an extension of the carrier current pilot relay system, because its principle is that fault current flowing away from the protected area prevents tripping. This principle has been successfully used in all carrier pilot systems and has also been successfully used in a number of d-c pilot systems. Basically, then we can concede that the method has been proven to be sound, and the only questionable point would be whether the addition of many more contacts in series would introduce any factor tending to decrease the overall reliability. Contact failure would, in general, tend to cause a failure to trip for an internal fault. This probability has been taken care of, to a certain degree, by the supervision of the normally closed series contacts.

There would appear to be at least two conditions which still would require a certain degree of dependence on the current transformer characteristics. The system shown in figure 1 of the paper limits the current in case of ground faults by means of a neutral resistor. The phase fault currents are apparently limited only by the generator and transformer impedances. On this type of system there is frequently encountered a very great difference in magnitude between the current flowing to a ground fault and that flowing into a multi phase fault.

Where such conditions exist it would be possible in the case of an external two phase to ground fault on a feeder circuit to have current transformer saturation reduce the secondary zero sequence current below the value required for correct blocking and an unnecessary interruption to the bus would result.

Another, but more remote possibility would be the case of an internal two phase-to-ground fault where again current transformer unequalities might cause the ground current relay on an ungrounded source to pick up and thereby prevent tripping when a fault actually exists.

It is not probable that these limitations would be encountered in the case of the 22-kv bus installation described by Mr. Steeb. It would seem, however, that this system of protection for other applications is still dependent upon current transformer performance although it is probably less seriously affected than some of the other methods which have been proposed. The system might be made less liable to failures if all the blocking relays were of the directional type but this would increase the complexity of the system.

In conclusion it does seem desirable to reiterate what I have said many times before. "Bus sections of all types and particularly those where large concentrations of power and services occur should always have automatic protection." There will probably be differences of opinion (at least for a few years) as to the best method of providing such protection, but I remain convinced that some form of protection is much to be preferred over none at all.

E. W. Knapp (Shawinigan Water and Power Company, Montreal, Can.): The arrangement as outlined in this paper undoubtedly constitutes an important development in the art of bus relay protection. Some years ago a scheme of bus protection, similar to the arrangement presently being discussed, was proposed for one of our 25-kv isolated neutral systems. In this case, impedance and directional relays were to be used for short-circuit protection only. Although the advantages of such a scheme were recognized it was felt that extreme care would need to be exercised with regard to such conditions as relay timing and contact bounce.

It is indeed encouraging to know that Mr. Steeb has been able to solve this problem in a satisfactory manner. A study of the paper appears to indicate that especial care has been exercised in the choice of relays. I have been particularly impressed with regard to the close timing which has been used to insure selectivity of operation. As a matter of interest, there are a number of points where further discussion might be desirable.

(*a*). In the case of cross-short circuits involving one phase to ground on the bus and a second phase to ground on one of the feeders, would it be necessary to clear the feeder before the bus protection can clear the bus? If so, how long would it take to clear the feeder and would this extra period of heavy fault current tend to cause a permanent bus outage? The same condition might also apply for multi-phase faults possibly during lightning, where the bus and one or more feeders were involved.

(*b*). As some of the current relays are set at a value of 300 per cent of maximum ground fault current, has any trouble been experienced due to a division of current between parallel circuit breakers or possibly due to one or more of the grounding banks being out of service or some other condition tending to reduce the amount of ground fault current?

(*c*). Has any trouble been experienced due to residual current or possibly sticking relays tending to retard the operation of the respective relays and thus destroy selectivity?

W. R. Brownlee (Commonwealth and Southern Corporation, Jackson, Mich.): It is worthy of note that even after a trial period of a year with the relay trip circuits blocked, the author deemed it advisable to make comprehensive short circuit tests before placing the bus protection relays in operation. If carefully planned,[1] short circuit tests will not only provide conclusive answers with reference to the new installation being studied but will frequently reveal enough unsuspected system or equipment conditions to justify the tests.

CHOICE OF SCHEME

Confining protection to ground faults greatly simplifies any bus protection arrangement and many operators will agree with the author that such protection is entirely sufficient if breaker tripping is initiated before the fault involves all three phases. Naturally this time will vary with different bus arrangements, but it is felt that the speed of one to two cycles obtained by the author (five cycles on a 60-cycle basis) is quite conservative and that operating times as high as 10 to 15 cycles on a 60-cycle basis may be sufficiently fast for typical outdoor high voltage busses.

Independence of current transformer characteristics is an important advantage even for new stations and though careful timing, coordination, and exhaustive analysis of system conditions are required, the directional contact scheme might be chosen more frequently in preference to differential protection (including the schemes confined to ground differential protection) except that a surprising number of "bus faults" appear as simultaneous flashovers of one or more bushings on the line side and also the bus side of a single oil circuit breaker which not only prevents correct operation of the bus protection relays as long as the breaker is closed but may confuse the tie line directional ground relays so as to prevent their operation also.

CO-ORDINATION OF RELAYS

The author is to be commended for his painstaking tests of the various relay elements to be coordinated. His conclusions on plunger relays were confirmed by recent tests in connection with pilot wire equipment in which two identical high speed plunger relays were energized simultaneously with a neon lamp connected to indicate whether the normally open contact of either would be closed in advance of the opening of the normally closed contact of the other. Observations were made both on energizing and de-energizing the relays. Perfect coordination was observed with currents from 4 per cent above the pickup setting of the plungers up to 300 per cent of pickup, at which current the circuit closing speed of the relays is one-half cycle on a 60-cycle basis.

LIMITATIONS OF SCHEME

From limitation 1 it appears that the author cannot trust the interval between the one-fourth cycle time required to open contacts on a feeder breaker and the one-third cycle time to close the normally open contacts of the neutral relay but that adequate coordination is secured between the one-fourth cycle circuit opening time and the three-fourths cycle closing time of the directional relays. An alternative arrangement would be to use an auxiliary relay with a delay of one or two cycles (which would not operate on an impulse shorter than about one cycle) interposed between the various contacts and the auxiliary tripping relay and then to use plunger elements with normally closed contacts in parallel with the directional relays on all sources instead of *B* fingers. This would remove limitations 1 and 2.

In addition to the limitations of the scheme as applied, there is the further system limitation that the station protected must be the only source of ground current and that none of the feeders from different bus sections can be connected together at remote points (except through transformation). With the auxiliary time delay scheme, each tie line breaker (with other sources of ground current) can be considered as a possible source, and provided with the combination of directional ground and plunger relays. It is interesting to note that a directional ground relay with its contacts normally closed could take the place of the plunger relay and directional ground relay with normally open contacts in such an application. A scheme of this nature has been in service for several years with no incorrect operations and two operations which were "correct" except that one of them required excessive clearing time, resulting in other relaying on account of the fact that bushings on both sides of one breaker were involved in a common fault.

REFERENCE

1. TESTING OF HIGH-SPEED DISTANCE RELAYS, E. E. George, AIEE TRANSACTIONS, volume 52, 1933, page 802.

G. Steeb: Mr. Crichton proposes a modification of the bus scheme in which directional relays with normally closed contacts are employed.

At the time the bus protection application, described in the paper, was made there were no suitable high speed directional relays with normally closed contacts available. However when such relays were placed on the market the author, realizing their advantages, developed and installed in one of the 110-kv 60-cycle stations a modified scheme which differs from that proposed by Mr. Crichton in only two respects.

The two points of difference are:

First, we use in each bus section one ground directional relay with its contacts normally open, and in series with the contacts of the fault detector relay. This safeguards against inadvertent tripping of the bus, either by human mistakes that may be made on the fault detector relay or by possible loss of the correct sequence in opening and closing of the various contacts. Second, we prefer to put the coil of the gang relay ahead of the normally open contacts; this prevents the coil from being energized in case of a short in the supervisory light circuit.

Mr. Bancker refers to the principles of carrier pilot relaying and its similarity to the described bus scheme. It is true that both require proper synchronizing of contact action. Since the reliability of carrier pilot relaying has been established, the similarity of the principle upon which the bus scheme is based should justify confidence.

As to his second point with respect to the effect on the blocking relays in case of a two phase to ground fault; that type of fault has occurred since the scheme has been put in service. The fault current was about 35 times the current transformer rating (400:5), and the relays performed correctly. It should be remembered, that all the blocking relays have a low pick-up.

Mr. Oliver suggests the use of overcurrent relays instead of the *B* auxiliary switches. In some installations this may be feasible, but at the station where the bus scheme was applied, the residual fault current through some circuits under certain operating conditions may be only 0.6 ampere, which would not be sufficient to operate reliably an overcurrent relay, hence directional relays were used because of their greater sensitivity.

Mr. Silver informs us about a similar bus scheme, which confirms that bus protection can be provided independent of matched current transformers.

Mr. Kennedy brings out an interesting point, in case of an internal two-phase-to-ground fault; this may have to be considered in other installations, but in this case the current transformer ratios of the ungrounded power sources are 1,200:5 and 2,000:5 respectively, and the fault current from these sources could be at the most about 3 times their current transformer ratings, and since the residual circuit is of high impedance it is unlikely that the relays would be affected; tests have confirmed this.

Mr. Knapp's reference

(*a*). The bus scheme will remain blocked until the feeder is cleared. The relay time on the feeders varies from one to twelve cycles (25-cycle basis). What will happen to the bus in the mean time, depends on the character and location of the arc.

(*b*). The maximum ground fault current is about 2,600 amperes whereas the relay in the station neutral is set to pick up at the equivalent of about 800 amperes, which ought to assure reliable performance. These current values are for all practical purposes not affected by the number of banks in service, although the residual current in the directional relays of the banks themselves will vary considerably. The current in the directional relay coils connected in the neutral current circuit will be of sufficient magnitude to insure safe operation of these relays.

(*c*). If residual current of sufficient magnitude should appear, the blocking relays would extinguish the indicating light and thereby announce its presence. As to sticking relays, the percentage is very small. In the Niagara Hudson system there are close to 20,000 relays in service out of which there may be four relays per year that fail to operate because of internal defects, which indicates a good record for the designer of relays and the men who maintain them.

Mr. Brownlee's conclusion that the station protected must be the only source of ground current is incorrect as is also Professor W. A. Lewis' belief, as expressed in his oral discussion, that all the neutrals must be connected together to a common ground, the fact is that the zero sequence voltage can be used for polarization or to operate an overvoltage relay, which acts as the fault detector relay. This principle has been used successfully in one of our 110 kv 60 cycle stations.

Mr. Henry's discussion clarifies some of the underlying points of the bus scheme. While it is true that this bus scheme was developed primarily for an application where it was impracticable to apply the conventional bus differential scheme, the author feels that the principle of this method of bus protection is not limited in application to this particular station, but rather that the scheme is general, and should be considered wherever bus protection is contemplated.

However in any future applications the modification of the scheme as referred to in the closing remarks of Mr. Crichton's discussion would be used, rather than the original scheme as described in the paper.

A Simple Method for Determination of Ratio Error and Phase Angle in Current Transformers

Discussion and author's closure of paper 41-109 by E. C. Wentz, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (October section), pages 949–54.

G. Camilli (General Electric Company, Pittsfield, Mass.): This paper gives an interesting review of the theory underlying the performance of current transformers. It shows that the much discussed "internal reactance" is still the stumbling block to the accurate predetermination of the accuracy of this type of apparatus.

Last year Mr. TenBroeck and the writer presented a paper, "A Proposed Method for the Determination of Current Transformer Errors" [AIEE TRANSACTIONS, volume 59, 1940 (September section) page 547], in which a very simple method was described for determining the effective internal reactance of a current transformer. The scheme required no exploring coils which are necessary in the scheme proposed by Mr. Wentz. It appears that Mr. Wentz's scheme loses some of its effectiveness for:

(*a*). It is admitted that some experience is necessary to predetermine the most effective position of the exploring coils in the magnetic circuit.

(*b*). In common with all the other schemes proposed so far, Mr. Wentz' proposal is not suitable for the calculation of the performance of a great number of current transformers within the metering range of secondary currents, due to the fact that most modern transformers are "compensated" by some special arrangements.

The experimental determination of the secondary internal reactance of a given transformer, however, is very valuable for the calculation of its overcurrent characteristics.

In performing the usual accuracy tests at very high currents, certain difficulties are encountered which can be overcome by indirect methods once the internal impedance and the excitation characteristics of the transformer become known.

For the above application, Mr. Wentz's proposal for the determination of the internal reactance should be a valuable addition to the schemes already known.

A. T. Sinks (General Electric Company, West Lynn, Mass.): As Mr. Wentz points out, his paper presents no new fundamental principles, but it does describe a relatively new method of solving an old problem. This new method has some very desirable features which should be taken advantage of. However, the method also has a number of limitations which restrict its usefulness. In order to alleviate these restrictions and increase the usefulness of the method, the following suggestions are offered:

1. The paper arbitrarily limits the method to five per cent error. In the case of high burdens and low currents, it should be possible to calculate larger errors than this without serious difficulty. The more fundamental limit on the usefulness of the method is a maximum ampere turn per inch exciting current in the core. A limit of approximately 300-ampere turns per inch is probably reasonable.

2. For transformers having cores with non-uniform cross sections of iron the method, as given in the paper, does not apply; first, because the exciting current tests will not give the unit exciting current characteristics for the iron; and second, because having these characteristics a knowledge of the relative lengths of the portions of different cross sections is necessary to apply the data. For transformers with non-uniform cores, it is therefore suggested that two magnetization curves, one corresponding to number 1 branch, and the other to number 2 branch of the figure 4 might be supplied, or computed on the basis of design data together with the value of X_L. The remainder of the calculation of the accuracy of a non-uniform core transformer could then be carried out as indicated in the paper.

3. As the author points out, the leakage flux generally changes at very high currents due to saturation of the iron, the flux which normally returns through the iron core being by-passed through the air. Therefore, any calculation based on the assumption that X_L in figure 4 of the paper is constant may lead to errors considerably larger than the actual values at high currents. It should not be assumed on the other hand that because a section of the core is closely approaching saturation the errors of the transformer are so large as to render it useless. There are some cases where, on the basis of methods of calculation given in the paper, part of the transformer core would exceed saturation at 10–12 times rating; yet, according to actual tests the errors are less than 10 per cent at 20 times rating.

This range of current, therefore, offers an important problem that present or previous papers have not solved. A suggested line of attack might be to try to arrive at a fictitious upper part of magnetization curve for number 2 branch in figure 4 which would satisfy the actual conditions of error.

4. While the subject of transient accuracy was mentioned in the paper, very little was said about the calculation of such accuracy. It would seem that methods previously discussed for computing transient accuracy could be equally well applied to figure 4, except just as in the case of steady state accuracy the amount of work would be approximately double that of calculating the accuracy of the transformer with uniform flux density in the core.

While one of the purposes of the paper stated by the author was to present a method which would reduce the actual amount of computation necessary for calculating the accuracy of current transformers, it would seem that unless a large number of conditions are to be calculated it would be easier to compute the errors directly from the magnetization curves rather than to plot so many curves as shown in figure 5 for each transformer.

While for high currents the four-coil secondary construction of the window type or bar type transformers undoubtedly has advantages in some respects over the two-coil secondary, the author's statement that it is practically impossible to make a two-coil window type transformer good for more than 25,000 amperes does not seem justified. Data is available on perfectly standard 3,000-ampere window type transformers of reasonable size rated at 3,000 amperes, having errors of approximately 6 per cent with 50 v.a. burden at 60,000 amperes. These transformers have non-uniform core cross sections, the cross section of core on the legs not enclosed by secondary coils being very much larger than the cross section of the other legs in order to take care of the large leakage flux. This brings out the advantage that sometimes may be gained by using a non-uniform core cross section, and therefore shows the importance of modifying the method of calculation presented in the paper to take such designs into account.

P. O. Langguth (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): 1. The author has very nicely worked out a simplified method of determining the performance of current transformers from the saturation characteristic and of determining leakage reactance. Such analysis will simplify the application of transformers for relay service.

2. Several schemes have been presented during the last few years to determine transformer performance by calculation for the particular conditions involved

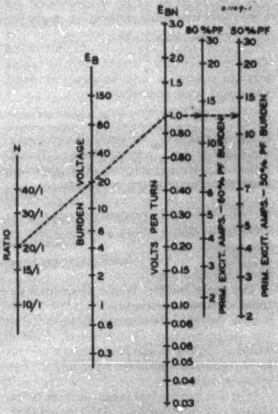

Figure 1. Nomograph for calculating current-transformer errors

Typical solution: Assume turns ratio—20/1
Burden 0.5 ohm, 80 per cent power factor
Secondary current = 40 amperes
Burden volts = 20
Lay straight edge on chart as indicated by dotted line for correct volts per turn and read primary exciting current = 13 amperes
Primary current = (20 × 40) + 13 = 813 amperes
Per cent ratio = 101.5

rather than use typical curves for standard burdens. Since all of these schemes have some inherent limitations, it seems desirable to work out a compromise method of determining leakage reactance and transformer performance from the saturation data. Such a scheme could be very well incorporated in AIEE Instrument Current-Transformer Standards or an AIEE standard test code. An arrangement of this nature would simplify the specification and use of current transformers for relay application where high overcurrents are usually involved.

3. The method disclosed by Mr. Wentz is sufficiently accurate for relay applications. Although no data have been submitted here to indicate variations at 20 times normal current, it has been my experience on bushing type transformers, that even with less complete analysis wherein leakage and excitation angle are ignored, the results are sufficient for most relay work. It is believed that the method outlined by Mr. Wentz would be more universally applicable if the computations could be further simplified. Possibly, some standardized graphical chart, including saturation data could be prepared for this purpose.

4. As an example in figure 1 of this discussion, a nomograph chart has been prepared for calculating the ratio error of bushing type current transformers. Turns ratio, burden voltage, volts per turn, and primary exciting current scales are plotted in logarithmic steps. A typical solution in the figure illustrates the simplicity of ratio error determination.

5. Phase-angle error if necessary for some particular relay application can be determined in a similar way by addition of a phase angle scale. It is believed that such a chart can be used for wound types by taking leakage reactance into account by some additional scale arrangement.

D. B. Masters (Commonwealth and Southern Corporation, Jackson, Mich.): Recognition of the importance of a thorough understanding of current transformer characteristics in the successful operation of certain types of protective relays has resulted in the devotion of much study to the problem of easily and economically determining current transformer performance characteristics.

The paper by Mr. Wentz proposes a detailed method, utilizing relatively few fundamental factors. It appears, however, that the determination of equivalent leakage which is the key to this method may present considerable of a problem especially at high primary currents.

It is not quite clear what degrees of accuracy can be expected. It is stated that, "When the ratio error exceeds five per cent, the iron is usually working near saturation, ... The result is that this method of calculation will give errors which are considerably too large when the error (real error?) exceeds five per cent." From this it would seem that the range of usefulness is rather limited for relay applications without some knowledge of the true error since it is implied that only errors greater than five per cent usually are of any consequence.

The author implies that the determination of the basic data must be made by the manufacturer. Any refinements and improvements in the method which could be made to enable it to be applied in the field to older types of transformers now in service would be a distinct accomplishment.

E. C. Wentz: Mr. Camilli correctly states that the much discussed "internal reactance" is still a stumbling block. However, the point of the paper written by Mr. Sinks, on which the author's paper is based, is that internal reactance is quite mythical and has an existence only as defined by any author. Mr. Camilli refers to his method for determining internal reactance, but his definition has been criticized before as defining a quantity of flux which bears no clear relation to the leakage flux in the core. The author's definition of leakage reactance is certainly based on the real flux in the core.

No great experience is necessary to place exploring coils. If there is some doubt as to correct placing, more than one location may be tried. The highest measured value of leakage reactance is the conservative one to use.

The method will not work in the metering range for transformers with Wilson compensation. This is a disadvantage shared with Mr. Sinks' paper. The method can conceivably be used with cores of non-uniform section, but, as pointed out by Mr. Sinks, its use is much more difficult, and probably generally impractical, unless the manufacturer supplies the special data for using it. Perhaps it is more economical to use four coil construction in through type transformers rather than to widen the core to get equal performance. While a wider core improves the performance, it is none the less true that widening the core will increase the total leakage flux so that this use of the material is not too economical.

Mr. Sinks points out that with low currents and high burdens the method can be used up to ratio errors much exceeding five per cent. The five per cent figure given in the paper is merely a conservative limit, and is the only one which can be stated thus simply. The ampere-turn per inch limit given by Mr. Sinks is the more fundamental, but the man in the field will have no idea of its magnitude. Further experience will, perhaps, indicate simple working limits which will be more nearly maximum values.

Whether the family of $F \cos \theta + M \sin \theta$ curves are plotted will depend on the application. It will no doubt pay to plot $F \cos \theta + M \sin \theta$ curves for standard lines of current transformers, but probably not for special transformers for special application. Of course, most manufacturers use a limited number of standard cores, and a limited number of master curves could be the basis for easily plotted curves for special designs.

Mr. Masters suggests that determination of reactance may be difficult at high currents. However, the reactance at high currents, as represented by leakage flux in the core, is always lower than at normal current. Therefore, as pointed out in the paper, the value at normal current may be used at higher currents with confidence that the calculated errors will not be exceeded on test.

The whole problem is not to be solved by any one paper or method in any short time. It is clear from Mr. Sinks' paper, which sets forth the fundamental principle, that absolute accuracy is impossible; the author's purpose is to outline a practical compromise between accuracy and simplicity for general use in the factory and in the field. It is hoped that the method will be given a trial by those interested in a simple method for determination of overcurrent performance.

D-C Machine Flashover and Bus Short-Circuit Protection

Discussion and author's closure of paper 41-122 by T. B. Montgomery and J. F. Sellers, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1168–73.

A. E. Anderson and **C. H. Black** (General Electric Company, Philadelphia, Pa.): From the viewpoint of circuit protection, the relative speeds of air circuit breaker operation are important only insofar as they affect the total length of time required to interrupt the current, or at least the total time required to start some current limiting action. With this in mind, the proposed new method of energizing the tripping means should be reviewed to determine whether it actually reduces the time required for current limiting action to start, and if so, how much reduction is obtained. These are the important points. The details of how the tripping is actually accomplished are entirely incidental.

The authors state that there is a reduction in tripping time under all conditions. It is conceded that this might be so under the limited condition of a flashover involving only moderate current and a very low rate of rise. Under a condition of severe short circuit (bus short), the authors (figure 9*b*) show an insignificant reduction as compared with a breaker operating in reasonable time from the series trip (Z versus $X = 0.002$ second). Experience with similar devices indicates that the instantaneous series trip will actually produce a *lower* contact-parting time (thereby taking less time to initiate the current-limiting action) than a shunt trip coil, even when there is no delay whatsoever in applying full voltage to the shunt trip coil. Lacking oscillographic data and admitting no experience with bus short circuits, in the installation described, it appears likely that the authors may subsequently find the actual current-limiting time may be *prolonged* (not *reduced*) by the proposed method of tripping where a severe bus short occurs.

In any case, the relative reduction of time appears small compared with the differences in operating times of the purportedly "similar" breakers. In figure 9*b* and in figure 11 the differences between X and Y are greater than the differences between Z and X. If the X and Y breakers were similar, then the operating time is quite inconsistent and do we have any real assurance that the "Z" breaker times were other than accidentally favorable tests? Again, actual oscillographic data would clarify this point.

T. M. Linville and B. H. Caldwell (General Electric Company, Schenectady, N. Y.): That the initial tripping impulse under fault conditions is faster when controlled by the voltage across the compensating field winding is very true. However, the reduction in the total time required to clear a d-c machine may not be significant. The authors are to be commended for their paper presenting an interesting study of protection of d-c machines. The results they derive from their analysis of short-circuit performance do not agree entirely with experience. Therefore, the following discussion is presented to give a more complete picture of the performance.

The primary cause of the discrepancy between test results and the results predicted by the theory (see equation 2 of the paper) presented by the authors is that the air gap flux and speed voltage generated in the armature winding do not remain constant during the transient as they have assumed, but is quickly reduced to a fraction of its open circuit value. For low values of armature current, equation 2 is essentially correct.

However, for higher values of line current this assumption is invalid for the following reasons: (1) The commutating pole becomes saturated. This means that the flux density in the commutating pole gap becomes less than that required for good commutation, and the effective center of current collection moves in the direction of rotation from its normal position, thus producing a component of armature reaction which is oppositely directed to the shunt field. (2) The high currents in the armature and pole face windings produce flux which saturates the armature and pole face teeth. This increases the reluctance of the main pole flux path, and decreases the inductance of the shunt field.

The combination of these two effects can greatly reduce the air gap flux without changing the linkage of the shunt field. In order to get an approximate idea of the magnitude of this change refer to the oscillogram of figure 1 of this discussion, and let the flux linkage of the shunt field be given by

$$\Psi = \Psi_g + \Psi_1$$

where Ψ_g is the linkage corresponding to the air gap flux, and Ψ_1 is the linkage corresponding to the interpole leakage flux. For this particular case the normal no load values are $\Psi_g = 1.0$, when $\Psi_1 = 0.2$. From figure 1 we note that the field current increases during short circuit to approximately 3 times its steady state value. Since saturation in the leakage path is negligible, it follows that Ψ_1 must increase to approximately 3 times its normal no load value; and if Ψ remains constant, Ψ_g and the air gap flux must decrease to 0.6 of its normal no load value.

The shift of the center of current collection also permits the commutating pole flux to produce a speed voltage opposing that produced by the main field. Also the decrease in the shunt field inductance permits a more rapid change of shunt field linkage than calculations based on the no load values of inductance would indicate. The field current from figure 1 decreases after the circuit is opened to approximately 0.90 of its value prior to the time of application of the short circuit. This is an indication of the magnitude of the change of the flux linkage of the shunt field.

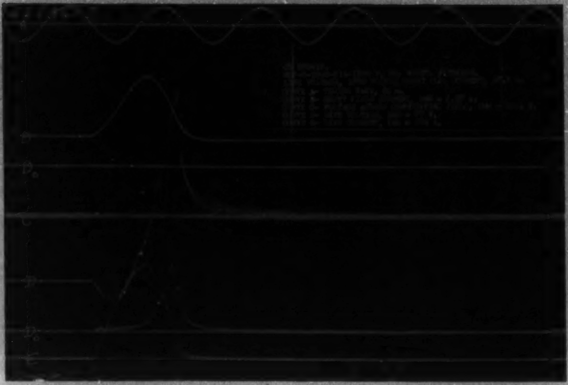

Figure 1

Curve *A*—Timing wave
Curve *B*—Shunt field current
Curve *C*—Voltage across commutating field
Curve *D*—Line voltage
Curve *E*—Line current

Shown in figure 2 of this discussion are the results of some short circuit tests taken on a 750-kw, 600-rpm, 1,500-volt, compensated, a-c generator designed for railway service (required to deliver 150 per cent load for two hours and 300 per cent load for five minutes, hence approximately equivalent to a normal rating of 1,000 kw). Tests were taken with two different breakers, one of which started interrupting the circuit in approximately 0.012 second and the other started interrupting the circuit in approximately 0.04 second. Several different values of external resistance were used as indicated. These curves show that increasing the resistance from 2.4 per cent to 9.2 per cent decreases the peak value of short circuit from approximately 17 to 10 times normal, while the peak value calculated as recommended by the authors varies from 41.7 to 10.9 times normal. This is convincing evidence that demagnetizing action in the machine is the principal factor limiting the current.

In figure 9*b* of the paper the initial rate of rise of current is given as 4,500,000 amperes per second. The formula for inductance is 25 per cent of rated volts divided by rated amperes divided by $\pi Pn/60$. Since the initial rate of rise must be rated volts divided by the inductance, 4,500,000 must equal the rated amperes (12,000) multiplied by $\pi Pn/60$ and divided by 25 per cent. This gives $Pn = 1{,}790$. If $P = 6$, $n = 300$. The speed is about as expected but from a standpoint of volts per bar and amperes per brush-holder bracket so few poles are not possible. The paper does not identify the examples given sufficiently. The formula for the inductance was given in a paper entitled "Speed Transients in Rolling Mill Motors" by L. A. Umansky and T. M. Linville, AIEE Transactions, volume 54, 1935 (April section), pages 387–94. The present paper states that for a compensated machine a percentage factor of 25 per cent is used. This is an interesting substantiation of the earlier presentation. However, the ratio between the inductance of a noncompensated and a compensated machine has been measured as more nearly three to one and sometimes four to one.

On very fast transients such as short circuit the effective inductance of the com-

pensating field circuit is appreciably reduced due to the solid frame of a d-c machine. This is not mentioned, but is a factor partly causing only about half the machine voltage to appear across the compensating winding as shown by tests. This would appreciably reduce below 100 the ratio of the voltage in the compensating winding on short-circuit to that on normal load transients.

There has been a great deal of speculation about the voltage across the arc during flashovers and short circuits. Observation of the forces existing during short circuit and knowledge of arc behavior indicates that possibly half the machine voltage exists on the average across the highly dynamic arc. The arc voltage changes chiefly with length instead of current and will be unstable as the arc elongates under magnetic forces and reflashes. Therefore, one flashover considerably less than three-fourths of rated voltage would be expected to be effective across the compensating winding.

The final conclusion of the paper, that bus construction may allow for lower short circuit stresses, is open to some dispute, as the peak current is nearly always reached even in the reduced time for interrupting the current claimed by the paper. That is, figure 9*b* of the paper does not agree with test experience since no machine builds up to 37 times rated current, as the curve shows, nor is the initial rate of rise as low as shown. The rate shown, 4,500,000 amperes per second, is equal to 375 times rated amperes in each second. As stated earlier, the initial rate is V/L which in amperes per second by the formula of the paper is $\pi Pn/15$ times rated amperes. For 12,000 amperes, 300 volts, and about 300 rpm, 16 poles might be expected. The expected rate of rise for such a machine would be 12,000,000 amperes per second instead of 4,500,000. The expected peak of 16 times normal current would be reached in 0.016 second which is too fast to be reduced by any of the interruption times given in figure 9*b*.

Figure 3 of this discussion shows the results from two oscillograms taken under the same test conditions except that in one case the breaker contacts started opening in 0.012 second and in 0.04 second in the other. The peak current is attained in 0.02 second or 1.2 cycles, and although the machine was shunt wound the current actually decreases after the peak is reached, and is still decreasing when the breaker starts opening at 0.04 second or 2.4 cycles. These tests indicate that in order to limit the peak current on short circuit, a breaker tripping time of less than 0.02 second is required, and that the reduction to 0.035 second cited by the authors is not sufficient to reduce the peak current in most cases.

The foregoing comments show the questions and uncertainty permitted by the paper which should be cleared up in the closing discussion by more complete data supported by test evidence.

J. F. Sellers: In regard to the discussion by Messrs. A. E. Anderson and C. H. Black, it seems that there may be a misunderstanding of the purpose of the proposed system. Perhaps it should have been made clearer in the paper, that this scheme cannot be expected to supplant the series instantaneous trip coil, which is still required for normal overload.

As shown from figure 5 of the paper, the breaker data were taken from oscillographic tests, conducted under maximum conditions of bus to bus fault which could be reasonably attained in the laboratory. This test was one of a number which were made with various amounts of inductance and resistance in series with the generator to investigate breaker operation, and it was found that up to five times normal current on the machine there was very good agreement between the calculated and actual current rise curves. This was the primary purpose of equation 2—to investigate the current values during the normal opening time of the breaker, rather than the ultimate values which would be reached upon failure of the protective means to clear the fault quickly.

Messrs. Linville and Caldwell have given a very fine explanation of the action of the leakage fields at very high current values, where the time involved is beyond the normal opening time of the breaker. The factors involved cannot be included in a simple equation, but most assuredly affect the actual shape of the curve. However, our investigations, as mentioned before need cover only the first part of the build-up curve wherein there is very good agreement between calculated and actual curves. We are very glad to find agreement with our method of figuring machine inductance as there has been a great deal of work done in calculating component parts of the inductance, and a short cut or empirical formula is necessary to reduce the labor involved when fitting several machine designs to a particular application.

The most decided advantage of the interpole trip is certainly on flashovers, which type of fault covers all of the heavy faults to date on the systems where it has been used, and offers advantage less in magnitude of time but nevertheless real on bus to bus fault.

Development in Lightning Protection of Stations

Discussion and author's closure of paper 41-102 by E. R. Whitehead, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 898–900.

M. C. Westrate (Commonwealth and Southern Corporation, Jackson, Mich.): This is a very interesting paper and presents the results of an analytical approach to a problem complicated by many variables. The degree to which tests substantiate calculations is very convincing but a station design engineer is very reluctant to specify choke coils in view of the many objections, structural as well as electrical, which have been experienced in the past. Also the number of transformers which fail when protected by modern arresters installed at or near their terminals are so few that the complication of station design by the addition of choke coils is questioned. Possibly the same results can be accomplished by installing gaps a number of circuit feet, perhaps one span, out on each line so that circuit impedance will do on steep waves what the choke coil did in Mr. Whitehead's experiments. Overhead shield wires could then be installed for this section of line and over the station to prevent direct strokes between the gaps and the lightning arresters.

E. R. Whitehead: I share Mr. Westrate's reluctance to specify choke coils in any normal lightning protection scheme applicable to stations. In fact, the Duquesne Light Company has removed the old choke coils in its protection improvement program over a period of eight years. It is evident, however, that many small stations fed from highly insulated wood pole transmission lines will not economically justify the installation of adequate ground wire shielding plus the necessary low impedance grounding along the line. Where the load and importance of the station do justify such an installation, I quite agree that such a system is desirable.

The suggestion that gaps or tubes installed one or more spans out from the station has frequently been considered, but it has the defect that the ground path impedance at the gap may be so high as to nullify the benefit obtained.

The reactor scheme may be thought of as

a means of contracting the physical dimensions of the span to the gap so that advantage may be taken of the closely interconnected and grounded structure of the station. This location eliminates the effect of ground resistance, and greatly reduces the inductance of the ground connection between the gap and transformer tank. In conclusion I should like to emphasize that the application of this protection system is by no means general, and care must be taken that other insulation elements electrically adjacent to the gap or protector tube must be adequate for the short high voltage peaks which will be experienced. In other words, the back-up gap or tube must be reliably coordinated with adjacent insulation.

The 220,000-Volt System of the Hydro-Electric Power Commission of Ontario—II

Discussion and authors' closure of paper 41-95 by A. H. Frampton and E. M. Wood, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1215–21.

W. W. Parker (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): This paper presents very valuable design data and results of operating experience. The lightning record of table I is of special interest. This shows a considerably greater number of the more severe types of faults than is the average experience, as follows:

Faults Involving	Per Cent
One wire to ground	65
Two wires to ground	20
Wire to wire	10
Three wires	5

This higher percentage of faults involving more than one wire described in this paper seems at least in part to be due to the high tower footing resistance at the locations where the majority of faults occurred. It will be very interesting to have a further report on the effect of the counterpoise on the percentage of the various types of faults.

The use of two wire to ground faults as a stability criterion in establishing the power limit of a system by calculator methods is a very common practice. This is not only due to the fact that on the average only five per cent of the total number of faults involve three phases, but also because on the calculator the fault is usually assumed to be at the worst possible location, under the heaviest loading condition and without arc, contact, or ground resistance. These considerations, added to the fact that damping and saliency effects of hydro machines are generally neglected, seem to indicate that two wire to ground faults are a sufficiently conservative type of fault to use as a stability criterion in calculator studies of power limits.

M. S. Oldacre (Commonwealth Edison Company, Chicago, Ill.): This paper adds a large amount of information to the existing knowledge of operating results with 220-kv lines so that even better results can be obtained in the future. The engineering organization in charge of the system described in the paper has been very generous in making its data available to others.

The first conclusion of the authors seems to be of the greatest importance in designing future lines, namely, operating experience largely confirms theoretical and experimental conclusions regarding protection from lightning, from sleet and wind, and from vibration.

An unfortunate operating condition was found in the high earth resistivity in the territory traversed by these lines. In spite of this, a reasonably good operating record has been obtained and the recent improvements in tower grounds should appreciably reduce lightning outages in the future. The authors' figure of 0.2 outage per 100 circuit miles per year for towers having footing resistances less than 25 ohms seems somewhat better than would be anticipated from a rough consideration of the original line design. It is conjectured that this may be at least partly due to the favorable impulse characteristics of grounds, as reported by Bellaschi [AIEE TRANSACTIONS, volume 60, 1941 (March section), pages 123–8], in comparison with the values of resistance measured by usual d-c methods.

Approximate calculations furnish an indication of the effectiveness of shielding by overhead ground wires. The original single-circuit towers provided shielding angles of 42 to 45 degrees. If such shielding had not proved effective, and a large proportion of strokes had contacted phase wires, the outage rate should have approached roughly 75 outages per 100 circuit miles per year, since lightning stroke currents of only about 10,000 amperes would have been required for flashover. The actual outage rate of these lines, however, has been only slightly more than one per 100 miles per year. The good correlation between footing resistance and outage rate and the relative predominance of faults involving only one phase give further indications that the majority of line contacts has been to the ground wires, showing that the shielding has been effective. It would be of interest to learn from the authors whether this has been confirmed by more numerous findings of burned spots on the ground wires than on the conductors.

The requirements for lightning protection have been adequate clearance and insulation from power conductors to ground, sufficiently small shielding angle by the ground wire, and finally low tower footing resistance. Possibly low tower footing resistance is of more importance than a small shielding angle. Some data in the paper point to this conclusion. Another way of stating this would be that if the ground wire is located to avoid trouble from sleet and wind as determined by the Lissajous figures, then it makes little difference what the shielding angle may be if the ground resistance is low. Extra money had probably best be spent in lowering of the tower resistance rather than in lowering the shielding angle.

The use of half-loop galloping assumptions is interesting and may be justified by experience and as a compromise for the conditions applying to the 1941 line built by the Commission.

When the 220-kv Powerton-Crawford line was designed in 1939, it was considered desirable to use full-loop assumptions for power conductors and ground cable, as it did not affect the cost appreciably. This line has been in operation only eight and one-half months but an observation during one sleet storm may be of interest. The station operator at the Chicago end of the line observed the ground cables to be galloping violently, his report stating that the cable was being lifted 10 feet or more, while the power cable was not moving at all. This is only one report, but it helps to justify the opinion of the authors that possibly the large conductors will not gallop appreciably and that half-loops may be an adequate assumption.

The storm in the Chicago area mentioned above was sufficient to take out 132-kv lines of early design which had inadequate clearances under the full-loop assumption.

Some experience on a line near Chicago with 500-foot spans of stranded, 750,000-circular-mil hollow copper conductor indicates that galloping sufficient to cause sleet outages has been almost of full-loop magnitude.

The vibration protection for the ACSR cable is very interesting. It seems that armor rods would be desirable, not particularly for vibration dampening but for protection from conductor damage from chance flashover and from any residual vibration. Then damping devices should be used for suppression of vibration. The actual experience will be of value.

A. S. Runciman (Shawinigan Water and Power Company, Montreal, Quebec, Can.): Information contained in the paper in reference to lightning again indicates that the high resistance ground sections are causing the most trouble. The conclusion is that lowering the ground resistance should effect improvement in operation through lightning storms. The authors state that 90 per cent of the located lightning outages occurred in the section of high tower footing resistance. Just what is meant by high tower footing resistance is not clearly defined by power men as yet. The term is very broad. In our company we consider low resistance to be one ohm or less and anything above ten or twenty ohms is high. These terms are not anything which can be completely agreed upon, but we do know that we can obtain resistances as low as a fraction of an ohm. One case in mind is that of a tower whose footings were measured to have the highest resistance on a new line constructed last year. The resistance measured 780 ohms for grillage bases alone, but after connecting in the usual two counterpoise wires and knowing that this tower had a greater resistance than 50 ohms, an extra two counterpoise wires were added and, in addition, the two sky wires were connected in. With this complete combination of grounding we then obtained one ohm for this tower. Every tower on this line which measured originally, with grillage footings alone, more than 50 ohms was joined up to its adjacent towers by an extra pair of counterpoise wires, making four in all. We expect good results from this line.

It is not easy to find out what the footing resistance of a tower on an old line actually is but we form an opinion by driving a deep driven ground rod as much as 150 feet down at times, measuring at each eight foot extension, and if the resistance at 40 feet or 50 feet is 50 ohms to this rod, we know the tower is in high resistance territory and we must either improve our grounding or expect lightning outages.

Two counterpoise wires in soils, which measure 50–100 ohms with a 50 foot rod, are not enough to prevent lightning outages on a seven-unit insulated line. On a 14-unit insulated line we believe less grounding is necessary than on a seven-unit insulated line. In other words, we have found that the operating voltage on a transmission line is not an important factor in comparing operation of transmission lines through lightning. We have a number of lines constructed with seven suspension units operating at 60 kv and 110 kv and no definite difference can be determined due to operating voltage.

It is interesting to note that the designers of the 220 kv, two-circuit line have decided to use a single high overhead ground wire. This presumably came about after studying the Pennsylvania Water and Power Company's experience, as reported upon by Mr. Waldorf. I believe this is a step in the right direction. It certainly removes mechanical hazards during sleet storms.

There is still the question, and I expect that I shall be criticized for saying this, whether the single overhead ground wire is required or not. This statement is based on information which is slowly being produced, that the leader path is established from the tower top. Whether or not lightning strikes a certain spot depends upon the resistance of the path before the strike; and whether or not damage is caused seems to depend upon the time which is required to discharge the cloud. If this discharge takes place quickly through a low resistance ground, the damage is a minimum.

The answer to the whole question is better grounding. The question of shielding does not seem to be so important as has been supposed in recent years. If the Hydro-Electric Power Company of Ontario should experience trouble from lightning in the section of the new double-circuit line where they have no counterpoise, it is to be hoped that they will not blame this on the use of the single overhead ground wire, but rather on the footing resistance not being low enough.

E. W. Knapp (Shawinigan Water and Power Company, Montreal, Quebec, Can.): The authors are to be congratulated on the concise, clear, and effective manner of presenting the various data contained in this paper. There are, however, a number of features where further discussion might be undertaken to advantage.

1. The completed scheme includes two 220-kv closed rings consisting of seven circuit breakers per ring, so arranged that the two rings can be interconnected. Is it the intention to operate with all the 220-kv circuits interconnected, and, if so, will it be possible to manually remove both of the tie banks nearest the loop interconnections without opening the loop?

2. The data contained in figure 4 were particularly impressive, with regard to the relation of high resistance grounds to lightning flashover. The policy of providing moderately high overhead ground wires and adjusting the amount of lightning protection to coincide with local tower footing resistances and nature of terrain appears to be a good one. However, it may be found that the excessively high overhead ground wire may be more effective in reducing troubles due to sleet, wind, and snow than in reducing lightning outages. Moreover, in extremely high resistance soil even two continuous buried counterpoise wires in association with overhead ground wires, may only reduce lightning outages to possibly 30 per cent to 50 per cent of the former value. Adequate lightning protection also appears to result in less severe faults by decreasing the percentage of LLg and $LLLg$ faults in relation to Lg faults, thereby improving the transient stability situation.

3. It is noted that the four 220-kv circuits are expected to deliver 675,000 kw in the future. This appears to be rather a high circuit loading and the loss of one or more circuits might create a stability problem. Has automatic reclosing been considered for these circuits? The Shawinigan Water and Power Company installed a form of automatic reclosing on two double circuit, 187-kv, 60-cycle lines in 1934. Although the overall reclosing time is in excess of one second, a considerable number of successful reclosures have taken place during single line faults for loads as high as 175,000 kw. These four 220-kv circuits would appear to be well suited to instantaneous automatic reclosing, if this offers any advantage.

4. The authors mention one case of permanent trouble where it required 27 hours to locate and repair the fault. It would be of interest to know how much of this time was spent in locating the point of damage. There is on the Canadian market today automatic fault locating equipment for transmission lines. The Shawinigan Water and Power Company have had some of this type of equipment in service since 1937. During the intervening period a considerable number of records have been obtained on several different types of systems and the experience to date has been quite encouraging. The indications are that line patrols may be reduced, a greater percentage of points of transient flashover may be located and the point of permanent breakdown may be located more quickly through the use of an adequate form of fault locating equipment. I would very much like to know the reaction of the authors towards the use of this type of equipment on long or moderately long transmission lines.

Edwin Hansson (Pennsylvania Water and Power Company, Baltimore, Md.): This paper furnishes additional proof of the influence of tower footing resistances on the lightning performance of a transmission line. In tables IIa and b the lightning outages on the system have been segregated according to tower footing resistances. Plotting these outages in percentage against footing resistance gives a curve of substantially the same shape as that accepted for lightning current distribution. This is as it should be. The design of the lines is such, that given reasonably low footing resistances they should be practically lightning proof, and the distribution of the flashovers along the line should be in proportion to the footing resistances.

The authors state that little or no benefit was derived from crow foot counterpoises in the rocky sections of the lines. Luckily, they have not been discouraged by this experience, as evidenced by the decision to lay a continuous counterpoise along the new line. The records from this line should go a long way towards settling the controversy of continuous versus crow foot counterpoise in a high resistance territory.

In connection with clearances, the diagrams are in some cases based on full loops—in others on half-loops. I wonder if the authors have any data in favor of one or the other. If so, where lies the line of demarcation expressed as the ratio of conductor diameter to weight per foot, or some such other figure?

C. Gliddon (Gatineau Power Company, Ottawa, Ontario, Can.): This paper gives a large amount of valuable information regarding an extensive 220-kv system most of which information may be applied to 220-kv systems in general.

The experience of Gatineau Power Company which operates 50 circuit miles of 220-kv line and 300,000 horsepower of generating capacity in this system is about the same as that outlined in the paper.

It is interesting to note that the ring-bus system of 220-kv switching originally adopted in 1928 is being used with some modification in the Burlington station.

New features such as carrier relaying, continuous counterpoise, and higher double circuit towers with one overhead ground wire instead of two will be watched with interest.

In 1928 when the original 220-kv system was placed in service there were some misgivings as to whether this comparatively untried high voltage of 220 kv would operate satisfactorily and some consideration was given to the possibility of providing for reconnecting the transformers to operate at a lower voltage in case the higher voltage did not work. However, these fears were not realized and to-day after thirteen years of operation the system has given less trouble if anything than the lower voltage systems.

L. F. Kennedy (General Electric Company, Schenectady, N. Y.): Messrs. Frampton and Wood have presented two items of considerable interest to protective relay engineers. The first of these concerns the use of distance type relays for protection against ground faults. While the theoretical principles which govern such applications have been known for considerable time, there has been only limited actual use of such relay systems and there is a great lack of operating data. As a result many operating engineers question whether or not ground distance relaying is generally practical from an economic standpoint. The general statement in the paper indicates that entirely satisfactory performance has been obtained with this type of protection in relatively simple form. It would be very helpful to other relay engineers if more details were available both as to the methods used and the operating experience. This would seem to indicate the desirability of a future paper on this phase alone.

The second point of interest to the relay engineer concerns the proposed use of carrier current as a "transfer trip" means.

When carrier current for relaying was first proposed by Fitzgerald in 1928 one of the requirements set up was that the carrier signal should not be used to cause tripping. The blocking type of carrier relay system was developed to meet this requirement and there are now several hundred such equipments in service with successful operating records. From the experience gained from these applications the reliability of a carrier channel now is considered to be very high. Despite this proven high reliability of the blocking channel, carrier would not be considered applicable for transmitting a tripping impulse over a faulty line except when a failure of the channel would be backed up by other means of protection. It must be remembered that the reliability of the blocking system is to a large degree due to the fact that the carrier signal is sent over only sound line sections.

Among the first applications of a "transfer trip" carrier system was to lines terminating in a transformer bank with only a low tension circuit breaker. Faults in the transformer or between the transformer and the low side breaker might not cause relay operation at the remote end of the circuit. Transformer differential relays were applied and used to control the transmission of carrier current to cause tripping of the remote end. This type of an application could be termed an automatic supervisory control system for tripping only.

Where such applications have been made, it has been assumed that the transformer windings offered sufficient impedance at carrier frequencies to prevent short circuiting the carrier when the transfer trip operation was required. If a greater degree of reliability was required it could be obtained by installing a carrier line trap between the transformer and the coupling point to the carrier equipment.

Another type of problem involving relay sensitivity is found on long, heavily loaded transmission circuits. Such circuits are frequently very difficult to relay because there is so little difference even to distance type relays between load and fault conditions. The application of the blocking type of carrier to such circuits is possible but may result in continuous carrier transmission under full load conditions. Also on such circuits, with grounded transformer banks at both ends, there may be very little evidence at one terminal of a single phase-to-ground fault at the other end of line. For such applications the transfer trip offers a means whereby nearly simultaneous tripping of both ends of the transmission circuit can be obtained through the operation of the protective relays at one end only. As long as the carrier channel is functioning this desirable feature is obtained, but in the case of a failure of the carrier tripping signal to get through, the relay system may still clear the fault with sequential or time delay tripping, if it is possible to set the second zone of the distance relays so that they do not operate for load currents.

Further comment by the authors giving more completely their reasons for the choice of the "transfer trip" method for some of the lines and the "blocking" method for others would be very interesting.

Another point of interest in connection with the transfer trip feature is the use of a 400-watt transmitter. The usual blocking systems have been installed with transmitters having output levels below 30 watts, and in the case of recent installations, operating directly from the usual 125-volt station battery, having a nominal 15-watt rating. Presumably one of the reasons for the choice of this materially higher output is to increase the reliability of the carrier channel. In the case of a three phase fault which would probably be all three conductors to ground, the probability would seem to indicate that the "transfer trip" signal would be short circuited by the fault and sequential tripping result. Since on any system the need for simultaneous tripping will be greatest in the case of a three phase fault then the reliability of the tripping channel should be greatest under such fault conditions. It will be of interest to note the operation obtained with this system but the probable infrequent occurrence of faults on these circuits will make it necessary to wait a long time for conclusive results unless specific staged tests should be made to demonstrate the reliability of transmission, particularly with faults on the coupling phase.

A. H. Frampton and E. M. Wood: In presenting the operating experience data contained in this paper, it was recognized that, in some particulars inconclusive evidence was being offered to substantiate the revised designs of the single-circuit and the new design of the double-circuit sections of the 220-kv transmission system. Data offered regarding the relation of footing resistances and outages are in this category, but unfortunately it has not been possible to collect the considerable volume of information regarding lightning current values, etc. that would be necessary to effect a more valuable coordination.

It has appeared, as Mr. Oldacre agrees, that the available data largely confirm the theoretical and experimental conclusions regarding protection from lightning and we are gratified to note that Mr. Hansson's approximate calculations indicate further agreement.

As to the relative effectiveness of shielding and of low footing resistances only the following comments are offered. It may apparently be anticipated that a footing resistance of the order of 25 ohms, with the degree of shielding provided, will result in good lightning performance. Whether better performance could be anticipated with such low footing resistances as Mr. Runciman mentions is open to question. Incidentally the authors are not sure what value of resistance Mr. Runciman is concerned with when he mentions a resistance measured with all counterpoise and ground cables attached to the tower.

In another line of the Commission, operating on steel towers at 110 kv, with horizontal configuration of power conductors and with a single ground wire arranged to be located some 25 feet above the centre phase conductor the following experience has been obtained. During approximately ten weeks of lightning season during which this construction was operated without the ground cable 19 outages due to lightning were experienced. In 13 weeks of the current lightning season, with apparently greater storm severity, but with the ground cable in place, two lightning outages have taken place. All but a few isolated structures on this line have footing resistances below five ohms, which would seem to indicate that strokes to the towers should not cause flashover. The obvious interpretation is that, without shielding, a proportion of the strokes will occur to the power conductors at mid span which will result in flashovers no matter how low the footing resistance.

The data offered regarding the sleet design of these lines are also somewhat inconclusive. It is considered that outages occasioned by accidental contact of the various conductors under sleet and wind conditions are much more likely to result in the transmission circuit becoming disabled than flashover occasioned by lightning. Adequate clearances both horizontally and vertically, are therefore essential. The extent of such clearances is not susceptible of simple mathematical treatment and the method of Lissajous figures is offered as a possible solution. Available data are still insufficient to permit any exact specification, as to the size and shape of the various figures, under any given conditions of span length or conductor size. The paper suggests that conductors as heavy as 795,000 circular-mil, ACSR at spans of 1,150 feet will not "gallop" in one single loop between the points of support. This suggestion is based merely on the fact that galloping has not been observed in similar construction and it is upon this fact that the use of half-loops in such design has been considered a suitable compromise. It may be assumed that Mr. Oldacre offers something of a confirmation when he notes that galloping of the lighter ground wire but not of the heavy power conductor has been observed on the Powerton-Crawford line, though galloping in a full loop has been observed on a heavy conductor at much shorter spans.

The designing of a line in such manner as to provide adequate vertical clearances between the phase conductors and the ground cable or cables appears to have the further merit that a suitable design on such basis will unquestionably result in a line with reasonably good shielding angles which, with good footing resistances, should result in satisfactory lightning, as well as mechanical performance.

Referring to the comments by Mr. Kennedy on the use of impedance relays for ground faults, good success has resulted from using the simple connection outlined in the paper, both on this system and on the 110-kv system network to which it is interconnected. On this latter system, which has resistance grounded neutrals, they are particularly useful. In all cases they have the advantage of low burden, and their functioning, particularly on first range, is less dependent on the amount of system generation than their alternative, the instantaneous residual current relay. However it is agreed that their use is not always warranted.

It is agreed in general that Mr. Kennedy's comments regarding the applications of carrier for relaying are pertinent. The application of transfer trip to the relaying on the long lines is frankly experimental but it is expected that by the use of the high power the trip impulse can be gotten through an arcing ground, even if involving three phases. It is at least expected that interesting data will be obtained by means of tests and from operation. The "blocking" type was used on the Leaside-Burlington line because it is a well-developed type which it is believed will be reliable on this short line.

Replying to Mr. Knapp's question re 220-

kv diagram, the rings can be operated separately or closed together as will probably be more usual. To remove a bank on the tie position it will be isolated by opening the ring breakers, then the bank disconnecting switches will be opened and the rings quickly reclosed.

The experience by the Shawinigan company on reclosing 187-kv lines is interesting. Our experience of manual reclosing (in as little as 20 seconds) has met the requirements to date, but further experience may indicate the desirability of making this automatic.

There is no question that devices to enable the location of a permanent line fault are very useful, whether these are in the form of automatic oscillographs or the simpler device to which Mr. Knapp has referred.

Conductor Vibration—Theory of Torsional Dampers

Discussion and author's closure of paper 41-94 by J. W. Speight, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (October section), pages 907–11.

R. G. Sturm (Aluminum Research Laboratories, New Kensington, Pa.): The theoretical analysis of the torsion damper as presented by the author is very interesting and concise. In general, the theoretical attack appears to be sound in so far as the author has gone. While the results of the analysis undoubtedly were of much value in a qualitative way, the analysis would have been of much more value if the author had continued it to a point where its application to a specific damper would be independent of measurements made on actual installations of that damper on the particular line considered. More explicitly stated, if the use of any theory is restricted to the interpretation of measurements it is of less value than if it could be used to predict behavior in advance. Consequently, there are a few questions which should be discussed more fully than appears in the original presentation of the paper but which are needed to establish the validity and to clarify the use of theoretical work thus far done.

With reference to the author's equation 2 it should be pointed out that this relationship refers only to the condition where the displacement of the cable is zero. If the displacement as given by equation 1 is not zero, then equation 7 automatically follows directly from the same consideration as equation 2 and does not need the reference to the Lagrangian function which apparently was not used.

In the introduction of the term, q, which depends upon the logarithmic decrement, δ, it should be pointed out that this is a measured quantity obtained from a given damper attached to an actual cable in service. The logarithmic decrement is observed and the quantity, q, is computed from this value. Consequently, the power dissipation indicated by equation 9 and subsequent equations is dependent upon observations made on a damper installed on the particular cable on which it is to give service, unless δ and τ are found to be constant values. Results from many tests on ACSR indicate that both δ and τ are not constant but will vary with both the amplitude, A, and angle of twist, θ.

The author gives simplified examples as to how the theoretical deductions may be correlated with actual observations but fails to point out specifically what observations are made and which values are computed. Presumably, one would make observations of logarithmic decrement and amplitude for a torsion damper installed on a conductor; then, using these observations compute the power dissipated. How the author would use this power dissipation value, P, is not indicated. It might be used as a basis for comparing the effectiveness of different designs of torsion dampers. It would be of still greater use to couple the rate of energy or power dissipation with the energy input of the wind into the conductor in such a way that the expected or predicted amplitudes might be obtained by computation and compared with the amplitudes found by actual observations as was done in an analysis of the Stockbridge damper.* The principal difficulty encountered is that the quantities given in equations 9 and 14 require that observations be made on a damper attached to a conductor subjected to actual service conditions under which a similar undamped conductor would vibrate. By sufficient study of prevailing tendencies of these dampers on different conductors under various meteorological conditions, including temperature and wind velocities, it may be possible to obtain functional relationships between the quantity, q, and the amplitude, A, such that solutions may be obtained which would be reliable for predicting amplitudes of vibration on conductors damped with torsional dampers. Such final solutions would be required in order to reliably conclude that any one set of conditions of damper proportions, location, and weight would be more satisfactory than some other set of conditions.

W. B. Buchanan (Hydro-Electric Power Commission Laboratories, Toronto, Ontario, Can.): It is possible that Speight's analysis of the so-called "torsional damper" might be clarified to some readers by a few additional remarks. A very limited amount of information has been made public on the principles upon which such dampers can be made to operate. The most direct, and possibly comprehensive, treatment thus far is incorporated in United States patent 2,215,541 and Canadian patent 377,602. Certain comments by Speight might be construed as setting certain limitations on their operation, whereas, the writer's view is that these limitations relate to particular designs and proportions that have been under test rather than to the principles involved.

During a rather extensive investigation by the writer on materials that might be used economically as festoons, it was found difficult to improve on the form of construction of the standard stranded conductor. The reversed spiralling of alternate layers proved better than any other scheme of binding, weaving, or otherwise bunching of strands that were devised. A moderate pressure between strands seemed desirable just such as occurs under normal stringing tension, yet, for best operation, festoons should be draped rather loosely. Hence, ways and means were sought to make use of the practically unlimited energy-absorbing medium existing in the cable itself by a suitably-controlled distribution of loss.

Normally, the motion which gives most concern is vibration in a vertical plane, and it was found possible to restrain such motion very effectively by the application of weights supported laterally from the axis of the conductor and alternating at short distances on opposite sides of the conductor.

Initial tests were made by a travelling wave-method and proportions adopted as a result of the data obtained, then practical field installations were made. Two restrictions were found to exist, a rigid mass of large magnitude would not be the ideal arrangement because it would constitute a hard spot on the cable and cause local concentration of stress in the conductors; and further an unnecessarily large amount of vibration might develop before the frictional effects noted would come into play. The latter limitation is obviously due to the elastic properties of the materials and would vary quite considerably with types of conductors and damper design. Development work has been based largely on the use of ACSR conductors of the larger sizes.

Hence it appeared advisable to limit the rigid mass of the damper to the clamping arm and have this arm support, at its outer end, a mass which would offer restraint to various motions of the cable. The most satisfactory material found so far to act as a resilient cushion between the arm and supported weight is a special grade of rubber. It is effective at low amplitudes of motion and has substantial damping characteristics, particularly so in shear.

Attention has been directed to the torsional action of these dampers on a cable but there are two other torsional motions involved in this design which improve the performance. Vertical motion of the conductor as at an antinode tends to cause relative rotation between the arm and supported weight about an axis parallel to the axis of the cable and in present designs subject the rubber pads to shearing stress with substantial damping effect. At a node point another rotary oscillation is set up about an axis through the arm at right angles to the conductor. The polar moment of inertia of the supported mass about this axis then acts as a buffer through the medium of the rubber in compression and this component can be designed to effect quite substantial damping even at node points.

Even a casual review of Speight's paper will serve to indicate the difficulty of extracting a practical solution by mathematical process alone. The nature of the losses are not all known, the coefficients representing losses of known type are not constants in the equations in which they appear. Coefficients indicating loss due to friction might be assumed constant while active, but discontinuous; other coefficients are continuous but vary in different degree according to the stress in the materials. Practically, however, it is possible to observe these reactions in dampers while in motion under forced vibration and to deduce some useful information as to the direction to follow in proportioning the units.

---

* Reference number 7 of the paper.

The theory of operation has been verified by a large number of operating tests, one of which in particular the writer would like to mention briefly.

A short span (140 feet in length) of 605,000 centimeters ACSR conductor was equipped with a pair of dampers located as indicated in figure 4 of Speight's paper. Forced vibration was maintained up to approximately fifty million cycles without any apparent deterioration of the dampers. At the conclusion of the test the cable was examined carefully and evidence of wear was observed at the cross-over contacts between strands of adjacent layers, throughout the length of section between the dampers. The electrical and physical properties of the conductor were unimpaired and apparently the original conclusion that the conductor itself could be used quite freely as an energy-absorbing medium was quite warranted.

J. W. Speight: Mr. Sturm's criticism of the lack of the detail is justifiable, but the scope of the paper necessitated a concise treatment. Equation 7 was derived by using Lagrange's equation and, as pointed out, does reduce to equation 2 for zero displacement of the conductor.

At first, the analysis was applied qualitatively in order to obtain a suitable damper for a specific conductor. With the accumulation of experimental data on the response of different types of conductors (see paper 41-97 by Mr. G. B. Tebo on "Measurement and Control of Conductor Vibration," AIEE TRANSACTIONS, volume 60, 1941, pages 1188–93), it was found that the formulas could be used in a quantitative manner for the design of dampers. It would have been, of course, much more desirable if the initial results could have been obtained entirely by calculation from laboratory test data.

The logarithmic decrement and angular elastic constant, as found experimentally on a short span of conductor, were approximately constant with respect to a limited range of frequencies and amplitude. However, I agree that these quantities are not generally constant but functions of the frequency and angular deflection. It seems that there is a great deal of work yet to be done on the behavior of physical constants under dynamic conditions.

Mr. Buchanan's remark that the development work on torsional dampers was confined to large size aluminum conductors steel reinforced is quite true. Since the paper was written, effective dampers have been designed for $^3/_8$ inch steel ground cable and 500,000 cir-mil H-H copper conductor. Eventually, dampers will be placed on stranded copper conductors which require protection from aeolian vibrations.

The theory of the damper with a resilient joint does consider the rotational motion of the resilient material about the axis parallel to the axis of the conductor, but neglects the rotational motion about the axis perpendicular to the conductor because it is of a secondary order.

The statement in the summary of the paper that, for a rigid damper, the distance from the center of the conductor to the center of gravity (1) should be equal to the radius of gyration about the center of gravity (k) is not very clear. This deduction follows from the assumption of a predetermined value of k. From a practical standpoint, the radius of gyration about the center of the conductor would be maintained constant for a given mass and the conclusion can be written more significantly that 1 should be greater than k. In fact, the theoretical energy dissipation for the latter hypothesis varies from $k=0$ to $k=1$ in the ratio of two to one.

Lightning to the Empire State Building

Discussion and author's closure of paper 41-115 by K. B. McEachron, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 885–90.

Edward Beck (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): 1. Mr. McEachron has mentioned in his paper dealing with lightning to the Empire State Building in New York, that "There is good reason to believe that ground resistance will have an appreciable effect on the currents in a lightning stroke." This is a very intriguing subject. The measurements and the study of arrester performance over a large area of the United States, discussed in the Wagner, McCann, and Beck paper lead to similar inferences. It is the purpose of this discussion to elaborate on these briefly.

2. In speaking of the possible effect of earth resistance on the currents in lightning strokes, it is not intended to infer that the earth's structure may influence the formation of the stroke or the frequency of lightning strokes or thunder storms, the discussion pertains only to the currents that flow after the formation of a stroke. Some speculations have been published by several Europeans on the possible influence of geological structure on the formation and frequency of lightning strokes. It is doubtful that such a relation exists, whereas observations now available do give some indication that there is a relation between the structure of the earth and the currents that flow after the stroke channel has been established.

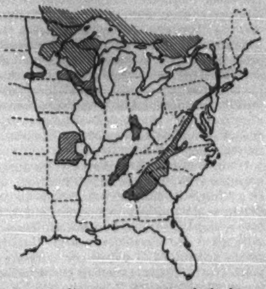

Figure 1. Known exposures of Archaean rocks (shaded areas)

3. An Institute paper by R. H. Card on "Earth Resistivity and Geological Structure" shows that earth resistivities vary between wide limits, from less than 10 to as much as 10,000 ohms per meter cubed. There appears to be a relation between earth resistivity and geological structure; in regions of great geological age, where the most ancient or so-called Archaean rock formations lie at or near the surface, high resistivities appear to prevail. In figure 1, the shaded areas indicate such regions. The data for this figure have been taken from "An Introduction to Geology" by W. B. Scott.

4. As reported in table V of the Wagner, McCann and Beck paper, with 40,000 arrester years of service on a new type of distribution arrester up to the first of 1941, there were 28 cases of arrester damage from all causes with 18 caused by lightning. The arresters whose performance was observed were distributed widely over the area shown in figure 1 of this discussion, but the failures were grouped in an irregular manner. All but two of them occurred in very limited areas. It is remarkable that these particular areas lie in the Archaean region. In one region involving three circuits where arrester damage occurred, Card's data indicate resistivities of 2,000 ohms per meter cubed or more. They all occurred on delta systems, but these are by no means the only delta systems on which this type of arrester was in service. Many more arresters than the total involved in the area in question were installed on delta systems in the non-Archean regions with negligible failures, only two in number. Moreover, there are other systems in the vicinity of the area under discussion on which these arresters were in service and on which none were damaged. However, those systems are either four wire or they are delta in areas that are not Archaean or high in resistivity.

5. In a paper presented several years ago by Messrs. McEachron and McMorris on "Discharge Currents Through Distribution Arresters," dealing with measurements of crest discharge currents through arresters obtained by means of surge crest ammeter links, they reported the highest arrester failure rates in Georgia where, as figure 1 shows, there is a large area of ancient geology in which Card's paper reports resistivities of from 6,700 to 10,000 meter ohms. They report few cases of arrester damage in other regions such as Michigan, which is of comparative geological youth and in which Card reports resistivities of only 33 to 74 meter ohms. Although the authors, in that paper, drew no such conclusions, their data corroborate the indications published in the paper by Wagner and his coauthors.

6. One is led to suspect that the correlation between observed arrester damage and resistivity or geology indicates a correlation between these attributes of the earth and the nature of stroke currents. While so far the data may not be entirely conclusive, it would seem that lightning currents of long duration are more prevalent in regions of ancient geology and high resistivity. The measurements reported in the Wagner, McCann and Beck paper also bear this out, since records of long duration

arrester discharges were obtained only on delta systems in such regions, whereas records of arrester discharge currents on a delta system in another region were all of relatively short duration.

7. It is recognized that other factors, too, no doubt play a large and perhaps controlling part in determining the character of the stroke, particularly in its formation, yet the analysis of the data along the lines discussed is too striking to be overlooked. After all, the earth is one of the two poles of the lightning stroke and apparently this seemingly inoffensive partner of the clouds merits more attention than has been given it in the consideration of the factors that may affect the currents in lightning strokes and those discharged by lightning arresters.

Paul M. Ross (Ohio Brass Company, Barberton, Ohio): In testing transmission line insulation in the laboratory it is desirable to know expected direct stroke rates of voltage rise. What rates of voltage rise may be expected from direct lightning strokes?

W. J. Rudge (General Electric Company, Pittsfield, Mass.): The lightning stroke data presented in Dr. McEachron's paper are fundamental to the protection engineer. For the first time we have statistical data on such items as wave fronts, and wave tails correlated with crest currents, rates of rise, frequency of occurrence, and stroke energy.

Dr. McEachron points out that the Empire State Building measurements give the total stroke currents and energy, and that when a stroke contacts either a distribution or transmission line the current and energy divide, hence only a portion of the current goes through the protective device.

With this in mind it is of considerable interest to compare the data on the actual stroke with the test waves which have been incorporated into the new AIEE Standard for Lightning Arresters.

For example, the Lightning Arrester Standard specifies a 10x20 microsecond wave of 10,000 and 20,000 amperes crest, for obtaining performance data. From figure 6 of the paper, it may be noted that 90 per cent of the stroke current peaks are less than 20,000 crest amperes, and from figure 7 approximately 75 per cent of the stroke waves have a time to half value of at least 20 microseconds. Hence, it appears that the test waves used for comparing performance values of arresters are within the range of waves occurring in the actual strokes.

The Lighting Arrester Standard specifies a 5x10 microsecond wave of 65,000 or 100,000 amperes to demonstrate arrester discharge capacity whereas the highest measured stroke current was 58,000 amperes, although the length of the wave was somewhat more than 10 microseconds.

The rate of current rise for a 5x10 current wave of 100,000 amperes crest is approximately 26,000 amperes per microsecond. Figure 11 of the paper shows that 75 per cent of the stroke currents measured had a rate of rise less than 26,000 amperes per microsecond.

Considering the fact that the total stroke current divides upon contact with a line, it appears that test waves set up in the new Lightning Arrester Standard are more severe than the greater portion of the waves which arresters are likely to be called upon to discharge in service.

The McEachron-McMorris data for actual discharge currents through distribution arresters on rural circuits indicate that 12 per cent of the discharges were over 5,000 amperes and four per cent over 10,000 amperes, whereas the data in the paper figure 6 show 12 per cent of the stroke peak currents to exceed 18,000 amperes and four per cent to exceed 25,000 amperes. This evidence indicates that the crest currents to be discharged by arresters are in the order of one-third of the stroke peak current, and supports the author's contention that the stroke current divides when the stroke terminates on a distribution or transmission circuit.

It will be noted that on 13 strokes there were 41 current peaks recorded, which is an average of about three peaks per stroke, also that the average stroke peak current is 9,000 amperes.

The new Lightning Arrester Standard requires arresters to withstand 30-impulse discharges in the operating duty cycle test with 5,000 amperes for distribution type and 10,000 amperes for station type arresters.

S. K. Waldorf (Pennsylvania Water and Power Co., Baltimore, Md.): Dr. McEachron again provides valuable new information about lightning characteristics, particularly as they are affected by tall structures. In his discussion of results the author uses the simple multiplication of lightning current times the surge impedance of an infinitely long wire to show that a 58,000-ampere stroke would produce a potential high enough to flashover any practical insulation. Readers of the paper may conclude from this that overhead ground wires add little or nothing to a lightning protective scheme. Experience has shown that this is not the case but that properly designed lines can take care of stroke currents greatly in excess of 58,000 amperes.

For instance, the Pennsylvania Water and Power Company has a record of 15 cases where indicated currents in overhead ground wires exceeded 29,000 amperes and no flashovers occurred. In these cases the mid-span clearances ranged from 34 feet down to 16 feet, and the span lengths from 800 to 1,750 feet. In 9 of the 15 cases, the indicated overhead ground wire currents exceeded 40,000 amperes, which produce calculated potentials even greater than that given in the paper. Thus there have been an appreciable number of instances where the simplified calculation indicates that flashovers should have occurred but where they did not.

If the value of 500 ohms for the surge impedance of a conductor in air is used for estimating the currents which flow in an overhead ground wire away from a struck tower, another lack of correlation between calculation and experience occurs. Usually towers adjacent to a struck one carry very much greater currents than are predicted by the simple calculation.

Operating experience differs so frequently and so widely from that predicted by the simple calculation that there must be some other factors besides the surge impedance determining the voltage and current distribution on a line struck by lightning. It would be very helpful to many engineers if these more or less obscure factors could be evaluated and incorporated into a simple and reasonably correct formula.

C. F. Wagner and **G. D. McCann** (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): As part of the lightning investigation being carried out by Messrs. Beck, McCann, and Wagner an effort is being made to determine the effect of the height of the stricken object upon the character of the data obtained. To this end, fulchronograms and initial rates of rise of the current are being obtained for strokes to objects of different heights. The data supplied by Dr. McEachron are particularly interesting to us as they supply considerable information regarding strokes to an extremely tall object, an object more than twice as tall as any upon which we have equipment installed.

The propagation of strokes to low objects is characterized by a stream moving from the cloud to earth with only a relatively small, if any, streamer proceeding from the earth to meet the downward leader. Strokes to the Empire State Building, on the other hand, are usually characterized by the propagation of an extremely long streamer proceeding from the building skyward. Thus the initial stroke should have entirely different characteristics in the two cases. Second and subsequent components of a multiple stroke might resemble each other more closely. It would appear, however, that the rate of rise of current would be dependent to a large extent upon the charge distribution along the initial streamer, and this in turn would be dependent upon the distribution of charge on the grounded object. In the case of the tall building, the charge would be distributed upon a vertical conductor whereas in the case of strokes to open ground or low objects the charge would be distributed on a horizontal plane. The rate of rise of current should then be dependent to some extent upon the ease with which these charges can be drawn into the stroke channel. The measure of this effect might be the surge impedance of the building in one case and the surge impedance and resistivity of the soil in the other.

Another characteristic of the stroke which one might expect to be affected by the height of the building is the duration of its high current portion. This is represented by the discharge of the charge lowered into the stroke channel by the initial leaders. This charge can be rapidly discharged since it lies in a preionized path. The rapidity with which it is discharged depends upon the velocity of the return streamer and the length of the stroke channel. For this reason it is expected that strokes to tall buildings having a shorter stroke path will be characterized by shorter times to half value.

It may be that the two types are similar but until they are so proved doubt still remains. In the discussion of his results, Dr. McEachron, after describing the characteristics of waves on transmission lines, jumps to the conclusion that the data obtained on strokes to the Empire State

Building may be applied to the transmission line conditions with reasonable accuracy. This may be true but in view of the doubts expressed above it should not be so applied without further demonstration of its applicability.

K. B. McEachron: Mr. Beck indicates that he feels that it is doubtful if there is a relationship between the geological structure and the formation and frequency of lightning strokes. While conditions on the earth may have a considerable influence on lightning storms, I do not believe that there is any evidence yet to indicate that the location of strokes or the number of strokes at a given location are particularly influenced by the earth's resistance at that point. I agree that our results tend to bear out Mr. Beck's contention that ground resistance will have an appreciable effect upon the lightning stroke once the path has been made between the cloud and the earth. It is of course rather difficult to know what the stroke characteristics would have been with other ground resistance conditions, but, as we learn more and more about the physics of the lightning stroke we are in a better position to visualize what the effects on the ground resistance might be. With present knowledge, it seems likely that areas of high ground resistance are much more certain to have continuing lightning strokes, just as it appears certain that cloud to cloud strokes are more likely to be continuing for a similar reason, since in this case the mobility of charges on both ends of the stroke is relatively low.[1]

Mr. Ross asked how rates of voltage rise may be determined from direct lightning stroke data. As indicated in the paper, some assumptions must be made when this is done in light of present knowledge. Perhaps the easiest method is to assume that the currents measured at the top of the Empire State Building are also the currents which would occur in a direct stroke of lightning making contact with a transmission line. On this basis then, if the stroke occurred at some point remote from the end of the transmission line the current in the line to be expected would be half that found in the stroke itself. Thus, in figure 6 of the paper, each of the kiloampere values would be divided by two, which would also be the method to be used in connection with figure 11. Thus from figure 11, a rate of rise of approximately seven kiloamperes per microsecond would be expected on a transmission line in 50 per cent of the cases. If it is assumed that the surge impedance of the line is 500 ohms, then the rate of voltage rise for 50 per cent of the strokes would be 3,500 kv per microsecond. The maximum rate of rise, according to figure 11 then, would be 9,000 kv per microsecond. These calculations are based on the assumption that the stroke of lightning is not to be used as a transmission line having a surge impedance.

I do not believe, from a consideration of the mechanism of the natural lightning stroke, that the use of the surge impedance for the lightning stroke will give us as satisfactory a result as the method explained in the preceding paragraph.

It is desirable to point out also that the results given in the paper record only results from initial upward leader strokes from the Empire State Building, and if these same strokes had made contact with a transmission line they would no doubt have been initiated by downward initial leaders. In this case the lightning stroke would have begun with a current peak. There is nothing in our data to indicate whether such a current peak would have been faster or slower than the data in the paper for subsequent current peaks. I feel quite confident that, in general, the rates of rise and durations for the subsequent peaks are not materially different than they would have been had the same stroke of lightning made contact with a transmission line having a similar ground resistance. It is hoped that data may be obtained at the Empire State Building in the immediate future which will show the magnitude of the initial current peaks for those strokes making contact with the building which do have initial downward leaders, thus assisting in answering Mr. Ross' question.

The discussion by Mr. Rudge indicates that the tests which have been set up for testing lightning arresters represent conditions of severity which correspond quite well with those given in the paper. It is recognized, of course, particularly in connection with distribution circuits, that there are many paths to ground, and, although the lightning stroke current at the point struck may have values such as those indicated in the paper, one would not expect to find equivalent values passing through the lightning arresters. Each distribution circuit would have to be studied in some detail, in order to properly subdivide the continuing current to ground. Such a calculation would include the primary of any grounded neutral transformer connected to the circuit. Short time discharges through arresters are often decreased in amount, compared to peak stroke currents, by the flow of current through other paths which may exist in the immediate vicinity of the stroke.

Mr. Waldorf pointed out a possible misconception which the careful reader of the paper may draw from the example given, in which a 58,000 ampere stroke made contact with a long circuit and through the action of the surge impedance of the transmission line and the 29,000 ampere current flowing in either direction, such voltage resulted in flashing over a woodpole to ground. Rather than indicating that overhead ground wires are not satisfactory for service, this statement may be equally well used to indicate the necessity of using overhead ground wires if such a flashover is to be prevented. The thought, however, in introducing this computation was to indicate that detailed data on lightning strokes to the Empire State Building have been obtained having a current magnitude sufficient to flashover a woodpole line to ground, if no means of diverting the lightning stroke were present.

It is obvious, of course, as indicated by Mr. Waldorf that, if overhead ground wires were provided grounded with low ground resistance, flashover would not take place. This is discussed in the paper in the last part of the paragraph referred to by Mr. Waldorf. The stroke is assumed to have made contact with an overhead ground wire at a tower having a ground resistance of 10 ohms, "the potential at the tower top would be only 580,000 volts" which would not cause a flashover on such a line.

Mr. Waldorf has pointed out that the simple calculation which was given in the paper was based on several assumptions which further study will no doubt modify, so that more accurate results may be obtained. I think it is only fair to state that the particulars of exactly what happens just prior to a stroke to a transmission tower, and just after the stroke, are not perfectly clear. However, I think they are sufficiently clear so that reasonable results may be obtained from using such assumptions as those indicated in the paper.

Messrs. Wagner and McCann have indicated in their discussion that they are studying the effects of various heights of structures on lightning discharges. That height might have some effect upon lightning discharges was recognized from the beginning in connection with the Empire State investigation, and when this study was started we constructed in the same year an observatory in Pittsfield on the roof of one of our manufacturing buildings. This building was arranged to make possible the photographing of lightning discharges with various types of revolving lens or revolving film cameras. Similar types of cameras were installed in New York, and it was expected that, by a critical examination of photographs showing the detail characteristics of strokes to the countryside around Pittsfield compared with those to the Empire State Building in New York, correlation would be obtained so that the effect of the height of the Empire State Building might be evaluated.

In addition to this, our cameras in New York are so located that not only do they photograph strokes to the Empire State but records have also been obtained of strokes to many other buildings in lower Manhattan. In most cases it has been possible to identify the building struck, which gives rise to a considerable amount of data with reference to the effect of height on the character of the lightning stroke. We have been collecting these data for the past six years and have records of about as many strokes to other buildings as to the Empire State. I hope that it will be possible to publish the results of both the Pittsfield strokes and the miscellaneous strokes in New York in the near future.

I must take exception to the statement made by Messrs. Wagner and McCann in their discussion in which they suggest that "The propagation of strokes to low objects is characterized by a streamer moving from the cloud to earth with only a relatively small, if any, streamer proceeding from the earth to meet the downward leader." I have published[2] a photograph of lightning striking a beach in New Jersey in which upward streamers several feet in length were found to exist from the beach before the stroke made contact. Similar photographs have been taken with reference to lightning striking water, showing streamers upward from the surface of the water to meet the downcoming leader. Photographs taken in New York, showing streamers from buildings not struck at times when downward leader strokes made contact with other nearby buildings, indicate quite clearly that upward streamers from the earth to meet a downcoming leader are probably quite common. Roughly 20 per cent of the Empire State Building strokes are initiated by downward step leaders. It appears that the upward step leader form of initiation results from the stress in the building being sufficiently great so that a stroke is formed at a time when a cloud charge was not sufficiently intense to have started a stroke from the cloud in the usual downward initial leader manner. Eighty per cent of the strokes which are initiated from the building begin with upward step leaders rather than "extremely long streamers" as suggested by Wagner and McCann. I have recognized the difference between upward initial leader strokes and initial downward leader strokes in that an initial high current peak is absent from the upward leader initiated stroke. It appears, however, from the comparison of the photographic results to structures of different heights and to the open countryside of Pittsfield, of which we now have 745 strokes which have been photographed, that the succeeding current peaks after the initial one will be substantially the same as would be found in the case of a stroke of equivalent length to a ground of the same resistance. Detail differences no doubt will occur, but the measurement of lightning is not an exact science when all strokes have different detailed characteristics. Perhaps Messrs. Wagner and McCann's discussion can best be answered by quoting from my Franklin Institute paper published in February 1939 as follows:

> "The picture of a lightning stroke as it appears to the author at present is something like the following.
>
> "The majority of lightning discharges photographed in the past were branched downward, indicating downward leaders, which is to be expected when the earth is more or less a plane surface as regards the cloud, which, due to its construction, automatically begins to act as a needle point as the charges accumulate in some part of the cloud. The discharges proceed from the cloud in a series of steps, always being fed by a streamer from the original cloud. As this streamer progresses, choosing the best path, the charges upon the earth's surface begin to flow into the region of increased field strength due to the approaching streamer. When the field strength becomes sufficient, streamers will form from grounded objects on the earth's surface. The stroke will usually contact the longest streamer; the return stroke follows, in which charges from the earth will pass up the stroke channel, their flow constituting the current in the discharge. The front of the wave will depend upon the rate at which charges flow into the point to be struck. The crest current will be determined by the number of charges flowing into the channel at the time of contact, and if the stroke is to be continuing, charges will continue to flow until the supply is exhausted in either the earth or the cloud.
>
> "Thus, the front of the wave of current of a lightning discharge with initial downward leader to a transmission line is probably dependent upon the amount of charge and the rate of its propagation toward the point to be struck, while the tail of the wave is dependent upon the amount of charge available. It is not known whether the percentage of strokes to open country which are continuing is as great as to the Empire State Building or not, but it is known that they do occur frequently, and are probably dependent to a large extent upon the distribution of charge within the cloud for their existence. If it is true, as suggested, that the maximum current in a discharge with a downward leader will occur (unless some new cloud charge is tapped), when that leader makes contact with either the earth or a short streamer from the earth, the magnitude of that current will be determined by the charge in the earth and its availability. The amount of charge in the earth will be related to the amount of charge in the cloud and so will the maximum current. A considerable portion of the charge associated with the particular stroke will move from the cloud down into the channel created by the leader. This channel of charges will extend all the way to the earth to unite with the charges from the earth when contact is made. This reasoning would lead one to believe that continuing strokes with downward leaders would be likely to have an initial peak followed by the more or less steady current flow due to the partial or complete discharge of the cloud center.
>
> "Presumably, discharge starts from the cloud without being much influenced by the earth configuration, but as it approaches it is more and more influenced, although as a rule that influence is local in character. However, the taller the conducting object the greater its influence. With strokes initiated by upward leaders, the case is different. It is believed that upward leaders will only occur when conditions on the earth simulate a needle point of sufficient height to have an influence on the propagation. Perhaps some natural configurations of the earth might be of such a nature as to produce the upward leader.
>
> "It seems to the author, however, safe to state that the downward leader stroke represents the type of stroke of greatest importance in the problem of protection of transmission lines and apparatus.
>
> "The effect of the continuing type of stroke must be determined. It seems that it will not be of great importance on grounded neutral electrical systems, because the continuous current can readily flow to ground through the transformer windings. The isolated neutral system may have trouble with protective apparatus connected to ground. Just how important this matter of continuing strokes will turn out to be is not known at present, but it may help explain some of the failures of lightning arresters attributed to arcing grounds or other system disturbances. The continuing type of discharge may have considerable effect on the blowing of fuses used to protect distribution transformers when operating grounded neutral."

It is probable as suggested by Messrs. Wagner and McCann that the great height of the structure may have some effect on the rates of current rise, since these will be affected by field distribution. The shorter length of stroke may also have an effect to shorten the length of tail, as they have suggested. On the other hand, normally no effort is made to determine the length of strokes between cloud and ground, so that whatever the magnitude of these effects may be they will still be within the range of strokes to ground, since lightning strokes do vary greatly in length and certainly many will have stroke lengths corresponding to those which occur to the Empire State Building.

Measurement and Control of Conductor Vibration

Discussion and author's closure of paper 41-97 by G. B. Tebo, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1188–93.

G. W. Stickley (Aluminum Research Laboratories, New Kensington, Pa.): This paper is a real addition to the knowledge of the problem of conductor vibration, and is of particular value in its application and correlation of the various kinds of test data with natural operating conditions. The vibration recorder which has been developed appears to have definite advantages over other types of recorders previously used, in that it records alternating bending which causes vibration failure.

The torsion type of damper, when properly designed and installed, apparently is effective in damping resonant vibration of conductors. Referring to figure 5 of the paper, we assume that the dampers used in obtaining records *D* and *E* were the same as shown in figure 13. It would be of additional value to know the mass, moment of inertia, length of torsion arm, and over-all length of this damper.

Referring again to figure 5, its title, "Typical Damped Span Vibration Records," appears misleading. According to the text of the paper, the records shown in this figure are typical of those obtained when the frequency is not over three cycles per second, which corresponds to a wind velocity of only one mile per hour. It is generally recognized that such wind velocities are very low, and seldom represent average conditions in service.[1] It also is known that the effectiveness of the Stockbridge damper is a minimum at such very low velocities.[2] Incidentally, it is generally considered that vibration at such low wind velocities is not very serious because the frequency and the alternating bending stresses are so low. Therefore, it seems that a similar set of records obtained at a more representative wind velocity should be shown.

It would clarify figures 4 and 5 if the vertical scale of each were stated. Apparently they differ considerably. It should be noted also that the wind velocities are not the same.

In the comparison of dampers and reenforcing devices the author states that "Devices which act primarily as reenforcements effect only a small reduction in vibration amplitude. . ." While it is sometimes true that only a small reduction is obtained it is of interest to report the results of some tests made by the Aluminum Company of America at their Massena laboratories using spans vibrated naturally by prevailing winds. With cables from $^1/_4$ to $1^1/_8$-inch diameter, and in spans from 400 to 1,500 feet long, these results show that armor rods may decrease the maximum amplitude of vibration as much as 50 or 60 per cent and the number of hours of vibration from 25 to 50 per cent. Armor rods, of course, are not usually considered as being dampers, but these data indicate that their damping effect may be of considerable importance.

Incidentally, it should be noted that the armor rods shown in part *B* of figure 14 are twisted the wrong way. Laboratory tests and years of field experience indicate that armor rods should always be twisted in the same direction as the lay of the outer wires of the cable. Laboratory endurance tests have shown that, when this is done, armor rods are at least four times as effective in preventing fatigue failure of conductors. Preliminary field tests indicate that the actual damping effect of armor rods also varies in a similar manner.

The author states that "the advantage of reenforcing devices in protecting conductors from flashover burns may be offset by wear or strand breakage under improperly installed or loosened clamps due to vibration." This same thing may be said, of course, concerning the effectiveness of dampers, and particularly certain types of dampers, if they are improperly installed or if their clamps become loose.

One of the ultimate aims in any vibration study like the one discussed in this paper is that of determining the safe stress conditions which can exist indefinitely without fatigue failure. This, however, is not a very simple task. In the second of the three methods described for determining safe stress conditions, it is suggested that a single endurance test be made on a stranded conductor at a single tension, and that then a conclusion may be reached by comparing the results of this single test with a fatigue curve such as the one shown in figure 16. Such a method seems open to criticism. Actual experience gained in hundreds of tests of cables indicates that it would not be wise to base conclusions on a single fatigue test of a conductor.

The first conclusion of the paper states that "Vibration of large diameter conductors used in modern ACSR long span construction without protective devices may be expected to produce fatigue failure of single strands in a few months to a few years. . ." Many examples could be given to show that this is not necessarily true. One is the transmission line from Massena, N. Y., to Cedar Rapids, Quebec, which was constructed in 1915 using 500,000-circular mil ACSR. Although vibration of this line can be observed almost every day of the year, repeated inspections at the most probable locations have disclosed no vibration failures.

2. VIBRATION OF CABLES AND DAMPERS, R. G. Sturm. AIEE TRANSACTIONS, volume 55, 1936 (May and June sections), pages 455–65 and 673–88.

G. B. Tebo: The author is indebted to Mr. Stickley, who, in his discussion of the convention preprint, made valuable suggestions which have been incorporated in the paper as published.

The damper shown in figure 13 of the paper was the type used in obtaining records *D* and *E* of figure 5. The essential physical characteristics of the damper are:

Overall length of dumbbell casting	12.5 inches
Weight of dumbbell casting	14 pounds
Effective length of torsion arm	4 inches
Torsional elastic constant of rubber connection between arm and dumbbell casting	71 foot pounds per radian
Moment of inertia of dumbbell casting about center of rotation	235 pound inches squared

In objecting to the title of figure 5 which describes the vibration record shown for a Stockbridge damped span as "typical," Mr. Stickley appears to be confusing "typical vibration record" with "typical wind velocity." His contentions that very low velocity winds occur infrequently, and that the resulting conductor stresses are low, are generally accepted. Figure 7 of the paper, however, shows these values in quantitative form for the first time, to the author's knowledge. This figure shows that, on the spans tested, vibration at frequencies of two to four cycles per second (plotted at three cycles per second) occurred about two hours per day and at deflections not exceeding 0.004 inch measured 3.5 inches from the clamp.

The incorrect spiralling of armor rods shown in figure 14*B* of the convention preprint was, of course, an error in drawing. The correct spiralling was used in all test installations as well as in the several thousand installations on operating lines.

In discussing the reduction of vibration amplitude effected by armor rods, Mr. Stickley's admission that "while it is sometimes true that only a small reduction is obtained . . ." indicates that it would be unwise to depend upon armor rods for substantial damping of vibration. It is surprising that Mr. Stickley should cite the Massena, N. Y., to Cedar Rapids transmission line as an example of "large diameter conductor used in modern ACSR long-span construction." The span length, tension, and conductor size of this line are believed to approximate the conditions of curve *B*, figure 8, conditions for which our investigations predict freedom from fatigue failures. Hence, Mr. Stickley's statement regarding the operating experience of the line, provides very satisfactory confirmation of our experimental results.

Field Investigations of Lightning

Discussion and authors' closure of paper 41-137 by C. F. Wagner, G. D. McCann, and Edward Beck, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1222–30.

K. B. McEachron (General Electric Company, Pittsfield, Mass.): The authors of this paper are to be commended for the development of lightning measuring instruments and for conducting an investigation having for one of its objects the determination of the relation between a stroke of lightning as such and the duty on insulation or protective devices associated with the line with which the stroke makes contact. The method used by the authors is, however, based on the comparison of statistical results and thus open to some uncertainty. As I see the problem, the most satisfactory correlation between a stroke and phenomena on the line will result when the current-time characteristic of a stroke itself is known in detail with sufficient accuracy, as well as the complete wave shapes of the current resulting from this same stroke in each of the wire paths of a distribution or transmission circuit. This observation does not detract from the value of the results to be obtained by the method used by the authors, since statistical data of the type shown in the paper are very useful, but to tie together direct stroke data and data obtained on circuits the statistical method will not be completely satisfactory.

When the Empire State investigation was begun in 1935 it was realized that the height of the building might well have a pronounced effect upon the character of the stroke. Therefore, at the same time an investigation was begun at Pittsfield using similar photographic equipment to that used in New York, that is, slow and high speed Boys cameras. In Pittsfield the strokes photographed were to trees, houses, and the terrain of the Berkshire Hills surrounding the observatory. An analysis of these results (745 strokes photographed to date), together with similar results published by B. F. J. Schonland, indicate that strokes to the Empire State building are not particularly different from those to ordinary terrain once the initial mechanism is completed. As indicated by the authors, it seems quite certain that as the height of the structure decreases the percentage of upward initial strokes will decrease. There is no evidence of which I am aware which would indicate that upward initial leader strokes occur to transmission lines of usual height. There is good reason to believe that once the current has started in a stroke of lightning it does not cease until all the stroke discharges in the same path are completed. The stroke is substantially a direct current arc between cloud and ground with superimposed current peaks.

In connection with figure 10 of the paper it is to be noted that photographic results are greatly dependent upon exposure, and exposure is a function of distance and visibility for a given film and lens speed. Thus the duration of a stroke as indicated by the photographic film would be quite different for a camera located five miles away compared to that obtained with a camera one-half mile distant. The number of current peaks, as shown in figure 11, are similarly affected by distance and visibility.

Nothing is given concerning the expected accuracy of the various measuring devices used. It would increase the value of the paper if the authors could give some idea as to the accuracy of the overall results obtained, bearing in mind the method of servicing as well as the accuracy of the devices themselves.

Paul M. Ross (Ohio Brass Company, Barberton, Ohio): In testing transmission line insulation in the laboratory it is desirable to know expected direct stroke rates of voltage rise. What rates of voltage rise may be expected from direct lightning strokes?

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): The authors' conclusion 5, that arrester duty on grounded neutral systems is less severe than on systems with ungrounded neutrals, in general agrees with our own experience. The Chicago 4,000-volt overhead distribution system, which is of the four-wire grounded-neutral type, has the interconnection form of transformer protection and the arresters are mainly types made 12 to 20 years ago. Laboratory surge tests on typical arresters removed from service, using a 10/20-microsecond wave, resulted in failure of some at only 1,500 to 2,000 amperes. Yet these arresters have a very low failure rate in service and provide good protection, the failure rate of transformers due to lightning being only about 0.2 per cent per year. The worst offenders among these old arresters are being gradually replaced, but it is evident that the duty on these arresters is not unusually severe—not enough to warrant a wholesale replacement with new types.

The authors of this paper present limited data on failures of arresters of one type when subjected to lightning discharges of partially measured characteristics, and show that arrester failures may occur for crest discharge currents of a few thousand amperes when associated with about a coulomb of charge. More complete data on this point obtained on other systems and on other types of arresters would be valuable.

It may be pointed out that the pending revision of AIEE Standard 28 on lightning arresters includes a discharge capacity test of 65,000 and 100,000 amperes for distribution (line) type and station type arresters, respectively. Due to the short impulse wave specified for this test, however, the integrated current is only of the order of one-half and three-fourths of a coulomb for the two types. Of course, since thermal effects are involved in arrester failures, this test would seem to impose a much higher duty on the arrester than one comprising an equal charge imposed by a small current of longer duration. Hence it appears, on the basis of such field data as are now available, that the modern arrester, designed to meet the proposed standard tests, has adequate margin to stand up under severe field conditions More important, operating records indicate that the modern arrester has satisfactory *protective* characteristics.

It is of interest to note the report in this paper of a maximum discharge current of over 160,000 amperes in a direct stroke to a tall structure.

It is hoped that the authors' field investigations will be continued.

E. R. Whitehead (Duquesne Light Company, Pittsburgh, Pa.): Messrs. Wagner, McCann, and Beck are to be congratulated on the resourcefulness with which they have attacked the refractory problem of lightning current wave shape. Data on the long-time character of lightning strokes are becoming conclusive, and it is to be hoped that much more data can be accumulated on the nature of the wave front of the high-current short-duration portion of the individual component.

Instances of equipment failure and transmission line flashover have occurred which require high rates of current rise for their explanation, and perhaps it may be said that when sufficient data have been obtained on this point we shall have at our disposal all the facts essential to a practical solution of the lightning problem.

H. N. Ekvall (Philadelphia Electric Company, Philadelphia, Pa.): In this paper the high current short-duration portion of a stroke is referred to as "cold" lightning, while the low current long duration portion is referred to as "hot" lightning. "Cold" lightning has the characteristic of shattering poles and crossarms, while "hot" lightning is less violent and has more of a thermal effect. Apparently the predominance of either of these forms of lightning is affected by soil resistivity. High soil resistivity apparently is conducive to discharges of long duration, or "hot" lightning. Some evidence to support this belief has been found from experience on the 33-kv wood pole lines of the Philadelphia Electric Company, which are in a territory of high soil resistivity as indicated by our average ground resistance of 150 ohms for ten foot driven rods. On these lines, which have no ground wire protection, there is very little shattering of poles or crossarms. This is in contrast to experience in the mid-west, where on similar construction pole shattering is so severe that ground wire protection is required. This difference in performance may be associated with low ground resistivity in the mid-west, as compared to high resistivity in the vicinity of Philadelphia.

C. F. Wagner, G. D. McCann, and Edward Beck: Mr. McEachron states that the statistical approach to the lightning problem employed by the authors is open to some uncertainty. We assume that he refers to the correlation of surge currents at various points in a system to the current in the stroke itself, for he advocates the measurement of all associated currents for individual strokes. Although we agree that such data would be desirable, contemplation of such an undertaking demonstrates the almost insurmountable practical difficulties of securing such complete data in any volume sufficient to be useful. In view of the indicated influence of factors of which there is little knowledge, and the fortuitous nature of strokes, the only way to accumulate the necessary data is by statistical observations under varying conditions. Moreover the correlation of stroke and traveling wave currents is not the only problem. Of outstanding practical importance is the probability factor of the various characteristics of surge currents in such apparatus as protective devices. This can be determined only by statistical methods, the approach pursued by the authors. Accumulation of such data in sufficient volume, it is expected, will permit the prediction of the performance of systems and the life of protective devices of known characteristics.

Mr. McEachron also states that his photographic studies of strokes to the Empire State Building and to open ground at Pittsfield are essentially the same once the initial mechanism is completed. This may be true with regard to certain characteristics such as the number of components and the intervals between them, but until data on the important factors of wave shape and magnitude of the current at the ground end of the stroke for strokes to tall objects and to open ground are available, the similarity is open to question.

The data on strokes to open ground plotted in figure 10, upon which Mr. McEachron comments, were obtained photographically by measuring the time from the beginning of the first component to the visible end of the last component. These data and similar data of figure 11 of the paper are open to the criticism mentioned by Mr. McEachron in that they are dependent upon the distance and visibility, and film sensitivity and lens speed. These same factors are present in the experimental data which prompted Mr. McEachron to conclude that the strokes to the Empire State building are not particularly different from the strokes to open ground observed at the Pittsfield Laboratory.

Mr. Ekvall's observations on the relation between pole shattering and soil resistivity are very interesting and well worthy of further consideration by the industry.

We agree with Mr. Whitehead that there is need for more statistical data regarding the rates of rise of surge current.

Because modern theories of line protection are built around current as the fundamental quantity, lightning investigations are concerned largely with determining the characteristics of the stroke with regard to this factor. In answer to Mr. Ross' question methods are available for determining the voltages associated with these currents, and impressed upon insulation. While it would be desirable to accumulate data on voltage directly, the results would be dependent on other factors such as tower footing resistance and the like. For this reason we have preferred to devote the means at hand to the collection of the more fundamental current data.

We are very much interested in Mr. Halperin's experience on a large distribution system, as it supplements in a valuable manner the data presented in our paper and theoretical computations in an earlier one. We agree that more data are desirable on the nature of the discharges associated with arrester failures, and we are continuing and extending our investigations.

Electric-Locomotive Application

Discussion of paper 41-101 by E. W. Brandenstein and D. R. MacLeod, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1210–15.

Sidney Withington (New York, New Haven and Hartford Railroad, New Haven, Conn.): This paper presents data of much interest and is a valuable addition to the literature on the subject under review. A number of points may be emphasized to advantage.

Momentum grade operation, which is described, constitutes an exceedingly valuable adjunct in railroad operation, of which full advantage has not been taken in times past, and which undoubtedly will be used increasingly in the future. As the authors have pointed out, there is no reason why a change of kinetic energy to potential energy should not be made under proper conditions, and with the high degree of reliability of electric motive power and with proper dispatching, the chances of a train being obliged to stop on a grade on which starting would be beyond the capacity of the locomotive, is nowa-days so negligible that it does not constitute an operating hazard.

As has been indicated, the short-time overload capacity inherent in electric locomotives, as compared with steam and Diesel locomotives of the same nominal rating, is of great advantage in the application of electric locomotives to operating conditions. Not only does the profile of a given section of railroad usually involve considerable variation in power demands, but after slow-down which may be necessary for curves, drawbridges, etc., the sharp concentration of horsepower required for a short period in resuming normal speed is important in permitting fast schedules economically. The voltage control by transformer tap-changing when single phase power distribution is used and the highly effective modern a-c series commutator traction motor provide an ideal combination for this most valuable characteristic. If overload capacity is taken into consideration and conforms, as it usually does, to the service requirements involved, it may be said that on an effective horsepower basis the electric locomotive compares favorably in cost with the other forms of motive power.

The authors refer to the separation between peak traffic in passenger and freight service as being a characteristic of railroad operation. While the Christmas holidays constitute a high passenger-train peak, there are also on most railroads other holiday demands which also may be classed as peaks, such as July Fourth, Labor Day, Thanksgiving Day (under the old pre-Roosevelt schedule), etc. Diversity of traffic is desirable on all these occasions regardless of motive power limitations, for limitations in track capacity often make it necessary to postpone freight train operation during the exacting passenger peak demands. The interchanging of electric locomotives between passenger and freight service thus works in nicely with the requirements. Diverting locomotives between passenger and freight service, however, will be found practicable only if the passenger and freight train facilities in a given terminal are relatively close together, so that a great deal of dead-head locomotive mileage is not required to get a locomotive from one terminal to another for a return trip.

In handling sharp peaks in passenger or freight service it may be found advantageous in a given electrification installation to plan to utilize spare *steam locomotives* in order to avoid the necessity for carrying excess capacity in electric locomotive units which would be little used at other times. This policy in using spare steam locomotives thus for peak loads may also well be of advantage under some conditions in avoiding establishing expensive peak loads in the power supply.

The use of inert cooling liquids for transformers has constituted an important advance in electric locomotive design of recent years. Formerly, while oil cooling was used largely abroad, American locomotives were equipped with air cooled transformers, which obviously had serious limitations for various reasons. The inert cooling liquid provides all the advantages of oil cooling without certain hazards.

An interesting reference is made to track platform capacity at terminals as affecting possible length of passenger trains. This is true, not only at certain terminals, but in many cases at stations along the line where platforms constitute serious limitation in train lengths. To have to make train stops at a station platform is of course disastrous in maintaining rapid schedules. It is pointed out also, in this connection, that electric locomotives may have fundamental advantages as compared with certain other types of motive power; certain 6,000 horsepower diesel locomotives of a type now operated, for instance, have lengths of more than two hundred feet which may on occasion seriously limit the length of a passenger train at a stub-end terminal.

Relative availability of electric and steam locomotives is referred to in the paper. In preparing comparative data in a given instance, care must be taken that the mileage of electric locomotives is not limited by traffic requirements, rather than by mechanical considerations. The fleet movement of both passenger and freight trains, which is often necessary in railroad operation, may sadly limit equipment mileage and prevent the intensive use which would otherwise be possible.

C. Kerr, Jr. (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): In his presentation, Mr. MacLeod has given an interesting review of accomplishments in the design and application of modern electric locomotives. Progress in this field is indicative of some of the creative action which has taken place to assist in maintaining a high level of railroad operating efficiency.

The heating and cooling curves devised represent the best type of information obtainable on locomotive application. The data serve as a means for accurately establishing electric locomotive performance under all conditions which are encountered in service. It is practicable to predetermine the heating of the traction motors at any location of a profile during a run. The completeness of the data is helpful in fixing tonnage ratings for the electric locomotives. There has been no necessity for downward revisions of tonnage ratings after they were once established. This reflects the usefulness of the heating and cooling curves.

Momentum operation is justly mentioned as an important factor contributing to the most efficient use of the electric locomotive. The a-c engine develops its maximum rating at high speed and securing full benefit of the available output is a problem. Momentum operation has done much to permit using the "high speed" capacity of the a-c electric locomotive. It has been beneficial in boosting tonnages—in fact, trailing loads have been almost doubled in some cases.

During the course of the test work, considerable time was devoted to investigation of train resistance. The results show unusually low values for heavy rail (130 pounds per yard). This is another contribution to "trailing tonnage increases" for the a-c electric locomotive. Full advantage is taken of this factor in fixing tonnage ratings.

Glass-Bulb Mercury-Arc Rectifiers for Traction Service

Discussion and author's closure of paper 41-100 by C. E. Woolgar, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (August section), pages 843–6.

W. E. Gutzwiller (Allis-Chalmers Manufacturing Company, Milwaukee, Wis.): The paper gives a very interesting and complete account of the application of permanently sealed glass tube, multi-anode mercury pool rectifiers for traction service. This type of equipment is being used very extensively on the European continent, in Great Britain, and over-seas countries served by British, French, and German manufacturers. On this side of the Atlantic, a few installations of glass tube rectifiers have been made in Canada with British made equipment, and in the United States with equipment furnished by this company. The following comments are based entirely on experience with this type of equipment in the United States.

Glass tube multi-anode mercury pool type rectifiers were employed very extensively some fifteen to twenty years ago in connection with the series type street lighting, using d-c arc lights. With the development and perfection of incandescent lamps for street lighting, the arc light, and with it the glass tube rectifier, disappeared from this field. Since that time up until just a few years ago it has been used mainly in small capacity sets for battery charging purposes.

Within the last three years this company has built glass bulb rectifier equipment for industrial applications, covering about twelve 200 and 400-ampere rectifier tubes. While the experience with these installations has been very gratifying, they have not been in service for a sufficient period to draw definite conclusions as to tube life and maintenance cost.

The experience gained so far, however, seems to indicate that the equipment does not lend itself very well to modern manufacturing methods, as the glass envelope, due to its complicated shape, must be "hand-made" by expert glass blowers. Likewise, the handling during the manufacturing, shipping, and field maintenance requires extreme precautions to avoid breakage.

Aside from these points, our experience indicates that glass tube rectifiers are particularly well suited for light duty applications, in ratings of a few hundred kilowatts, where generally the ratio of peak to average load is low, d-c short-circuits are relatively infrequent, and where short-circuit currents, due to limited amount of power in a-c and d-c systems, are comparatively small. Under such conditions very satisfactory tube life can be obtained.

It is believed, however, that for heavy traction service as encountered in metropolitan areas for subways and elevated railroads, calling for loads of 300 per cent of normal for one to five minutes, the more rugged, pumped steel tank type rectifier would, in the long run, be more economical.

Our limited experience with the direct forced-air cooled glass tube rectifiers has been extremely encouraging and has induced us to develop pumped metal tank, multi-anode rectifiers in smaller ratings, with direct forced-air cooling. A number of such installations have been made, and have been very successful.

While water-cooled rectifiers in large capacity converting substations are not objectionable, but, to the contrary, have many advantages, particularly in cases where the atmosphere is contaminated with dust or corrosive chemical fumes, in small rectifier stations cooling water becomes rather expensive, both in regard to installation and operating cost. The forced air-cooled rectifier in such installations greatly simplifies the layout and reduces operating cost by eliminating water, corrosion, sweating of pipes, and danger of freezing.

In the United States, the development trend in the rectifier field has definitely been towards the rugged steel tank rectifiers in multiple and single-anode types, which can be manufactured with modern methods and machine tools.

While until about five years ago railways were the largest users of power rectifier equipment in the United States, recently a rapid change has taken place and today at least ninety per cent of the sales of power rectifiers are going to the electrolytic industry. Because a large part of the remaining ten per cent is being used in the steel and associated industries, the traction field has become of less importance. Therefore, it would be of interest to know whether glass tube rectifiers have found any application in the electrolytic industry outside of the United States.

Information on the part of the author of the paper explaining how anodes are paralleled off a common rectifier transformer, where there are as many as forty or forty-four rectifier bulbs per substation; likewise, information on the type of connection of the secondary winding of rectifier transformers supplying a large number of parallel tubes, would be desirable.

Henry M. Hobart (retired, General Electric Company, Schenectady, N. Y.): The merits of glass bulb rectifiers for traction service are clearly and concisely set forth in the paper presented by Mr. Woolgar. The paper gives just the kind of information which will be helpful to application engineers. One could only wish that the case he presents could have been available in as clear and convincing form some twenty years earlier. Substations equipped with rectifier cubicles and transformers in accordance with the principles described by Mr. Woolgar, might, in conjunction with the great decrease in weight of modern traction motors, and the improvements which were already being made at that time, in permanent way and rolling stock construction, have saved the day for urban and suburban electric traction on rails.

At that period, a considerable number of British and other European firms were manufacturing both steel-tank and glass-bulb mercury-arc rectifiers, and many useful fields of application were being found for each type. But in this country, no sufficient interest could be aroused at that time, in the glass-bulb type. There then followed in America an almost complete abandonment of the use of synchronous converters in new installations, and the rapid introduction of steel-tank rectifiers instead.

Had American manufacturers adopted the plan of providing both types, it is evident from Mr. Woolgar's data and explanations that today the glass-bulb type would have been conceded to be in many applications superior in reliability and efficiency, and of lower initial cost for apparatus, foundations, and buildings, as also with respect to lower maintenance and operating costs.

It would appear superfluous to emphasize any particular parts of Mr. Woolgar's presentation, but it might in addition be suggested that the present heavy national defense demand for all qualities of steel is liable to make it more difficult to obtain the high quality essential for rectifier tanks. The price will increase with the increasing acuteness of the defense situation and the importance of considering first the needs in military matters. Thus Mr. Woolgar's reminder of the excellence of the glass-bulb alternative is decidedly timely. Even in fields of application which are well met with large steel-tank rectifiers, the alternative of employing groups of glass-bulb rectifiers certainly would not be attended with any disadvantages comparable with the importance of national defense considerations.

The feature of using many component sets of small rating instead of one or a very few larger sets, must play a considerable role in decreasing the capital cost as compared with having large units and the correspondingly necessary large and expensive spares. The cubicle system also contributes toward less floor space. Mr. Woolgar particularly stresses the interesting technical advantage of distributing the total current amongst a great number of anodes, and thus decreasing the liability of arc-backs. This greater distribution also must contribute toward lower anode temperature.

The multiplicity of small units presents a fine opportunity for reducing costs by mass production methods. By concentrating on a very few sizes, these can be combined to provide sub-stations of any desired small or great rated output, and any desired total voltage and total current. The highest direct current voltage provided in a single glass-bulb rectifier is indicated in the paper as 1,500 volts. But it is a simple matter to supply two or more star-connected anode groups from two or more windings on the cores of a single transformer or group of transformers, and by placing the two or more groups properly in series, there will be obained sets for 3,000 or more direct current volts. Thus it is seen that with respect to total rated output and voltage and current, a great range of ratings can be provided by simple combinations of the proper number of component rectifiers.

The complications entering into the design of transformers for meeting the requirements of employment with mercury-arc rectifiers were not realized or even suspected in the pioneering period. But gradually the transformer has come to represent a rather large portion of the total cost (made up of transformer plus rectifier). Thus if the cost of the transformer can be decreased with no sacrifice in quality, it is important to do so. At present the customary self-cooled oil type of transformer is widely employed. The immersion in oil necessitates its being made large enough to avoid the occurrence of such temperatures as may occasion sludging. So by doing away with oil and using a compressed-gas design, the transformer can be greatly reduced in weight and in cost. The requirements as regards foundations and floor space are also reduced. The high temperature permissible in such a design opens the way for many attractive and novel designing possibilities. The heat may be removed by forced circulation of the compressed gas, first amongst the windings and then through a heat exchanger. Only a practically negligible amount of power is required to circulate the compressed gas at such high speeds as to remove the heat much more effectively than is practicable in the self-cooled oil type.

The turn and layer insulation may be composed of some mica or asbestos materials or of glass tape. In this application the fundamental purpose of the compressed gas is to effectively remove the heat from the windings. Transformers for rectifier service usually are not operated from any particularly high voltage source. In the exceptional cases where the transformer is supplied directly from a high voltage line, the great dielectric strength of a suitable compressed gas will also constitute a useful feature.

In order that there shall not be an unduly great increase in the resistance of the transformer windings, they must be vigorously cooled by the gas circulation. But as to the laminated core, it is now 30 years since it was shown by MacLaren in two AIEE papers, that at very high temperatures, the hysteresis loss decreases considerably in some kinds of core material. A simple plan for sufficiently limiting the temperature rise in the windings and at the same time, providing for a high temperature in the core, is to interpose between the core and the windings, a thermal screen of, for example, a thickness of asbestos or mica sufficient to occasion the desired thermal drop. In the discussion of this proposal, it has been suggested as an obstacle, that the magnetizing current increases rapidly with increasing temperature at the high-temperature range under consideration. But in the case of some excellent modern high-permeability core material, it has been determined by tests that the rate of increase of the magnetizing current with increasing temperature in that range, is much less than in the older brands of transformer core material and is, indeed, not sufficient to interfere with the success of the project.

When freed from the temperature limitations applying to oil transformers, and which have for decades stood in the way of various transformer improvements, one of the interesting directions for progress is in the use of vaporization cooling which can now (with compressed gas cooling) be applied in various extremely effective and economical ways.

It is believed that some of these transformer proposals will fit in very effectively with the features of the cubicle design of glass bulb sub-station described by Mr. Woolgar. Taken together, there will become available a type of railway-traction sub-station of less cost and weight, higher service efficiency, and greater dependability than any yet employed.

The AIEE has been very fortunate to be privileged to publish Mr. Woolgar's admirable paper, and it is to be hoped that electric railway people in particular, will investigate very thoroughly the possibilities of the glass-bulb mercury-arc rectifier.

C. E. Woolgar: Mr. Hobart's suggestion that glass-bulb rectifiers, in conjunction with improved design of traction motors and improvements in permanent ways and rolling stock, might have saved the day for urban and suburban electric rail traction is most interesting particularly in view of the fact that in Great Britain particularly so many tramways are supplied from this type of equipment and even where tramways have been superseded there has been a strong movement towards the use of electric trolley-busses instead of gasoline or oil-driven vehicles favoured on this continent.

The author apparently did not make clear the range of d-c voltage for which single glass-bulb units are suitable, as Mr. Hobart suggests a series arrangement to obtain 3,000 volts d-c. This is unnecessary as single bulbs can readily be built for any practicable d-c traction voltage.

Mr. Hobart made a number of most interesting suggestions concerning the use of compressed-gas filled rectifier transformers to replace the more usual oil-immersed type. The author is not competent to reply to these suggestions and has referred the entire discussion to his principals in England for detailed comment.

Mr. Hobart also makes the interesting suggestion that due to heavy national defense demands in the United States for all qualities of steel, glass-bulb rectifiers could be used to advantage in many cases. Under present conditions the ability to supply such rectifiers will largely depend on the degree to which the manufacture of glass-bulb rectifiers has been developed in the United States. It may be of interest, at this point, to mention that in Great Britain there is ample evidence of the ability of glass-bulbs to withstand concussion due to bombing. In one case, a bomb fell 15 feet from a rectifier substation, made a crater 40 feet wide by 20 feet deep and demolished the substation. The undamaged glass-bulb rectifier units were removed, the station rebuilt, and the rectifiers restored to service without any necessity for repairs.

Mr. Gutzwiller's comment that glass-bulb rectifiers do not lend themselves to modern manufacturing methods due to the necessity of hand-work by expert glass blowers should be thought of in terms of modern shop practice where machining to a fraction of one thousandth of an inch is done by highly-trained, expert workmen. Concerning special handling, the paper mentions that large numbers of glass-bulbs are shipped to all parts of the world and handled safely by native labour.

The author attempted to make it clear in the paper that glass-bulb rectifiers are most suitable for heavy duty applications, for any kilowatt rating, for any ratio of peak load to average load, and for any frequency and intensity of short-circuit current. It will be appreciated that for any given conditions of service severity, the steel tank rectifier manufacturer must select a rectifier suitable for those conditions on essentially the same basis as the glass-bulb manufacturer. It becomes simply a matter of knowing the characteristics of the different ranges of rectifiers and choosing a unit or units capable of meeting the required conditions. In view of the fact that a large number of glass-bulb traction installations of 2,000 kw to 4,000 kw and installations for other types of service with outputs up to 15,000 amps. have been operating satisfactorily for a number of years, it is difficult to justify Mr. Gutzwiller's suggestion that these rectifiers are mainly suitable in ratings up to a few hundred kilowatts.

Mr. Gutzwiller also refers to the high overload capacities obtainable with steel-tank rectifiers, but (*b*) the paper states that it is a simple matter to supply a glass-bulb rectifier with any overload capacity required. As a typical example, the New Zealand Government electrified railways between Wellington, Johnsonville, and Paekakaviki are supplied by glass-bulb rectifiers in six substations totaling 6,000-kw capacity at 1,600-volts d-c. The overload ratings are:

$1^{1}/_{2}$ times full load for 1 hour
2 times full load for $^{1}/_{4}$ hour
3 times full load for 5 minutes
$3^{1}/_{2}$ times full load for 1 minute
4 times full load for momentarily

The method of supplying power to the anodes of a multi-unit glass-bulb rectifier installation is quite straight-forward. Such installations are usually arranged in a straight line and six or twelve leads (as the case may be) are brought from the transformer to busbars running along the top or bottom of the cubicles. Taps taken off at each cubicle pass through anode chokes mounted inside each cubicle, thence to the anodes. The transformer is wound for six or twelve phase operation, as required, in accordance with standard practice.

The author wishes to make one correction to the paper. The percentage of plant failures attributed to various components of steel tank rectifiers given in the paper actually refers to the amount of attention given to the various components for maintenance purposes. The results of an analysis of faults which occurred on 32 steel tank rectifiers on the same system over a period of 12 months showed the failures distributed as follows:

Component Causing Failure	Percentage of Total Failures
Control gear	50
Circulating-water system	12.5
Vacuum system (mercury pump and rotary vacuum pump)	12.5
Rectifiers	12.5
Rotating auxiliaries	6.25
Unexplained failures	6.25

A Distribution System for War-Time Plant Expansion

Discussion and author's closure of paper 41-136 by J. L. McKeever, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 862–5.

R. H. Kaufmann (General Electric Company, Schenectady, N. Y.): This paper is of great interest to all individuals concerned with the problem of industrial plant distribution and more particularly so in that the present paper reports an actual system installed. The general system design which is used is in line with the present general trend toward the use of high voltage primary feeders in combination with distributed load centers stepping down to the utilization voltage. The use of many load centers, each of identical size and design, possesses many obvious advantages.

The low tension system incorporates good voltage regulation characteristics, and incorporates a simple switching system capable of reasonable operating flexibility. Good utilization of secondary conductors is obtained through the combination of tie circuit and feeder functions on common electrical circuits. The proposed system is laid out for a utilization voltage of 550, although in this country the preference for 440-volt apparatus would generally dictate its use even at somewhat lower overall economy.

The high tension primary loop circuit has been designed for low investment cost through the use of circuit breakers only at the supply terminals to the loop and air break disconnect switches installed at each load center, one in each branch of the loop. The reduction in primary circuit investment cost is accomplished with certain sacrifices in operating flexibility, namely: a high tension cable or transformer failure results in a temporary power outage on the entire area; unless the location of the fault is evident by the presence of smoke or flame, the power outage may be somewhat prolonged during location and isolation of the faulty section; the switching of energized 6,600-volt circuits presents certain hazards and a flashover attendant therewith would result in a power outage on the entire area.

For general application, it would be advisable to incorporate a more extensive primary switching system, such as to incorporate the ability to localize the area affected by an electrical failure, insure the ability to quickly restore service to any particular load area, and minimize power switching operations which must be performed on disconnecting switches.

John S. Parsons (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. McKeever has written an interesting and instructive paper on a very timely subject. The distribution system described, however, is not a low voltage or secondary network system. The term secondary network system is generally understood to refer to a system comprising a secondary circuit, loop, or grid supplied over two or more primary feeders through step-down transformers. The loads are fed radially from the common secondary circuit or grid. The system is designed so that a primary feeder and its associated transformers will be automatically disconnected from the system without any interruption to service when a fault occurs in a transformer or on the feeder. Under the condition of at least one primary feeder out of service full load can be carried without appreciably overloading any part of the system. The system described in the paper is usually referred to as a banked transformer system in which a number of transformers are so connected that they operate in parallel between a single primary feeder and a common secondary circuit, loop, or grid.

The banked transformer system of distribution is a definite improvement over the radial distribution systems usually employed in industrial plants. It can be designed to incorporate all of the important advantages of the secondary network except service reliability. Unlike the network system a primary feeder or transformer fault results in a shut-down of all loads fed over the feeder until the fault can be located and manually isolated from the system. The system does as pointed out by Mr. McKeever possess such important advantages of the network system as flexibility and good voltage regulation. To take advantage of flexibility, however, the sectionalizing dis-

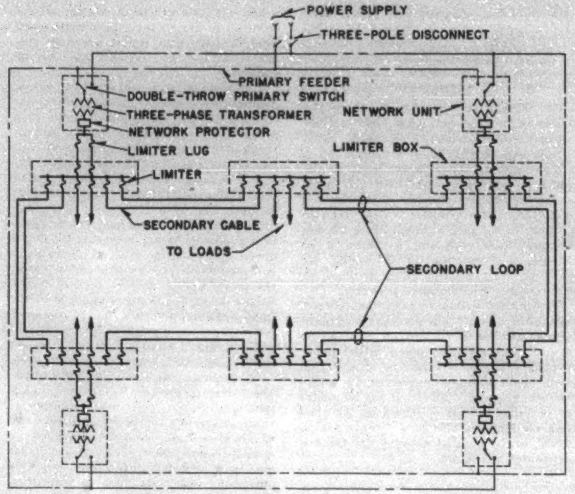

Figure 1

connecting switches in the primary loop should be capable of breaking load current, so as to permit switching transformers and sections of the loop out of service for maintenance and extension work without shutting down all load fed from the primary feeder while the switching is being done. Apparently the primary disconnecting switches in the system described by Mr. McKeever, based upon his description of switching procedure in the paper are load break switches, however, from the picture of them shown in figure 3 of the paper they do not appear to be.

Obviously any type of distribution system may take a number of different forms and we believe a form of secondary network system such as that shown in figure 1 of this discussion, having all of the advantages of the system described plus the important advantage of much greater service reliability could have been installed for the same or possibly less money. Such a network system would employ a grid or preferably one or more secondary loops consisting of two cables per phase, protected by limiters in each end of each secondary cable. The two cables per phase would be bussed at suitable points at which loads are tapped off the loop, and also at the points where power is fed into the loop. With this arrangement a faulty secondary cable will be cleared from the loop by means of its two associated limiters without interrupting service to any load. Only faults at a bus point or on the short radial circuits from a bus point to the individual loads will cause any interruption to service.

The secondary loop or loops would be fed through network units, each preferably consisting of a three-pole double-throw load-break primary air switch, a three-phase non-inflammable, non-explosive air transformer, and a network protector. Both radial primary feeders, each capable of carrying the entire plant load or that portion of it connected to their associated secondary loop or loops, are brought to each network unit. Normally half of the network units are connected to each primary feeder. When one feeder and its associated transformers are automatically disconnected from the system as the result of a fault the transformers associated with the faulty feeder are manually switched over to the good feeder by means of their double-throw primary switches. In this way the transformer capacity required can be kept down to the same value as that needed in the banked transformer system.

The same general form of system as that briefly outlined above can, of course, be used in the banked transformer system by replacing the two radial primary feeders with a single loop primary with load-break disconnecting switches between the points where the transformers are connected to the primary loop, and by replacing the network protectors with disconnecting switches. Such a system should cost less than that described by Mr. McKeever and has the advantage that a fault in a cable of the secondary loop or grid does not interrupt service to any load.

J. L. McKeever: Mr. Kaufmann suggests that for general application, it would be advisable to use a more extensive primary switching system to minimize the effect of 6,600 volt cable fault. It was stated in the paper that switching had been deliberately simplified and that short interruptions of power at very rare intervals were of small consequence. We believe most applications would be similar to ours and it would not be economical to aim at greater insurance than necessary.

Mr. Parsons' criticism is somewhat similar to that of Mr. Kaufmann and Mr. Parsons has described the system propounded by Messrs. Powel and Barnett in their paper given at the last winter convention. Rough estimates we have made do not indicate that their system could have been installed for less money. So far as the disconnecting switches for the primary loop in our system are concerned, these are not load-break switches as we do not consider such to be necessary. If one disconnect is opened it simply means a redistribution of load current from the two ends of the loop and the voltage behind the arc is merely the slight difference in voltage drop in the loop cables. Tests have shown ordinary disconnecting switches to be adequate for this purpose and also for breaking the transformer magnetizing current.

One point might have been given greater emphasis in the paper and that is the benefits to be derived both by the user and the electrical manufacturer in the use of standardized substation units. If the paper helps this idea along in any degree the writer will consider it to have been worth while.

A New Mercury Rheostatic Element for Regulation and Control

Discussion of paper 41-98 by K. A. Oplinger, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (August section), pages 846–9.

R. E. Hellmund (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): The author in presenting a new regulating element has stressed the fact that all such elements really serve as amplifiers and that his particular device has an exceedingly high ratio of amplification. Incidentally, it is stated that in addition to such regulators and the well-known amplification methods using electronic tubes, rotating machines with commutators also act as electric amplifying devices. In any Ward-Leonard control system, for instance, the voltage of the generator, and consequently the speed of the driven motor, is governed by the field current of the generator. The latter is about one per cent of the output of the machine, which therefore corresponds to an amplification ratio of 100:1. If this is not sufficient, as may be the case with larger generators, double amplification can be obtained by using an exciter for the generator and controlling the field of the exciter. Machines for the latter purpose have been designed with a ratio of 400:1, so that a total ratio of 40,000:1 can be obtained. Recently the well-known cross-field generator having two fields at right-angles to each other, one of which is excited through short-circuited brushes on the armature, has been employed for double amplification. This arrangement, however, is limited to the smaller machines. For large machines very high ratios can be obtained by a combination of the amplification available in the main machine and a regulating device as described in the paper. This is only one of many possible combinations for obtaining a high ratio of amplification.

These amplification ratios, however, are only one of the factors to be considered in the solution of many kinds of regulating problems. Other factors to be considered are anticipatory features, anti-hunting features, speed of response, temperature influence, etc. It is therefore well to realize that we have at our disposal several types of standard apparatus, such as tubes, regulators, rotating machines, etc., which can be used for this purpose; also, that each of these basic members has certain advantages and disadvantages and that it is therefore unwise to use one of these means to the exclusion of the others. The best results undoubtedly can be obtained by using the device or combination of devices which will give the best all-round performance and lowest costs for the particular case at hand. I believe that with these devices at the disposition of the engineer, there are a great many unexplored possibilities for working out automatic controls of all kinds, not only for electrical machines but also for the great variety of non-electrical processes in industry.

The Incandescent Lamp Situation From the Engineering Point of View

Discussion of paper 41-123 by P. S. Millar, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1174–80.

Walter C. Wagner (Philadelphia Electric Company, Philadelphia, Pa.): Mr. Preston Millar has been too modest in his statements relating to the outstanding contribution which he with his associates have made along engineering lines to the progress of the development of the incandescent lamp. May I present but one of the elements of contribution in this connection.

The electric supply company with which I am associated began its career under the personal direction of Mr. Thomas A. Edison. We have until recently supplied incandescent lamps to our customers in order to assure that they enjoyed at all times the greatest price-quality advantages. In this connection it cannot be too forcefully stated that we, among many other supply companies, have entirely and satisfactorily depended upon Mr. Millar's guidance over the years.

Referring to his comments on the related progress of interior wiring developments, he has truly indicated that to an extent it has hampered the advance of incandescent lamp lighting. I will present a brief paper on the subject of interior wiring at a Conference Session tomorrow.

Mr. Millar, as President of the International Commission on Illumination, and Chairman of the United States Committee of that body, on which the speaker also serves, should not have refrained from a statement concerning the importance of its work. He should also have indicated that his own contributions, among those of others, have in no small measure contributed to the outstanding international progress in the incandescent lamp art.

M. L. Sloan (General Electric Company, Nela Park, Cleveland, Ohio) (contributed): It has always been one of the objectives of the General Electric Company to pattern its improvements in lamp design along lines of sound engineering analysis rather than by promoting style changes intended to gratify the eye or offer an opportunity to increase sales merely by campaigning something different than the existing mode. In this manner, the composite result of all the improvements made over a period of years has been increased quality at a decreased price to consumers. When deciding whether suggested improvements should be incorporated, the final criterion has been whether the value of the article to the ultimate consumer is enhanced thereby.

We have always felt it fortunate that the utility companies who sell power have maintained such an interest by and large in the quality and efficiency of lamps used on their lines, and the activities which have been carried on by the Electrical Testing Laboratories in their behalf have ably supplemented the efforts made in our research laboratories to determine by exhaustive tests the merits of suggested changes in lamp design.

In this manner the substitution of coiled filaments for straight, the introduction of gas filling, the use of inside frost finish, the adoption of smaller bulb sizes, the use of coiled coil filaments in certain suitable lamp types, and many other improvements long since recognized as standard specifications, have all been tested and thoroughly analyzed by the Electrical Testing Laboratories before their stamp of approval in behalf of the ultimate customer was given, signaling the universal adoption of the improvement as standard practice.

In fact, such helpful influence as has been rendered by this type of testing and research work has been an instrumental factor in attaining the high degree of standardization which exists in the lamp industry, without which standardization it is doubtful if the present low prices for lamps could ever have been attained.

We believe any manufacturer can be considered fortunate to have the assistance of a well organized, thoroughgoing testing laboratory whose purpose is to check and recheck the findings of the manufacturers' engineers and to carry such tests into the field of usage as a regular means of appraising the value of innovations in product design, and in supervising manufacturing control of quality.

Philip Sporn (American Gas and Electric Service Corporation, New York, N. Y.): Mr. Millar's paper is altogether too brief a summary of the development of the incandescent lamp over the past fifty years, and particularly those engineering developments which have had a determining effect on the efficiency, reliability and economy of this great illuminant which has had such a tremendous effect on the development of what has come to be known as the modern world. It is particularly revealing to examine this development from the standpoint of efficiencies, cost, and use together with electric energy, to produce the electric light, and to find the enormous progress that has been made even in the last two decades not only to bring down the individual components but in combination to bring down the end product, that is, electric light. One cannot help but feel in reading this concentrated summary of Mr. Millar's that here is an outstanding example of a development made entirely under the advantages and handicaps, whatever they are, of the free enterprise system.

In that regard when so many of our citizens today are preaching the obsolescence of that system, and others are attracted to waves, of one kind or another, of the future, it is particularly worth while to examine table V cited by the author and compare the number of hours' work required to purchase an incandescent lamp in the United States in 1937 with the corresponding requirements in most of the countries of Europe. Some of these were at that time operating on a free enterprise basis, but a greater number was definitely restricted in its free enterprise or on an entire totalitarian basis. One must be forced to conclude after studying that table and similar figures, revealed in the original source cited by the author, for other items of living, that while the important components of the economic system, and the entire system, which produced these results in the United States may not be the very best from a social economic viewpoint and may have possibilities in it for much improvement in the future, no other system that has up to the present made its appearance on the scene of human society has as yet shown itself capable of coming anywhere as close to matching the results of this system of ours.

W. C. Kalb (National Carbon Company, Inc., Cleveland, Ohio): Mr. Millar brings out a fact of importance to manufacturers of electrical equipment of all types in the statement that "purchasing interest will stimulate producers to provide good quality while purchasing indifference will fail to bring such results." The progress in incandescent lamp production which Mr. Millar attributes in part to organized purchasing interest has a parallel in another field of illumination.

In one branch of the latter field there has been for many years organized demand for higher intensity and better quality of light, together with improved efficiency in light production. As a result, progress in this particular branch has been definitely more pronounced than in other branches of the same field. Charts of progress, recently prepared, show a striking resemblance to those presented in Mr. Millar's paper.

These observations suggest the thought that progress in other lines, where purchasing interest is not organized, might be stimulated by closer analysis of consumer needs on the part of the manufacturer.

E. M. Strong (Cornell University, Ithaca, N. Y.): Any one of the younger generation today who surveys the broad field of electrical engineering without benefit of history is unlikely to suspect that it all began with the development of the incandescent lamp.

Every school boy in the United States knows of Edison as the inventor of the incandescent lamp. He does not know that his contemporaries in other lands would differ with him in this particular but, what is more important, he is unaware that Edison's lamp is but symbolic of his larger contribution, the widespread distribution of electric power which contributes so largely to the better elements of our current civilization. Edison was not so much concerned with the incandescent lamp itself as he was with the larger project of making available, in the home, artificial light in an economically feasible abundance then unknown.

The subsequent years are eloquent testimony to Edison's practical wisdom in choosing and developing the incandescent principle as the proper vehicle for achieving his concept. Since the excitement which accompanied its successful introduction, the incandescent lamp has developed with notable absence of spectacular or revolutionary change. Nevertheless, over the years, its evolutionary development integrates into a remarkably impressive total.

The last decade has been marked by notable developments of a revolutionary character in the field of illuminants, which make signally appropriate some survey or "inventory" of the field of artificial illuminants with particular reference to the status of the incandescent lamp.

That Mr. Millar is uniquely qualified to perform this service for the profession, needs no emphasis for one in the field who reads his paper. We are indeed indebted to him for writing into the record so timely and well-balanced an account of the stewardship of industry for Edison's incandescent lamp.

In the heat of enthusiasm for that which is glamorously new it is especially important that we not mar its true value by injudicious application or utilization. I refer, at the moment of course, to the fluorescent lamp in particular. It is not appropriate here to discuss in detail the relative qualifications of fluorescent and incandescent lamps for specific applications or fields of application. In the main the two lamps are more complementary than competitive. It rests with the engineer to see to it that the development and application of the new be not marred and impeded by the public tendency toward misappropriation of his brain-children.

Measurements of Pre-Breakdown Currents in Dielectrics With a Cathode-Ray Tube

Discussion and author's closure of paper 41-96 by H. H. Race, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (August section), pages 854–8.

Herman Halperin (Commonwealth Edison Company, Chicago, Ill.): Doctor Race's data are of interest not only from a fundamental scientific standpoint but also from a practical standpoint. This applies especially to the results for number 5314 oil. The finding that pre-breakdown currents and breakdown stresses are greatly affected by the electrode surface is of special interest in connection with the recent use of conducting or semi-conducting layers adjacent to the electrodes of power cables.

That the breakdown stress seems to be little affected by the ionic conductivity is in agreement with observations on commercial oils where serious oxidation affected the conductivity, but not the breakdown strength in many cases.

In table I of the paper it is not made quite clear whether the second shot was obtained without change of oil or without repolishing of the electrode, or both.

With regard to the studies of the mechanism of conduction at high field stresses, in addition to the investigators referred to under item C3 of Doctor Race's paper, Dr. H. J. Plumley has investigated this problem in connection with studies done under the sponsorship of the Utilities Research Commission. His findings have been the subject of a recent paper in the *Physical Review* (volume 59, number 2, pages 200–07). Doctor Plumley's theory attempting to explain the current-voltage characteristics at high stresses is based on the assumption of ionic dissociation, but in contrast to Onsager and others he assumes that not polar impurities, but the molecules of the dielectric itself, become ionized.

It is of interest to compare figure 13 of Doctor Race's paper with Doctor Plumley's theory and test results for pure heptane. The theoretical slope according to Doctor Plumley's theory would be about 0.01 while the slope of his test results is about 0.015. It appears that Doctor Race's data obtained with the cathode ray oscillograph give a slope of roughly 0.01, while his data obtained with an FP54 amplifier give a slope of roughly 0.017.

Work such as done by Plumley and by Race may very well become of practical value, especially in connection with commercial insulation operated at very high stresses.

J. B. Whitehead (Johns Hopkins University, Baltimore, Md.): The increase of the conductivity of insulating liquids under high values of stress has been the subject of discussion for some time. It will be recalled that Baker and Boltz have proposed thermionic electron emission at the cathode as an explanation; Nikuradse proposes collision ionization; and more recently H. J. Plumley offers experimental evidence that the high stress conductivity is really electrolytic in character, and that, in fact, all insulating liquids have some inherent electrolytic dissociation which increases in the higher range of values of the applied stress.

Dr. Race's paper is interesting as showing that just before breakdown there is a relatively small increase in the pre-breakdown current and that the approach to breakdown is very rapid. From this he concludes that the breakdown is electronic rather than ionic in character. These results, therefore, seem to point away from collision ionization as a forerunner to breakdown. If, however, in accordance with Plumley, the high stress conductivity is electrolytic, it is probable that the ions present, though small in number, may still play a part in the accumulation of space charge concentration with resulting high local stress at the electrodes. From this point on it is easy to picture breakdown as electronic, as suggested by Dr. Race.

H. H. Race: In answer to the question in the third paragraph of Mr. Halperin's comments, the second shot was taken without either changing the oil or touching the electrode surface. Sufficient time was allowed to let the large gas bubbles rise to the surface of the oil. In the past we have repeatedly observed that the finely divided carbon resulting from a previous breakdown is swept out of the field by the motion of the oil long before breakdown occurs so that we attribute the changes in pre-breakdown currents to changes in the metal surface.

I agree with Dr. Whitehead's interpretation of Dr. Plumley's paper (*Physical Review*, volume 59, January 1941, page 200) that electrolytic ionization results in the intensification of electric gradients by space charge formation and thus may be a contributing factor in the final electronic breakdown.

Diode-Rectifying Circuits With Capacitance Filters

Discussion and author's closure of paper 41-105 by D. L. Waidelich, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1161–7.

F. E. Terman (Stanford University, Stanford University, Calif.): Several years ago we had occasion to make a study somewhat analogous to that reported by Professor Waidelich. We included the effect of leakage reactance of the transformer, and found that this reduced the ratio of peak to average amplitude of the current pulse passing through the tube, and rounded off this pulse, but did not alter greatly the fraction of the cycle during which current flowed.

We also did some experimental work at the time using mercury-vapor rectifier tubes. We found difficulty under certain conditions, however, because the ignition voltage of the tubes that we used was normally greater than the voltage drop under operating conditions. That is to say, it took more voltage across the tube to start the conduction than it did to maintain the flow of current thereafter, and with some tubes the difference was considerable. This resulted in transients being set up which were especially troublesome during light loads, and which sometimes caused one of the tubes to fail to operate at all for brief moments as evidenced by flickering of that tube.

It would be interesting to know if Professor Waidelich has encountered any of these experimental difficulties, or if he was more fortunate in the characteristics of the rectifier tubes he was working with.

Reuben Lee (Westinghouse Electric and Manufacturing Company, Baltimore, Md.):

In AIEE paper 41-105 (May 1941) D. L. Waidelich has written a valuable paper on "Diode-Rectifying Circuits With Capacitance Filters." Previous analyses have dealt only with the case in which diode internal resistance is negligible. In the cases of appreciable diode resistance, calculation of performance required extremely involved equations, and many designers avoided them by resorting to experiment. Waidelich has now made both of these alternatives unnecessary by the plotting of his results in curves which reduce the designer's task to one of ease. At least, such is true of the relation between a-c and d-c voltage, and of the angle of conduction β-α.

In view of this accomplishment, it might seem regrettable that curves for maximum tube current, inverse peak voltage and ripple voltage are given only for the negligible diode resistance case. But while the paper does not so state, these latter relations can be found readily to close approximations for other values of diode resistance. For example, Waidelich shows in Figure 2 tube current of approximately quarter-sine wave form over the angle β-α. The average of this wave over 360 degrees is $0.636(\beta-\alpha)/360$ times the peak value.

Whence $i_m = \dfrac{360I}{0.636(\beta-\alpha)}$

How close this value is to actual peak current depends upon the ratio R_L/R_R. Series resistance R_R effectively rounds off the top of the tube current wave, making it more nearly a half-sine wave over β-α, the average value of which is the same as for a quarter-sine wave. For much practical work, the approximation is within five per cent of actual value.

The inverse peak voltage E_p is closely given by E_m+IR_L when the ripple voltage is small, as it is in many cases.

Ripple voltage, as found from Figures 15 and 16 or from equation 6 is true within a few per cent for all cases where $\omega CR_R \leqq 1$. This would be true, for example, if $\omega CR_L =$ 50 or less and $R_L R_R = 50$ or more. Usually ripple-voltage accuracy is not so important as accuracy in d-c output voltage or peak-tube current. The values from Figures 15 and 16 or equation 6 are always higher than actual when diode resistance is not negligible.

D. L. Waidelich: Reuben Lee and F. E. Terman have both contributed interesting discussions on the subject of the paper.

Mr. Lee offers some helpful approximation methods for the calculation of maximum tube current, inverse peak voltage, and ripple voltage for certain values of the circuit parameters and tube resistance. The values of the above three quantities may be obtained from the angles β and α given in the paper, but the work is tedious, and for design use the results should be given in curve form. These quantities are given in the paper, however, for the case of zero tube drop while conducting, and a project to complete the work for any tube resistance is being carried on at the present time.

The effect of an ignition voltage greater than the conduction voltage for mercury vapor tubes as reported by Professor Terman was not observed during this study, but it may have been masked by the high a-c voltages employed at the input to the circuit. Oscillatory currents of relatively high frequency were observed, and transients such as these may have led to the troubles experienced by Professor Terman.

It is possible by the use of the results given in the paper to take account of the resistance of the transformer by including it with the tube resistance. The effect of leakage inductance must be considered in some other way, but the general effect of leakage reactance is to reduce the peak to average ratio of the tube current and to round off this current wave shape.

Analytical Methods of Solving Discrete Nonlinear Problems in Electrical Engineering

Discussion and author's closure of paper 41-107 by E. G. Keller, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1194–1200.

H. Poritsky (nonmember, General Electric Company, Schenectady, N. Y.): A great deal of general, sometimes rather vague, discussion of nonlinear problems has been going on recently, and it is gratifying to see an interesting paper like the present one which gets down to brass tacks and deals with explicit methods of solving nonlinear problems. I might as well confess that I had been stirred by intentions of writing a paper of a somewhat similar nature; therefore my former colleague's paper strikes a sympathetic chord in me.

The term "discrete" in the title makes one wonder at first what would be regarded as an "indiscrete" problem, until one discovers that by "discrete" is meant that *ordinary* rather than *partial* differential equations are referred to.

It is worth pointing out that Dr. von Kármán's recent paper, "The Engineer Grapples With Nonlinear Problems," which Dr. Keller describes as dealing primarily with nonlinear problems of continuous fields governed by *partial* differential equations, also contains a very illuminating discussion of several important problems in *ordinary* differential equations, as well as a good sized bibliography of this field.

As regards the first two methods of solution, they can both be grouped under the parameter method, the difference between them being merely the way in which the parameter enters. Indeed, if the functions f_4 occurring in the right-hand side of 13 reduce to zero, then equations 13 reduce essentially to the form 5; hence it follows that the first method is a special case of the second one.

The choice of the parameter r is an art in itself. Often no "natural" parameter presents itself, and it is advisable to introduce one artificially, for instance as a factor multiplying the "bothersome terms," that is, the terms whose absence would leave the differential equation soluble. When r is introduced artificially as a factor in this way, it is eventually eliminated by putting it equal to 1.

The parameter method consists in expanding the solution in powers of r. When these power series are substituted in the original differential equations with the parameter, themselves expanded in powers of r, and coefficients of similar powers of r equated on both sides, there result successive differential equations for the successive coefficients. The first equation must agree with the original equation in which r has been equated to zero, and should by hypothesis be soluble. The further equations turn out to involve one new function at a time and likewise should be soluble. If this is not the case then the choice of the parameter has not been a successful one. That the parameter can always be introduced so that the various differential equations are soluble at least for one or two stages may be seen from the fact that it can be introduced as a factor multiplying the right-hand members of 3 or 4. In the astronomical problem of motion of several planets (and the corresponding now old-fashioned Bohr theory of the atom) the parameter is often introduced as a factor in the interaction terms of the planets (or the electrons). Thus for $r=0$ each planet moves as if it were attracted only by the sun. The correction terms then correspond to the perturbation caused by the interaction of the planets. Very often the parameter r is chosen so as to leave a linear system for $r=0$.

The analytical existence theorems show that the series in powers of r converge for sufficiently small numerical values of r, but the estimate of what is sufficiently small may not be good enough for the problem at hand. Thus, as is usually the case in practical solution, what determines whether or not enough steps have been taken is whether the last term may be considered to be small for the desired accuracy, and more generally, whether the patience of the computer has not been exhausted to the breaking point.

The method of variation of parameters, which is well-explained in Dr. Keller's paper, might perhaps be even easier to understand if the reference to celestial mechanics were explained at greater length. In that field, it will be recalled, the orbit of a planet revolving around the sun is specified in terms of several parameters such as the eccentricity, the major axis of the elliptical path, and the orientation of the plane of the ellipse and the major axis in space. When interactions of other planets are included, resulting in a difficult nonlinear problem, it is customary to regard the perturbed motion as still taking place in an elliptic orbit but with slowly varying parameters. This is equivalent to changing from the original cartesian co-ordinates, in terms of which the motion is first described, to parameters specifying the osculating elliptical orbit. Needless to say, in general the method of variation of parameters is awkward to carry out.

As regards the hyperelliptic method, it is not clear to this reviewer from the example treated in section 4 just what this method is. This example is apparently worked out by the method of parameters along with several notions regarding the periodicity of the desired solution. There is nothing "hyperelliptic" about either of these two features illustrated in the example. The term "hyperelliptic" is commonly applied to integrals of the form $\int R[P^{1/2}, x]\, dx$ where P is a polynomial in x of degree 5 or higher, and R is a rational function of its two variables. Such an integral occurs in integrating the equation of motion $\ddot{x}=P'(x)$, where $P'(x)$ represents the force of a nonlinear spring. Indeed the first integration of the equation of motion leads to $x=[2P(x)]^{1/2}$ whence separation of variables and further integration results in $t=\int(2P)^{-1/2}dx$. However, this method of integration in general breaks down for nonlinear problems as soon as the number of degrees of freedom rises beyond 1. Therefore the example illustrating this method in section 4 could, in this reviewer's opinion, be omitted without harm and replaced by a description of just what the author had in mind.

Passing on to the method of treating nonlinear integral equations, the uninitiated would probably be scared by the mere appearance of these equations. For his benefit may it be said that differential equations may easily be converted into integral equations; in fact, the example given by Dr. Keller is derived from a differential equation. The method of solution outlined may be described as a method of successive substitutions. It is similar to the parameter method (say if the parameter were introduced as a factor of the right-hand integrals in (41)), yet in general it is not equivalent to it. In this reviewer's opinion, integral equations, particularly nonlinear integral equations, have not occurred sufficiently frequently in electrical engineering applications and their discussion could still be properly left best to the privacy of mathematical experts.

As regards the last method, the method of Galerkin, while an example in it is given, the logic of this method is not exactly clear from this example. What this method consists in at bottom is in choosing a solution involving only a finite number of arbitrary parameters, for instance a polynomial in time (this is the case in the example treated), then, finding that it is impossible to satisfy the original differential equation, trying to satisfy it as nearly as possible by minimizing the error. To obtain this error let ϵ be the result of substituting the assumed solution in the differential equation after all its terms have been transposed on the left-hand side; the error may then be measured by the integral of the square of ϵ over the interval in question.

Very often the solution of even *linear* differential equations is by itself a difficult matter. The various methods illustrated, of course, apply to linear systems too, and in introducing them it is perhaps not improper to illustrate their use on linear systems. With this in mind, and hoping that the readers will excuse the highly elementary nature of the following example, consider the first order, yea even linear, differential equation

$$\frac{dy}{dt}=ry, \quad y=1 \text{ at } t=0$$

What does the parameter method look like in this case? Assuming an expansion of y in powers of the parameter r, it turns out that the various powers of r yield the successive terms of the expansion of the exponential solution

$$y=e^{rt}=1+rt+r^2t^2/2!+\ldots$$

in powers of t. This means that in the present case the expansions in powers of the parameter are completely equivalent to the expansion in powers of the variable itself. The method of solution which consists in expanding the solution in powers of the variable itself, is perhaps the oldest of all the methods of solution and presumably has not been included by Dr. Keller because it is too elementary, or possibly because it does not converge rapidly enough. The present example shows that, at least in some cases, its convergence is no better or worse than the convergence of the parameter method.

Incidentally, the most thorough application of the parameter method has been to *linear* differential equations with periodic coefficients. The equations arise often in engineering and are fully as bothersome as nonlinear problems.

One often runs into the question of stability or instability of solutions of differential equations of the form

$$\frac{dx_i}{dt}=f_i(x_j)$$

near a singular point at which all the fs vanish. Here a proper linear system can be used to advantage in discussing the nature of the singular points and the resulting stability. A brief and very readable exposition of the second order case may be found in von Kármán's and Biot's book, "Mathematical Methods in Engineering," pages 150–7. (It is surprising, in fact, that no reference to this text has been made in the bibliography.) Thus at least in this case a real analytical aid exists, whose application may save a great deal of labor.

It has apparently been the author's intention to comfort the electrical engineer by means of examples chosen from his domain. The nontechnical reader should be cautioned however, against using the examples away from their context. Thus equation 22 has been called "the equation of hunting"; it is perhaps more correctly an equation of pulling into step of a synchronous machine.

The bibliography is one of the most valuable parts of the paper. Yet it seems to be aimed at the mathematical expert, as the average engineer would find most of the references forbiddingly difficult reading.

The reader is reminded that in addition to various analytical methods there are, of course, well known all-powerful numerical methods available for solving differential equations, these methods applying equally well to nonlinear as well as linear problems.

In conclusion it appears that the differential equations of electrical engineering are soluble by the same general methods that have been developed for treating differential equations of other domains—dynamics, celestial mechanics, and other fields. It is to be hoped that the electrical engineer to whom this paper is addressed will not be completely discouraged by the apparent complexity of the various methods so as to desert analytical methods altogether and revert entirely to numerical methods and the use of the differential analyzer.

Ernst Weber (Polytechnic Institute of Brooklyn, Brooklyn, N. Y.): Though any engineering problem, if somewhat rigorously formulated, leads to nonlinear differential or integral equations, it has been customary to introduce sufficient simplifying assumptions in order to arrive, preferably, at linear differential equations for which fairly exhaustive mathematical methods of solution are available. The solutions of the nonlinear relations, as desirable as they may seem in many cases, are usually left to professional mathematicians because of the strenuous requirements with respect to the selection of attack, the tediousness of even the most opportune method, and the danger of losing contact with the physical interpretation of the successive steps.

In order to stimulate a greater interest, at least among electrical engineers, in the promotion and more extensive use of advanced methods, the committee on basic sciences sponsored a conference on, "Principles of Nonlinear Analysis," which was held at the summer convention in Swampscott, June 1940. Four different methods were presented and discussed: namely, graphical, numerical, machine, and analytical ways of solving nonlinear problems. The excellent response of an interested audience caused Professor Keller to give us the benefit of his studies by preparing this formal paper. Its particular value lies in the logical presentation of the most powerful analytical methods supported by important practical applications, and in the clear emphasis on the essential phases of each method; so that a decision can easily be made in the selection of the most suitable method in a special case. Extremely valuable is also the extensive bibliography, in its arrangement according to theory and applications; and the helpful subdivisions in each field. It may be hoped that the leadership expressed in the publication of this basic paper in the field of applied mathematics, will bring us other important contributions; since fundamental progress in engineering is very intimately connected with a broad background and a far-reaching appreciation of the basic sciences.

E. G. Keller: The author wishes to express his deep appreciation to Drs. H. Poritsky and Ernst Weber for their splendid discussions of the present paper. With the two following exceptions there is nothing to be added which would not detract from their clarifying discussions. References to a noteworthy paper "Operational Methods in Nonlinear Problems" by Dr. Louis Pipes and to the well-known text "Mathematical Methods in Engineering" by Th. von Kármán and A. Biot (McGraw-Hill Book Co., New York) have been added to the bibliography.

Current Rating and Life of Cold-Cathode Tubes

Discussion of paper 41-117 by G. H. Rockwood, presented at the AIEE summer convention, Toronto, Ontario, Can., June 16–20, 1941, and published in AIEE TRANSACTIONS, 1941 (September section), pages 901–03.

P. L. Alger (General Electric Company, Schenectady, N. Y.): This paper is both timely and useful, because it gives valuable information on the life expectancy and proper rating methods for cold cathode tubes, and because this information is helpful in connection with the study of rating methods for other types of apparatus.

Most electrical apparatus has temperature limits that are set by the rate of deterioration of the organic insulation, which follows the approximate rule that the life of the insulation is halved for each 8 degree to 12 degree centigrade increase in temperature. Apparently the life-current relationship for a cold cathode tube can not be expressed by any such simple logarithmic law. It will be interesting, however, to know whether tests made at different ambient temperatures with a given current would show a reduction in life expectancy with increase in temperature, similar to that for insulation.

It seems to me very important to give further study to this general subject of life-output and temperature laws for different types of apparatus, since only by such knowledge will it be possible to design thoroughly coordinated and economical systems involving a variety of types of equipment.

Whatever the type of life expectancy law, we may be sure that with every type of apparatus the life will be shorter the greater the load that is put upon it. On this basis, it seems desirable to use a rating system in which the nameplate tells the safe value of sustained load that can be carried on a typical short time application, and then to indicate the permissible load that will insure an indefinite life by a service factor or multiplier applied to the nameplate rating. From this point of view, a satisfactory way to rate these cold cathode tubes when used in intermittent duty, should be to make the nameplate rating equal to the current that would give a safe life expectancy of say 100 hours, and also give on the nameplate a service factor which would indicate the current corresponding to a safe life expectancy of 10,000 hours or more.

R. E. Hellmund (Westinghouse Electric and Manufacturing Company, Schenectady, N. Y.): The presentation of this paper is very timely and it should be of considerable assistance to the subcommittee on conduction in vacuum and low-pressure gases and vapors recently organized by standards coordinating committee 7. This subcommittee of course realizes that there are many factors involved in any basic standardization of electronic devices and considerable time will no doubt be consumed before much of the work is completed.

The basis for the standardization of the tubes discussed in this paper is, of course, quite different from the conventional considerations of the past in the standardization of machines and other electro-magnetic apparatus. However, there are some similarities in so far as the influence of time together with temperature is now receiving attention in machine standards. During the early stages of the standardization of machines it was the general belief among engineers that if certain temperatures were exceeded for even short periods it would be detrimental to the insulation of the machine. Railway engineers, confronted with severe space and weight limitations, first exceeded the conventional temperature limits, expecting, however, very short life as a result. Considerable trouble actually was experienced and frequent re-winding was necessary, but this probably was caused by improper methods of applying and supporting the insulation to a greater extent than by its being roasted. Somewhat later, higher temperatures were used in some cases for short-time ratings, but only during the last few years has it been generally recognized that insulation life is affected not by high temperatures alone but to an appreciable extent by the length of time high temperatures prevail. It is only very recently, however, that this basic principle has been fully recognized in a standard (No. 1-A) under preparation by standards coordinating committee 4. Since electro-magnetic machines have been in commercial use for more than sixty years, we have been a long time in arriving at standards recognizing the influence of time and temperature upon the life of a machine. However, the standardization of electronic devices, in spite of its complexity, will not take such a long time, because, in contrast to the early practices in machine design, the electronic groups have the benefit of well organized research activities and scientific methods of attack, a good example of which is the present paper.

The Recovery-Voltage Analyzer for Determination of Circuit Recovery Characteristics

Discussion of paper 41-145 by G. W. Dunlap, presented at the AIEE Pacific Coast convention, Yellowstone National Park, August 27–29, 1941, and published in AIEE TRANSACTIONS, 1941 (November section), pages 958–62.

W. F. Skeats (General Electric Company, Philadelphia, Pa.): The engineer has in general two ways of determining the magnitude of quantities in which he is interested. He may measure, or he may calculate. For the determination of individual values, the most reliable figures are usually those obtained by full scale measurement. When one wishes to obtain enough values to acquire perspective, however, to see the effect of the variables involved, or to survey a field, this method may require so much time and expense as to be wholly impractical. In such cases, calculations often serve well, but in some cases, on account of their complexity or the difficulty of obtaining the data on which to base them, they become impractical or uncertain. In many such cases, measurements on small scale apparatus or measurements of a small scale simulation of the actual event may be very helpful. Quite often it happens that a combination of two or three of these methods of attack yields results far surpassing what can be obtained from any one of them.

The subject of Dr. Dunlap's paper is an apt example of the last situation. Here the acquisition by full-scale circuit breaker tests of sufficient information for reliable generalization would be hopelessly time-consuming and expensive. Calculations of the recovery voltage characteristic can generally be made, but they often require simplifying assumptions and sometimes involve uncertainty of data. While the equipment described by Dr. Dunlap does involve the inconvenience of deënergizing the circuit to be tested, it is hoped that it will be found possible to make sufficient application of it to confirm conclusions based on calculation.

Self-Excitation of Induction Motors With Series Capacitors

Discussion and author's closure of paper 41-139 by C. F. Wagner, presented at the AIEE Pacific Coast convention, Yellowstone National Park, August 27–29, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1241–7.

C. Concordia and **J. W. Butler** (General Electric Company, Schenectady, N. Y.): In previous discussions of the possible self-excitation of induction motors when their supply line reactance is compensated with series capacitance, we have based the specification of conditions under which self-excitation may arise, and also the specification of the proper corrective means (if necessary), on the operating condition, that is, on normal motor speed and load. It was recognized (see reference 1, page 981 and figure 11) that at low motor speeds, as during starting, an unstable range as shown in figure 4 of the paper might have to be traversed, but it was concluded that with normal starting conditions, this region could safely be tolerated. We would be interested in learning Mr. Wagner's experience which leads him to stress the low speed condition.

We wonder also why Mr. Wagner did not pursue further the method which we have found so successful and which he has briefly mentioned in appendix I. It has always seemed to us that a proper theory should be more or less self-sufficient, that is, it should not depend on knowledge of the answer in order to obtain it. It is believed that a defect of the explanation and method as given in the paper is that it does not really get to the root of the matter and discover the fundamental reason for self-excitation. Even though performance can be calculated under many conditions, it remains essentially an empirical method, unless the self-excitation evidences itself directly in the formulae developed. The direct, physical, simple, and rational method of merely writing down the differential equations of the system and then testing them directly to see if the system is stable or unstable has always appealed to us, and we cannot sympathize with the effort to avoid the differential equation at all costs, even at the cost of trying to obtain from the steady-state equations evidence of an instability, the real determining factors of which have inherently been left out.

For instance, equations 10 and 11 in Mr. Wagner's paper show that instability exists in the region $f^2X_b < X_c < f^2X_M$. In this region the circuit is unstable, but it is not necessarily stable outside of this region. Referring to figure 10 of the Butler and Concordia paper (reference 1) it is seen that an unstable region exists for values of $X_c < f^2 X_B$, and curiously enough, this is the region where most series capacitor applications seem to fall. The intersections of the dotted curve on the X_c axis are the limits defined by Mr. Wagner—and it can be seen that an unstable region exists for X_c lower than 0.4, which is the $f^2 X_B$ point, for $r = 0$. Mr. Wagner's equations 10 and 11 define the regions that are surely unstable, and what we would usually like to know when applying series capacitors are the regions that are surely stable. And the steady-state equations cannot give us this as the real determining factors have been left out, as mentioned above.

C. F. Wagner: The discussion by Messrs. Concordia and Butler being the only written discussion, the following remarks are directed in reply to it. Emphasis was placed by the author upon the starting condition because such condition was one of the few cases with which trouble was experienced. This treatment also served to illustrate and verify fundamentals involved in the problem.

The author did not pursue the method of Concordia and Butler, first, because it appeared more complicated than other methods and, second, because it was incomplete. Any problem involving spontaneous oscillations can be solved by either of two methods. First, since the oscillations are sustained, steady state solutions can be used and the conditions determined for which both the resistance and reactance are equal to zero. Second, the differential equations governing the problem can be set up and the roots of the auxiliary equation obtained. These roots determine the free oscillations of the circuit, the imaginary part fixing the frequency and the real part the time constant. The conditions for which the real part of one or more roots is equal to zero determine the limits for which the circuit becomes self-exciting. Both solutions are equally exact. Messrs. Concordia and Butler preferred the latter, and the author the former except for the development in the appendix. This choice was made because of the simplicity of the attack and because the physical processes involved are more apparent. The relative simplicity is apparent by comparing the type of solution resulting from solving either equation 6 or 7 of reference 1, and the type of solution obtained by solving simultaneously equations 10 and 11 of the paper.

Messrs. Concordia and Butler labor under the impression that the author's solution is approximate. They state in referring to figure 10 of reference 1 that the "intersections of the dotted curve on the X_c axis are the limits defined by Mr. Wagner." Such statement and the remainder of the discussion in their last paragraph indicate an utter lack of understanding of the method. The f used in the paper refers to the frequency of the resonating currents. In using equations 10 and 11 to compute a curve such as figure 10 of reference 1, it will be found that for small values of X_c, f likewise becomes small and a curve such as the full line will be obtained.

A further distinct advantage of the author's approach lies in the retention of the conception of the physical processes involved. For example, the purely mathematical approach indicates that both the lower and the upper resonant speeds of figure 3 constitute boundaries between stable and unstable operation. The mathematics shows that between these limits the resonating currents tend to increase and above the upper speed and below the lower speed the currents tend to decrease. Actually, however, as shown in the paper, only the lower speed is a stable operating point. The power fed into the resonating circuit is dependent only upon the ability of the 60-cycle circuit characteristics of the motor to feed power at this speed. This is at complete variance with the statement appearing on page 980 of reference 1 which reads, "This low-frequency current is limited only by the impedance of the supply circuit at the low frequency, and may reach relatively large values," and on page 982 which reads, "the current builds up until the circuit constants change to a value that will not permit further excitation."

The lack of consideration of the speed torque influence in the stability criterion leads to further errors. If a particular set of motor characteristics is assumed and the series capacitor varied, then, as the reactance of the series capacitor increases, the frequency curves shown in the lower part of figure 3 move upward and their maximum abscissa decreases. The speed curves are affected similarly. For speeds near synchronous it will be seen that points on the speed curve occur on the dotted portion of the curves until larger values of series capacitors are used. In terms of figure 10 of reference 1, this implies that portions of the curve to the left of the maximum resistance are unstable.

Messrs. Concordia and Butler have not disagreed with the author's statement regarding instability at the upper resonant speed. In view of the voluminous criticism of other points, the lack of criticism of this implies approval and acknowledgment of the omission of a real factor in their analysis. Rather than the author omitting "real determining factors," it appears as though the analysis by Messrs. Concordia and Butler does just that.

The author is at a loss to understand the discussers' statement that "a proper theory should be more or less self-sufficient, that is, it should not depend on knowledge of the answer in order to obtain it." Perhaps this is further evidence of their lack of understanding of the paper.

Lightning Strokes in Field and Laboratory—III

Discussion and author's closure of paper 41-141 by P. L. Bellaschi, presented at the AIEE Pacific Coast convention, Yellowstone National Park, August 27–29, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1248–56.

R. C. Mason (Westinghouse Research Laboratories, East Pittsburgh, Pa.): Since the electrical processes of the electric arc are intimately connected with the energy input to the arc electrodes, the "heat balance" at the electrode has long been of interest to physicists studying gas discharges. The subject is equally vital to welding engineers who are concerned with melting rates of electrodes. In this paper, Mr. Bellaschi has shown how important information about lightning discharge can be gained from the study of the terminals of the discharge. His contribution can rest solely on the correlation of field and laboratory data, on empirical calibration established by observation of effects produced by currents of known duration and magnitude; but what is its relation to the theory of the arc? The theory of the arc is still so incomplete that instead of one attempting to predict from theory what Mr. Bellaschi should have observed, it is much more to the point to ask what light does his result show on still obscure questions?

The proportionality of metal fused to electrical charge suggests that very probably the current density at electrodes was approximately constant for the arcs studied by Mr. Bellaschi. Further, his work indicates equal heat inputs to cathode and anode, of about six watts per ampere.

Although heat may be given up to the electrodes by the hot gas of the arc column, both by thermal conduction and by recombination of dissociated atoms, it seems certain that this mechanism is of much less importance than direct electrical means. At the cathode, current is carried both by positive ions arriving at the cathode from the gas phase, and by electrons leaving the cathode metal. The positive ions impart to the cathode the energy they have gained from the cathode fall of potential, plus a certain experimentally undetermined heat of condensation. In some arcs, known as "thermionic arcs," the electrons are emitted by virtue of the high temperature of the cathode, and in these the electrons leaving the cathode cool the metal by a definite amount, the electron "work function" of the metal. In other arcs, of which the copper arc is believed to be one, known as "high field arcs," electrons are emitted because of an extremely high electric field at the cathode. In the latter case the electron emission actually heats the cathode slightly. Thus the uncertainty of cathode fall, positive ion heat of condensation, type of cathode mechanism, and, above all, of the fraction of the current carried by electrons and the fraction by positive ions, makes an exact determination of the heat balance at the cathode impossible. The observed figure of six watts per ampere can hardly be obtained, however, unless $^1/_4$ to $^1/_3$ the cathode current is positive ion current.

At the anode, current is carried only by electrons flowing from gas to metal, so the heating effect is simply the energy of electrons in the positive column, plus that gained from any anode fall which may exist, plus the latent heat of condensation of the electrons. The last is a little over four watts per ampere for copper, while the average energy of electrons in the positive column is not much more than one watt per ampere. The observed six watts per ampere thus leave scarcely any to be attributed to anode fall. Indeed it may be possible that a practically zero anode fall may have existed for these arcs. The only factors neglected have been the thermal conduction *to* the anode, and loss of heat *from* the anode by vaporization of anode material; it appears probable that neither of these is large compared to the factors actually considered.

P. L. Bellaschi: The discussion Dr. Mason presents on the theoretical considerations of the electric arc is interesting indeed, for it emphatically shows the practical difficulty in attempting to determine the relation between the fusion at the electrode and the electrical quantities from a purely theoretical approach. It is clear throughout the paper that the investigation, the correlation between field data and the laboratory results, and the conclusions rest entirely on an experimental basis. The usefulness of the findings in other connections, such as pointed out by Dr. Mason, is apparent.

High-Voltage D-C Flashover of Solid Insulators in Compressed Nitrogen

Discussion and author's closure of paper 41-146 by John G. Trump and James Andrias, presented at the AIEE Pacific Coast convention, Yellowstone National Park, August 27–29, 1941, and published in AIEE TRANSACTIONS, 1941 (November section), pages 986–90.

Henry M. Hobart (retired, General Electric Company, Schenectady, N. Y.): It is noted that the authors deal exclusively with d-c flashovers. The flashover strengths over the surface of corrugated cylinders of $^{1}/_{2}$ inch height, fitted between electrodes in dry-nitrogen at a pressure of 200 pounds per square inch are:

For Lucite,	550 volts per mil of height
For Textolite	340 volts per mil of height
For Isolantite	260 volts per mil of height

For a $^{1}/_{2}$ inch spacing in dry nitrogen at 200 pounds per sq inch, the value of the gradient at breakdown of the nitrogen is seen from figure 4 of the paper, to be about 800 volts per mil.

It would be much appreciated by the writer if he could have the advantage of the comments and suggestions of the authors with respect to an important case which is analogous, except that instead of employing d-c, the stresses are 60-cycle a-c.

All will agree that for instantaneous and short-time breakdown tests of solid insulating materials, the volts per mil through the mass, which can be withstood, will, speaking broadly, usually be of much the same order of magnitude for a-c as for d-c. But when the duration of the application of the stress is extended to hours, days, weeks, and years, the solid material ultimately fails with a-c stresses which are of but a small fraction of the magnitude of the d-c breakdown stresses. For example, an underground cable with solid-filled paper insulation of 1 inch radial thickness interposed between a 1 inch-diameter conductor and an outer lead sheath, could be employed in service for many years with a d-c stress of 500 kv between the copper conductor and the lead covering, the average stress thus being 500 volts per mil. But for a-c service, such a cable would fail inside of a very few years if subjected continuously to a 60-cycle stress of as little as 100 volts per mil.

The writer has considered that the insulating supports and spacers in a 60-cycle compressed-gas underground cable of such a design as shown in the accompanying sketch, would not be adequate for their purpose unless the total distance through the interposed solid insulating material amounts to several feet rather than a couple of inches (which is all that would be necessary so far as relates to the compressed gas itself). Also, since the path through the mass of the solid insulation is so crooked, and in other respects so unfavorably proportioned, there would be severe stress concentrations.

For a 345-kv three-phase transmission system, with a separate pipe for each of the three conductors, there would be a 60-cycle stress of 200 rms kv between the outer surface of the conductor and the inner surface of the pipe in which it is enclosed. The compression may appropriately be 68 absolute atmospheres, and it is evident that the radial thickness of compressed-gas shown in the sketch is liberal so far as relates to the gas alone. For this hypothetical case, would the authors, on the basis of their experience with solid insulating supports in compressed gas, consider that it would be sufficient to have a lateral spacing of some three feet between the porcelain rings *A* and *B*? This provides an average stress of 5 volts per mil through the mass of the solid insulation. Do the authors consider that the stress concentrations in this approximately 40 inch-long dielectric path would be liable to occasion stresses of more than some 50 volts per mil at any of the places where the concentrations are greatest?

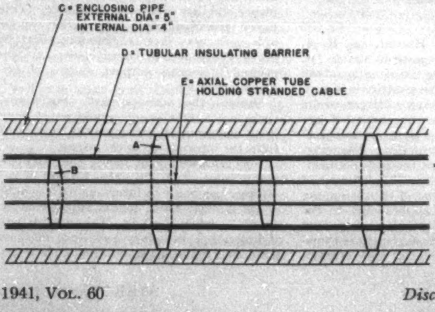

Figure 1. High-voltage pipe-enclosed underground conductor with compressed gas insulation

The design shown in the sketch is only one of several good alternatives which could be employed. Taking into account (1) insulation strength, (2) dielectric constant, (3) mechanical strength, (4) cost, and (5) freedom from all forms of aging (especially on the surfaces), would the authors express an opinion (based on the experience gained by them in the course of the valuable research which they have described in their paper), as to the best insulating materials to employ for *A*, *B*, and *D*?

The results set forth in their paper are very reassuring as regards d-c applications for compressed gas insulation. But the writer's present interest is particularly with the 60-cycle transmission of large amounts of power to great distances. His project includes the provision of large compressed-gas power transformers, and the data in the paper are also of interest in that connection. The power transformers will be entered from the compressed-gas underground line through pipe connections into the transformer tank, thus avoiding the need for the very expensive high-voltage bushings of present practice. Lightning cannot readily enter the underground line. Any surge gaining access to the underground line is gradually attenuated in the course of its journey, and the transformer will require little or no shielding and hence will cost less than a transformer connected directly to an overhead transmission system. Its size and cost will also be decreased because the temperature rise may exceed the limits imposed by sludging in oil transformers.

The writer wishes to take this occasion to express his indebtedness and thanks to the authors of this paper for their fine research work on the fundamental principles underlying the use of compressed gases as insulation. There is need for many more such fundamental researches in this important field.

John G. Trump: Since the flashover studies reported in this paper were for constant potentials applied under nearly ideal conditions and in a uniform field, it is difficult to use these data to comment quantitatively on the 60-cycle transmission line design which Mr. Hobart discloses. From general considerations, however, it would appear that the lateral spacing of three feet between the porcelain rings *A* and *B* is sufficient from the point of view of average gradient along the length, but that difficulties will arise because of the electrical dissymmetry in the regions between the porcelain rings and the tubular barrier and between the rings and the inner and outer conductors. I should expect that, with the dimensions used and at the voltage contemplated, the electric field concentrations in these regions would be sufficient to cause ionization, space-charge accumulations on the barrier, and final breakdown. While Mr. Hobart's method of supporting the central conductor is quite ingenious, I would be inclined to use a single corrugated insulated ring to support the inner conductor, thereby sacrificing compactness for simplicity. Perhaps the best material for such a ring would be hard glass rather than porcelain, since this will exhibit considerably higher dielectric strength through the volume.

Mr. Hobart's generous comments are much appreciated.

An Analysis of Transient and Sustained Voltages in Ground-Fault Neutralizer Systems

Discussion and authors' closure of paper 41-148 by S. B. Farnham, E. M. Hunter, and H. A. Peterson, presented at the AIEE Pacific Coast convention, Yellowstone National Park August 27–29, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1257–66.

Eric T. B. Gross (College of the City of New York, N. Y.): It seems worthwhile to mention that the miniature system study proves the results of previous investigations in which both the effects of unbalanced capacitances-to-ground of the systems[1] and those of the saturation of the coils were fully analyzed.[2] It is of historic interest that even the first coil put into service (1917, in Europe) was a saturable iron core reactor and no other type has ever been used abroad.

As in all cases of resonant circuits, the losses of the various elements of the circuit play an important role and must not be neglected; as the in-phase component of the fault current in a compensated network lies between about 5 per cent and 15 per cent of the charging current to ground, the influence of the losses is considerable. In the previous investigations mentioned, the losses were not neglected.[3] Jonas showed[1] how the resonance voltage was limited by the losses and the late H. Gruenholz gave a very ingenious solution for the influence of both saturation and losses.[3] Small unbalances of the capacitances to ground of the system are completely harmless,[4] and because of this earth fault coils are applicable in systems where relatively short line sections consist of only two conductors connected to two of the three phases. No dangerous resonant overvoltages will occur under such conditions even if the earth fault coils are only slightly saturated; for various reasons, it is advisable to choose the factor K not exceeding about 1.6.

Concerning the "Effect of Bus Capacitance" and the suppression of overvoltages due to switching in the single line case,[5] I would refer to a previous discussion.[6] Then it was said that this is the only case in which dangerous transient overvoltages can be induced by the coil, however the installation of a modern-type arrester-by-pass reduces all overvoltages to harmless values.

In connection with the chapter, "Switching Off Neutralizers," and conclusion 3, we know from theoretical considerations and practical experience with more than 2,000 coils abroad that there is no difference to speak of between self-extinction of arcs-to-ground with the coil out of tune in the one or other direction, that is, coil reactance higher or lower than the tuned value. Ten per cent undercompensation is a very distant approach to the condition of isolated neutral operation; the frequency of the oscillation after arc extinction is only about 5 per cent different from the tuned condition and because of this the extinguishing action of the coil is of very slight difference from the case with exact tuning. Of course, arc extinction with the coil 10 per cent (plus or minus) out of tune is better than with ±25 per cent; however, both values, plus *and* minus, are valid if one of them, plus *or* minus, is permissible. Advisable limits for the adjustment of the coils are about ±25 per cent in the case of operating voltages up to 30 kv, about ±20 per cent in operating voltages up to 60 per cent and ±10 per cent with higher operating voltages. It is well known too and recognized by all operating companies really using fault coils that such out-of-tune conditions do not hinder the self-extinction of arcs-to-ground, and it is for this reason that earth fault coils do not offer any difficulties to system operation even in systems where growth and development is experienced and where system switching may change from day to day, or week to week. In a number of cases abroad, it has been the successful practice for many years to keep the coils somewhat undercompensating if all the line sections were switched in, and in this way extinguishing conditions were procured even if larger sections were temporarily switched off. It is a long and well established fact that not the amount of the remaining current at the point of the ground but the degree of unbalance is responsible for the self-extinction of arcs-to-ground.[7]

S. B. Farnham, E. M. Hunter, and **H. A. Peterson:** The authors wish to thank Dr. Gross for again directing the attention of the institute to the European practice in regard to ground-fault neutralizers. His comments in general substantiate the results of our study, and, for the most part, are in agreement with American practice. Nevertheless, several points merit further comment.

1. The statement, "Small unbalances of the capacitance to ground of the system are completely harmless," applies only to the arc-extinguishing ability of the ground fault neutralizer. This statement is by no means true from the point of view of practical system operation, since it is well recognized that in a ground-fault neutralizer system any appreciable unbalance of the system capacitance to ground produces substantial inequality among the three line-to-ground voltages and causes continuous circulating currents. The resulting adverse effects on adjacent power and communication circuits, as well as metering and relaying difficulties, may make this a troublesome operating problem. The practical limit to capacitance unbalance is roughly one per cent, and line transpositions or other balancing means must be resorted to if this figure is exceeded.

2. With reference to the section, "Switching Off Neutralizers," and conclusion 3 of our paper, it is unfortunate that Dr. Gross has overlooked the significant feature of this part of our study. The question is not whether successful arc extinction can be obtained with the neutralizer somewhat out of tune: we know from experience that under favorable conditions, the arc has been extinguished with the neutralizer 30 per cent out of tune. The essential point is that saturation of the neutralizer is very effective in preventing overvoltages, and if the neutralizer is initially out of tune in the direction of undercompensation, then this beneficial effect of saturation cannot be realized. With the remotely controllable tap changing switches being furnished in modern ground-fault neutralizers, there is little reason why correct tuning should not be maintained.

Criteria for Neutral Stability of Wye-Grounded-Primary Broken-Delta-Secondary Transformer Circuits

Discussion and authors' closure of paper 41-147 by H. S. Shott and H. A. Peterson, presented at the AIEE Pacific Coast convention, Yellowstone National Park, August 27–29, 1941, and published in AIEE TRANSACTIONS, 1941 (November section), pages 997–1002.

A. T. Sinks (General Electric Company, Lynn, Mass.): This paper covers a subject which, although infrequently a source of trouble, can be a considerable nuisance at times, particularly when there is reason to believe that instability may exist and a knowledge of what to do and how much to insure stability is also not available. This paper gives sufficient information to be able with very little engineering effort to apply Y-connected transformers on ungrounded systems without danger of unstable operation.

Besides the authors' own conclusions, there are a number of corollaries of very great and practical value that can be derived from the information in the paper.

For instance, it is shown that for the worst value of X_{co}/X_m the amount of resistance per phase to insure stability is only $^1/_7$ of X_m for $E=1$, and is approximately $^1/_3$ of X_m when $E=0.58$. This means that if individual secondary resistance burdens are connected to the transformers, the watts that have to be dissipated in the resistors and supplied by the transformers are about seven times the magnetizing volt amperes of the transformer at rated voltage. In many designs of potential transformers such a burden would considerably exceed the rating of the transformer. On the other hand, if line-to-line transformers are connected in Y so that $E=0.58$, the watts in the individual burdens would be only $\left[3\times\frac{1}{(\sqrt{3})^2}=1\right]$ times the magnetizing volt amperes. Consequently it is a simple rule to remember that if line-to-line rated potential transformers are connected in Y on a system of the same voltage rating, the amount of watts per phase in the resistance burden necessary to insure stability under any conditions is equal to the magnetizing volt amperes with rated voltage on the winding. If one wants to be sure of stable operations under any conditions without providing stabilizing impedances, it is necessary to use the value of $E=0.2$ or less, which would mean poor performance from the potential transformers with respect to accuracy, besides a much over-rated transformer. It would, therefore, appear that the practice of using line-to-line rated potential transformers connected in Y on systems of the same rating, whether arrived at by accident or good judgment, is nevertheless a reasonable procedure.

In discussing the watts or volt amperes necessary for stabilizing the Y-connected transformers under the worst conditions, it should be noted that if the transformers are so connected that impedance can be inserted in the broken delta of the secondary indicated in figure one, the volt amperes consumed under normal operating conditions will be very small, and the capacity of the impedance could therefore be reduced and the load on the transformers would at the same time be minimized.

Since most generally the secondary burden will consist of combined reactance and resistance, it is only natural to ask what the effect of such combinations would be on stabilizing the transformers in order that one might make use of a normal burden to provide the necessary stabilizing influence. Since for insuring stability the value of the resistance burden is given by $R=0.34X_m$ and the value of the reactance burden is given by $X_L=0.28X_m$ in the case of $E=0.58$, it would seem reasonable to expect that for this particular voltage a combination of resistance and reactance having an impedance approximately equal to or less than $0.28X_m$ would be adequate. I would like to know if the authors have any information on this subject.

When one looks over the possible practical means of connecting potential transformers in Y on ungrounded systems so that stability will be insured, it is evident that with the information provided by this paper it will be in many cases simpler to provide the necessary impedances to insure stable operation regardless of the ratio X_{co}/X_m than to determine the possible values of X_{co} under operating conditions.

It should be noted that if reactance burdens containing iron in the magnetic circuit are used for stabilizing purposes, the burdens should operate well below saturation in order to be effective. Otherwise, they will simply add additional magnetizing current of the same character as that of the transformer. Whether this is also true if the reactance is used in the broken delta of the secondary it is not so easy to answer, and I would therefore like to know if the authors have any information on this question.

The title of the paper and lack of any specific statement to the contrary might lead one to believe that any Y-connected potential transformers are subject to unstable operation. It should therefore be emphasized that the type of unstability discussed in the paper does not apply to Y-connected potential transformers on a solidly grounded or impedance grounded (if low enough impedance) system so long as the system remains grounded. Neither does this type of instability occur if the secondary delta is closed and it is not likely to occur if the neutral of the transformers is not grounded.

T. M. Blakeslee (Bureau of Power and Light, Los Angeles, Calif.): The classic papers on neutral instability, references 1, 2, and 3 pointed out and therefore warned the engineer of this peculiar phenomenon. The demonstration by Shott and Peterson of the correlation of neutral instability with the ratio X_{co}/X_m almost places the situation on a practical design basis.

Tests were recently conducted by the Los Angeles Bureau of Power and Light in the attempt to obtain a stable neutral or Y-Y-connected potential transformer on a 115-kv ungrounded bus section. No measurement or calculation of the capacity (X_{co}) involved was made and this quantity was not varied. The other parameter set up by Shott and Peterson, X_m, was varied by using two designs of potential transformers and by operating one of these designs at two excitations. The results are interesting in that they confirm in the actual case the results from the miniature system tests.

The potential transformer units tested had 500-volt-ampere ratings; the voltage rating of one design was 76,200/63.5 volts and of the other 79,677–66,397/66.4 volts. The excitation characteristics of the two designs were quite different. By operating the transformers on the 115-kv bus (66,400 Y-voltage) on all voltage ratings; three values of X_m were obtained.

The tests were conducted by merely energizing the 115-kv bus and noting the condition of the transformer neutral. These tests showed that for small values of X_m (large values of X_{co}/X_m) the instability takes the form of a displaced neutral at fundamental frequency. For high values of X_m (small value of X_{co}/X_m) the instability manifests itself as a neutral displaced at approximately half normal frequency. These situations are similar to those described by the authors.

In the fundamental frequency case the tests gave a displaced neutral such that one of the transformer units was forced to operate at 2.5 times normal voltage. Resistance loads up to 5 kw per transformer were applied in the effort to stabilize the neutral. It was possible to obtain a stable neutral by these resistance loads but upon energization of the transformer bank, periods of instability lasting from zero to 2 seconds would occur before a stable neutral was obtained. These periods of instability could not be tolerated in many cases of practical application.

Boyajian and McCarty stated that the resistance loading to obtain stability should be of the same order of magnitude as X_m. The present paper indicates that 33 per cent of X_m is the proper loading in the resistance case. The tests made on the 115-kv circuit described above indicated a resistance value about 60 per cent of X_m is required.

H. S. Shott and H. A. Peterson: Mr. Sinks raises a question regarding the amount of impedance required for stability when that impedance is a combination of resistance and reactance. While we have presented no quantitative data for this condition, it is reasonable to expect, as Mr. Sinks suggests, that in the case of $E=0.58$, a combination of resistance and reactance having an impedance approximately equal to or less than $0.28X_m$ would be adequate.

The question regarding the effect of saturable reactance in the broken delta cannot be answered by inspecting the data in the paper. Predictions of non-linear circuit characteristics sometimes are likely to be in error. It would be desirable to check this point in the miniature system in cases where this additional factor is encountered.

Mr. Blakeslee has presented some valuable data from actual field tests. His remarks concerning the long transient periods obtained in some cases are apparently similar in time duration to those obtained in the miniature system. The value of resistance equal to 60 per cent of X_m required for stability in his case is consistent with the value of 33 per cent indicated as a minimum in our paper for $E=0.58$. Our value of 33 per cent was obtained for a particular value of $X_{co}/X_m=0.02$. For values of X_{co}/X_m either greater or smaller, the value of resistance required for stability increases. The authors greatly appreciate such checks from field tests for they serve as excellent bench marks for continued investigations.

The Modern A-C Network Calculator

Discussion and author's closures of paper 41-143 by W. W. Parker, presented at the AIEE Pacific Coast convention, Yellowstone National Park, August 27–29, 1941 and at the AIEE South West District meeting, St. Louis, Mo., October 8–10, 1941; published in AIEE TRANSACTIONS, 1941 (November section), pages 977–82.

Discussion and closure at Pacific Coast Convention

Jean V. Kresser (Westinghouse Electric and Manufacturing Company, San Francisco, Calif.): The tedious mathematical calculations required for analyzing electrical systems are generally no longer necessary and little used, particularly in the case of large or complicated systems. The faster and more efficient network calculator is rapidly superseding the older less accurate method. Indeed, the analysis accomplished on the calculator is far beyond that reasonably possible by analytical methods. It is possible to bring the "system" into a laboratory, load it and make measurements of voltage regulation and power flow or set up faults and various kinds of disturbances and determine their magnitude and whether the system is stable under these conditions.

It is further possible to expand in the laboratory an existing "system" and thereby learn exactly what the results will be before construction of the new expansion is started.

Although at first glance this seems mysterious, it is in fact very simple. The network calculator is essentially a combination of different kinds of impedance circuits susceptible of connection in any manner or fashion needed to represent in exact replica whatsoever system is to be analyzed. Suitable instruments provide for accurately measuring the various quantities in the miniature replica. The results then need only be multiplied by a factor representing the ratio of "size of the actual system" to the replica to obtain the values which would occur on the actual system.

The d-c network calculator is still used for the majority of short-circuit studies. It is rigorously accurate when the impedances of the system branches all have the same phase angle. When the phase angles depart only slightly from a mean angle, the error is slight. If the impedances of the branches are used rather than either the resistance or reactance components, the real and reactive components of power must be differentiated. In cases where the d-c calculator becomes inaccurate and for the analysis of complicated systems, the modern a-c network calculator is used.

Since all types of loads are represented by static impedances and generators are represented by voltage regulators and phase shifter, or combinations of these, the direct analysis of stability on a calculator is not possible. Although a-c miniature systems with synchronous machines have been used in stability studies, no attempt has yet been made to represent rotating machines by scale models on a network analyzer. Questions of stability involve mechanical inertia and electrical damping, and the relationship between these cannot be retained with the ordinary type of rotating equipment as the scale of the miniature system becomes small. Special machines for use with network analyzers of laboratory convenience and accuracy have not been built for obvious reasons of cost, complexity, and space requirements. For these stability studies a "step-by-step" method is employed, the calculator giving the electrical conditions for each step. The speed and precision with which results are now obtained obviate any need of employing other and more complicated methods.

The several years of use of a-c calculators have developed skilled operators who can largely anticipate results. Hence, under such guidance, much of the time that might otherwise be spent can be saved through the avoidance of superfluous measurements and also saving of unnecessary work.

We are indebted to Mr. Parker for the clear explanation of the manifold purposes and achievements of the a-c network calculator. It has come to be an indispensable tool, analyzing and also accurately forecasting the proper engineering program in power system management.

H. P. Kuehni (General Electric Company, Schenectady, N. Y.): Mr. Parker's paper entitled "The Modern A-C Network Calculator" is of particular interest to designers of instruments of this type. Such papers offer valuable design information to the art, and the presentation and discussions provide for an exchange of engineering views.

The paper does not mention the motor generator set and associated control equipment which furnishes the 440-cycle power to the calculator. However, on the basis of the rating data given on the 12 generator units, we estimate that the total power requirement of the calculator should be of the order of 15 kva. A large motor generator set appears necessary, therefore, and a considerable amount of heat must be dissipated. In our own low base analyzer the total maximum power input into the analyzer from the 12 generator units is 0.750 kva on the basis of 250 per cent volts and 1000 per cent current per generator unit.

In table I, in which are listed network calculators in use or under construction, special reactors are tabulated for many of the installations. It is assumed that these reactor units refer to low R/X ratio units commonly used to represent internal generator reactances. Reactors of this type are not listed in the table giving the range of the circuit elements, nor are they described in the text. We have built special reactor units of this type having a ratio of R/X as low as one per cent and have also built electronic units of this type in which the power factor can be adjusted to zero.

A centralized instrument system has been adopted in the modern a-c network calculator which Mr. Parker described. This contributes immeasurably to the speed and convenience of taking readings. The same feature has proved its value during the four years of operation of our Schenectady analyzer. An enormous number of system problems were solved during this period and for many months the analyzer has been operating on two shifts to satisfy the great demand.

In the calculator described in the paper a compact 25 push button circuit selector is described. It is stated that only one circuit can be connected at a time because of electrical and mechanical interlocks. We have found, in many studies, that it is often necessary to use more than one circuit selector switch at one time. This need arises particularly in connection with problems involving equivalent circuits. The possibility of using more than one circuit selector switch simultaneously is often very convenient for totalizing multiple circuits which terminate on busses. Our most recent design incorporates controls for interlocking the circuit selector switches or for removing such interlocks. The prevailing interlock condition is indicated by pilot lights.

It is also interesting to note that in Mr. Parker's design electronic amplifiers are used to furnish the power for operating the indicating instruments. These amplifiers completely eliminate the former instrument burden difficulties. In the earlier designs the instrument burden almost entirely determined the analyzer base rating. This is no longer the case today, and considerably lower base ratings may now be used. Our central arrangement of the master instruments and circuit selector switches and the use and design of the instrument amplifiers were described in a paper entitled "A New A-C Network Analyzer" presented at the AIEE winter convention in January 1938.

It is gratifying to learn that the instrument amplifier system which we introduced has been adopted by others. Well designed amplifiers of this type are very accurate, extremely stable, and completely reliable. An instrument amplifier system of this type has been in regular use in the Schenectady a-c network analyzer for over four years with an exceptional performance record. During this time we first made monthly check tests of the amplifier instrument system. However, it was soon found that such frequent checks were unnecessary. The other analyzer installations show the same reliable amplifier performance.

A low analyzer base rating has many advantages. As already pointed out above, the power requirements are small and there is little heat to be dissipated. The losses in the circuit elements may be minimized so that the temperature rise of these elements is too small to produce drifts in the adjusted circuit constants. It is true that the use of a low voltage and current base requires due consideration to inductive and capacitive coupling effects. By giving proper attention to these effects the desired analyzer accuracy is obtained.

Besides the usual power system problems our a-c network analyzer is also being used, for the solution of many other electrical and mechanical problems. These problems relate particularly to equivalent circuits. In these, pure reactances and negative resistances often occur. Therefore, the addition to the network analyzer of zero power factor reactors and negative resistor units materially increases the flexibility and usefulness of the network analyzer equipment. Because of our low analyzer base rating the design problems of producing special units of this type are materially simplified and these units can readily be built around vacuum tube circuits. Standard vacuum tubes easily handle the power required for these units when the base rating is small. Both the zero power factor reactor units and the negative resistor units are of the same size as the other circuit units and fit into the network unit compartments of our analyzer unit cabinets.

R. N. Slinger (General Electric Company, St. Louis, Mo.): The author has presented some very interesting information relating to the design features of the latest a-c network calculators manufactured by his company. Some clarification of certain features of the paper and a few added comments, however, may be helpful to others interested in this subject.

Without adding some qualifying statement, it is rather misleading to include short circuit studies in the list of different types of problems for which the desired quantities may be read directly. The statement is correct for three-phase short circuit problems, but ordinarily would not be correct for unbalanced faults. Symmetrical components employing the various sequence networks are usually used in solving problems involving unbalanced faults and, of course, the various sequence quantities must be added vectorially.

In connection with transient stability studies the author has neglected to call attention to one of the very important advantages of the network analyzer form of solution. As he has pointed out, any a-c network calculator makes it relatively easy to handle multi-machine transient stability problems, but in addition it also makes it easy to include in the solution of one of these problems a change in operating conditions such as the opening of an oil circuit breaker.

The statement that "The a-c calculator frequency has been established at 440 cycles" if taken literally, would imply that that particular frequency is one of the prerequisites of a modern a-c network analyzer. As a matter of fact, there is nothing sacred about that particular frequency. In designing an a-c network analyzer, consideration of cost, weight, and size together with certain other design features, leads to the conclusion that the optimum frequency is at present in the neighborhood of 400 to 500 cycles.

In describing the generator units, Mr. Parker makes the statement that "the phase-angle adjustment corresponds to changes in the governor position." Under steady state conditions this would be correct, but not under transient conditions; therefore, it would be more general to say that the phase angle adjustment corresponds to rotor position with respect to flux in the armature of the synchronous machine represented.

Raymond C. R. Schulze (Public Service Electric & Gas Company, Newark, N. J.): This paper describes the latest Westinghouse a-c network calculator, with a little history concerning the development from the original to this model.

The first point for discussion is the power level. The Westinghouse design allows capacities up to 400 per cent for voltage and 300 per cent for current. It seems to me that 400 per cent voltage is more than is necessary, while the maximum limit of 300 per cent on the current is not enough. The units on our network analyzer (built by General Electric) are rated at 125 per cent voltage and 500 per cent current, and these limits seem to meet our requirements very well. The only times that we have been cramped by these units have been when using synchronous reactances or when studying for 180 degrees out-of-phase conditions, when 200 per cent or more voltage was needed, and in a very few cases we have found that 500 per cent current was not quite enough. When necessary, we have gone over the 125 per cent voltage limit without worrying about it, but we have been careful when the current exceeded 500 per cent. If the currents are much in excess of 500 per cent, we have the advantage on our analyzer of being able to change to 50 per cent or 25 per cent voltage (reducing the currents accordingly) by simply operating a switch on the front of the board.

Concerning the generator circuits, I presume that you have some good reason for using two three-phase regulators rotating in opposite directions to get the voltage adjustment. The analyzer installed in our office is somewhat simpler in this respect, since it utilizes a single phase induction regulator to adjust the voltage. There apparently is no choice between the two from the operating viewpoint.

You mention the instruments for measuring the outputs of the generator units. I see that you still insist on using an ammeter instead of a varmeter. Our analyzer uses a watt-varmeter on each individual unit for making the first rough adjustment. After that, the master meters are used for reading the generator output. These master meters include a voltmeter, an ammeter, and a watt-varmeter. Our experience has been that the ammeter reading is practically never read except when finally recording the data, and then it is read only because the value is there. During the balancing period the watt-varmeter is used exclusively to determine the generator output. The use of voltage, watts, and vars for adjusting the generator outputs seems to be entirely satisfactory. Just incidentally, I can remember the large amount of adjustments and slide rule work necessary to adjust the generators when using the voltmeter, wattmeter, and ammeter.

Considering the range of values for the various classes of circuits, it seems to me that the ratio of $R{:}X$ in the line impedance units should be 300 to 399, rather than the 399 to 300 as used. A review of the ratios of R to X of different kinds of equipment shows that the R is practically always less than the X except for very small open wire lines and medium or smaller multi-conductor cables. Also, in my opinion, the load impedances should have more reactance for the given amount of resistance; the present values place some unnecessary limit on the minimum kva at low power factors.

Concerning the capacitances, I am wondering if the microfarads mentioned are actual microfarads, or whether they are equivalent values at 60 cycles, that is, are the ohms for the impedance units and the microfarads for the capacitance on the same frequency basis?

Concerning the load adjuster units, it would be awfully nice if the voltage always came to an even per cent, but it is more likely to be 104.5 per cent than 105.0 per cent. Therefore, it seems to me that the auto transformer is not a complete answer to the problem, and if one is really careful about the load settings, the load impedance will have to be adjusted by hand whether the load adjustor is there or not.

I presume that equations for the series and parallel connections are necessary when using ohms, but we have a much simpler scheme when using per cent reactance. A table of reciprocals is posted on the front of the a-c table (a Public Service idea) so that the settings for parallel connections can be read and set very quickly. A diagram has been made up for series connections, so that the R and X values can be read quickly from it for given kva and power factor values. These settings, as well as the values obtained from your equations, must be corrected for the resistance in the reactor, and also for the fact that no one can guess exactly what the various substation voltages will be. The use of per cent reactance at 100,000 kva simplifies the operation of a calculator considerably, because of the ease with which the load units can be set and adjusted.

The description of your selecting keyboard is interesting, but the question which promptly comes up is—how does one know that one is metering the circuit he selected? When one pushes buttons 2-3-4, is it possible to get 4-3-2? The indicating lamp on your figure 4 is apparently the answer to that question.

The relaying for the metering scheme sounds somewhat complicated, and I am wondering which is worse—all the complications of that relaying, or the very slight inaccuracies due to bringing the metering leads to the metering desk. I am also wondering if you can read voltage from either end of any impedance. Our metering scheme is quite flexible in this respect.

Our analyzer uses one set of meters for both scalar and vector quantities. The scalar quantities are used almost exclusively. Once in a while when vector quantities are needed, it is easy to flip a couple of switches and use these same meters for reading the vector quantities. The meters on our analyzer cannot be read quite as accurately as yours with knife-edge pointers, since our meters use a light beam and the light beam must have some width. However, the slight loss of accuracy is insignificant. The reduction in strain on the operator's eyes, and the fact that these meters can be read from any where in the room, thus making this a one-man analyzer, amply make up for the negligible loss in accuracy due to the use of light beam meters.

W. W. Parker: 1. Mr. Kresser has compared the application of a-c and d-c calculators. One important additional use of the a-c calculator is for unsymmetrical fault studies in which the zero sequence network simulates multiple circuits with mutual coupling. Mutual transformers in the a-c calculator provide means for accurately including these coupling effects.

2. Mr. H. P. Kuehni asks about the size of the motor generator set and the power requirements. The motor generator set is very small, being five feet long and approximately eighteen inches in height and width. The power required for operation of a calculator with twelve generator units will average less than two kilowatts for most problems. With all twelve generator units loaded at 100 per cent values the power required would be approximately 3.5 kw.

3. The "special reactors" on the Westinghouse calculators have a range of 0 to 2,100 ohms. They are used in representing magnetizing current of large banks of transformers or in conjunction with the load circuits for small low power factor loads.

4. The removal of interlocks to obtain totalized readings does not appear to be good practice as it may lead to errors in metering or interruption of operation. On the Westinghouse calculator these difficulties have been avoided by providing "totalizing" or "jumper" cords with metering facilities. The interlock system is never removed.

5. The assumption that our instrument amplifier system is the same as that employed by the General Electric Company is in error. The instruments are entirely different being conventional type with simple zero adjuster and knife edge pointers. The amplifier uses current feed back instead of voltage feed back. The advantages of this circuit were outlined in the Parker-Osbon discussion of the Brown and Cahoon paper as published in AIEE TRANSACTIONS, volume 58, 1939 (November section), page 598.

6. Due to adequate design the Westinghouse calculators do not show any change in the adjusted circuit constants. With the

base used, the capacitive coupling between circuits is entirely negligible avoiding all necessity for compensation. This simplification is a further advantage over a low base design.

7. With reference to Mr. Slinger's comment regarding the frequency to use on an a-c calculator we can see no difference between 440 or 480 cycles which justifies comment. During our early preliminary investigation we explored the range from 60 to 2,000 cycles and found the optimum frequency to be between 400 and 600 cycles. Mr. Slinger's subsequent investigation substantiates our fundamental conclusions.

8. The calculator design to which Mr. Schulze refers, has been completely described in the Kuehni-Lorraine paper referred to in the bibliography. Apparently this has proven satisfactory for problems on his specific system. Our wider experience in solving problems on all types and sizes of power systems has proven the value of the improvements in calculator design for such application. Moreover, this design has received wide acceptance from the industry.

9. There are distinct advantages in having a means for completely and continuously showing the generator conditions. Our calculator has a voltmeter, ammeter, and wattmeter within constant view so that the effect of adjustment of one generator on the other is immediately indicated. This is not possible with a watt-var instrument and its associated switch. The ammeter has the distinct advantage of indicating directly whether the generating station represented is being called upon to carry more than the assigned kva. Plainly, such a condition is immediately obvious because of the use of the pre-set pointers.

10. The microfarads are actual microfarads and not ohms at any frequency.

11. Practical determination of load values does not require obtaining voltages across the load impedances within one-half of one per cent or less. One per cent steps on the load adjusters have proven entirely adequate. The distinct advantage of the load adjusters is that the load impedance can be set up from a rough estimate of voltage and these impedance values do not need to be changed. The load adjuster raises or lowers the load without affecting the power factor until the desired value is obtained. For the very rare cases when loads have to be set within one per cent slight adjustments of the impedance values can be made. Clearly, that considerable time is saved for the average problem is not open to question.

12. The keyboard and selector relays are so wired that it is impossible to get an incorrect selection. The relays are of well-proven supervisory type. The circuits are simple and easily checked. With this circuit selector the metering of the calculator elements is materially expedited and inaccuracies due to bringing circuit leads to the desk have been avoided.

13. The conventional type of instruments used is entirely satisfactory in high intensity uniform room illumination. This is the illumination used and is recognized to minimize eye fatigue.

Discussion and closure at South West District meeting

H. Weichsel (Wagner Electric Corporation, St. Louis, Mo.): The paper presents in a very clear and precise manner the design and function of this very useful apparatus. There are, however, a few items which to me personally are not clear and some further explanations by the author will be appreciated.

In Figure 1, lower box two from the left, is shown an autotransformer. Is this autotransformer supposed to imitate the effect of the step up transformer shown in the upper part of the diagram? If this is the case, are there any specific reasons why the step up transformer is represented by an autotransformer in place of an equivalent circuit containing the corresponding resistance and reactance of the step up transformer? Naturally in this case the resistance and reactance capacity in the lower box 3, Figure 1, representing the transmission line would have to be calculated for values equivalent to the actual transmission-line values but reduced to the voltage of the calculator.

The article also speaks about "mutual reactance circuits." None of these is shown. A statement as to where these mutual reactance circuits are located and what their purpose is will assist the reader.

In the second last lower box of Figure 1 a combination of resistance and apparently capacitors is shown. There are also three rectangles given without any letters assigned to them. Do they represent switches?

Edward W. Kimbark (Northwestern University, Evanston, Ill.): Mr. Parker's paper shows the present status of a-c calculating boards, both as to the number of boards in use and as to the improvements in design of the boards built by his company since 1929. The improvements described—that is, generators having low-voltage regulation and independent control of voltage phase and magnitude, the provision of instruments on each generator with markers for the desired reading, the addition of amplifier-type central scalar instruments, the centralized control of meter insertion with interlocking, the provision of series-parallel switches on the load units, and the addition of load adjusters—all these increase the speed and convenience of securing results.

After hearing about the increasing use of a-c boards and about improvements in design, one is naturally led to speculate on future developments. I firmly believe that the a-c board is so useful that every large power company should have one. At present the cost of an a-c board is so high that few power companies feel that they can afford one. It would be very desirable to decrease the cost. Though I cannot say how to do this, I can point out what has been accomplished in this direction with d-c boards. The conventional d-c board is the size of a large bookcase, but a man in Chicago has built a portable d-c board, consisting of 40 adjustable resistors, power supply, and instruments, all contained in two suitcases, and at a cost commensurate with the size. Perhaps Mr. Parker and his associates can eventually effect a comparable reduction in the size and cost of a-c boards.

W. W. Parker: 1. Mr. H. Weichsel asks about the autotransformer units. These are used for quickly simulating the effect of changing transformer taps. The resistor-reactor circuit is used to represent the equivalent circuit of the transformer (the exciting current can generally be omitted from consideration). Resistance and reactance of the calculator circuits representing the transmission line are set on values calculated from consideration of normal transformer turn ratio and the ratio of the calculator quantities to the corresponding power system values.

The "mutual reactance circuits" are located in the bottom of the connection cabinet (Figure 2). These are one-to-one ratio transformers for representing the coupling (mutual induction) of circuits. These transformers reproduce the effect of current in one circuit inducing a voltage in another, the value of which depends on the value of the current and the mutual inductance.

The unmarked rectangles in Figure 1 represent switches.

2. Remarks of Mr. E. W. Kimbark are much appreciated because of his experience with calculators. Due to the technical features of an a-c calculator as contrasted with those of the d-c calculator, it is doubtful that any considerable reduction in size and cost of the former will be possible in the near future. However, this is one of the goals of calculator designers.

A Cathode-Ray Method of Wave Analysis

Discussion and author's closure of paper 41-156 by V. O. Johnson, presented at the AIEE South West District meeting, St. Louis, Mo., October 8–10, 1941, and published in AIEE TRANSACTIONS, 1941 (December section), pages 1032–6.

James S. Malsbary (Wagner Electric Corporation, St. Louis, Mo.): Many methods and machines have been proposed for the determination of the harmonics appearing in harmonic motion with particular reference to electrical waves. Due to the complexity of the machines with their attendant cost, very few are used in practice. The cathode-ray oscillograph is to be considered an exception to this rule, not because of its use in wave analysis but because of its use in determination of wave shape.

The author makes a statement as follows: "The complex wave is applied to the horizontal plates which give the cathode beam a vertical displacement." This is not in accordance with the accepted definition of deflecting plates. Quoting from "The Cathode-Ray Tube at Work" by John F. Rider, published 1935, page 26, lines 3 to 6 inclusive. "The term 'vertical deflecting plates' refers to the motion given the beam and the spot by those plates with respect to the normal position of the tube, and not to the orientation of the plates with respect to the normal position of the tube." Also the *DuMont Oscillographer* dated December 1938–January 1939, page 4, which pictorially represents the deflecting plates of the cathode-ray tube as items 16 and 17. Item 16 has the faces of the plates in the horizontal or X axis but they are referred to as the "vertical-deflecting plates," while item

17 has the faces in the vertical or Y axis but refers to them as the "horizontal-deflecting plates." The above, however, does not affect the conclusions arrived at in the paper.

Without detailed study, it is hard to see how an area of an irregular figure determined by inspection can be used to calculate harmonics with sufficient accuracy for practical use.

It appears that after the Lissajous figure (polar diagram) has been photographed, an amount of work must be done thereon in order to arrive at the final answer which is equal to or more than that required to analyze the wave recorded in the rectangular co-ordinate system. It is concluded, therefore, that for the industrial and audio frequencies that this method might not be as practical as other well known methods but as the author points out, with very high radio frequencies where no other oscillograph can be used and no other measurements can readily be taken, the instrument and method may prove very useful.

In the matter of analyzing mechanical vibrations, this is now being done by the use of harmonic analyzers in combination with crystal pickups and vibration-measuring equipment.

Vincent O. Johnson: The cathode-ray oscillograph as Mr. Malsbary states is used in many laboratories for many purposes, although seldom for wave analysis. It has been used for checking the harmonics introduced by a piece of equipment which is supplied by a sinusoidal source. Properly connecting the sinusoidal source to the vertical plates of the oscillograph and the output voltage of the device to the horizontal plates produces a Lissajous figure from which the fundamental component of the output voltage can be calculated in the usual way. This obviates the use of the auxiliary oscillator and the problem of synchronization. The difference between the fundamental component thus obtained and a voltmeter reading of the output voltage is a rough indication of the amount of harmonic content.

Use of the expressions "vertical plates" and "horizontal plates" in the above paragraph and in the body of the paper, meaning plates with vertical and horizontal faces respectively, is questioned. After consideration, it seems possible that these expressions may cause some confusion as to whether "vertical plates" are plates that have a vertical axis or whether their faces are vertical. The expression referred to in "The Cathode-Ray Tube at Work" by John F. Rider and in the *DuMont Oscillographer* is "vertical-deflecting plates" meaning plates which deflect in a vertical direction as distinguished from "vertical plates" as used in the preceding paragraph. It is hoped that this explanation will clear up any misinterpretation of the expressions in question.

It is agreed with Mr. Malsbary that any determination of the area of an irregular figure by inspection can only be approximate, but the time required to obtain the area by accurate means is not appreciable. With the areas obtained, the only remaining step is to substitute the values obtained in the proper formula and turn out the answer. This method is shorter than graphical methods with which the author is familiar, if a comparable degree of accuracy is to be obtained. It is true that the method probably has its greatest advantage in the higher frequency range where graphical methods are not applicable.

The Equal-Volt-Ampere Method of Designing Capacitor Motors

Discussion of paper 41-157 by P. H. Trickey, presented at the AIEE South West District meeting, St. Louis, Mo., October 8–10, 1941, and published in AIEE TRANSACTIONS, 1941 (November section), pages 990–2.

Raymond W. Ager (Cornell University, Ithaca, N. Y.) and **Thomas C. McFarland** (University of California, Berkeley, Calif.): Mr. Trickey first calculates a normal two-phase motor. His second step is to change the winding ratio so that an approximate match is obtained between the voltage triangle and the power factor at full load. In this step he compensates for stator and condenser resistance. The new winding ratio having been determined, the proper capacitor is chosen. A single-phase motor built to this design would have rotor conditions which would closely match those of the two-phase motor at this particular load. These two steps form the basis for Mr. Trickey's previous paper, his reference number 1.

The present paper deals with a third step in modifying the winding ratio and the capacitor size for economic reasons. He has shown that the resulting motor has satisfactory characteristics. Certainly the slightly lower efficiency indicated is not sufficient handicap to offset the decreased capacitor size and cost. In this paper Mr. Trickey has presented a simple, straightforward method which works. This discussion is presented in order to point out a few additional relationships together with some test data bearing on this method of design.

In taking this third step the nice balance of the motor is destroyed. The design developed in the first two steps was balanced, that is, the power and the reactive volt-amperes supplied to the rotor by the main phase and those supplied by the auxiliary phase were made equal. Any change in the winding ratio and the capacitor size upsets the balance in either or both of these quantities, since it causes a shift in the angle and magnitude of the current in the auxiliary phase. Thus, even though the capacitor volt-amperes are maintained constant, the balance no longer exists.

The amount of unbalance may be best illustrated by considering these two components separately. The power input to the auxiliary phase will be a maximum for a winding ratio $K=1$, if the capacitance is varied as indicated in Mr. Trickey's present paper. The more this ratio differs from unity the less the power supplied to the capacitor phase. The reactive or magnetizing volt-amperes will increase as the winding ratio is increased. In the example used, the winding ratio for the balanced design was 1.746. This was increased to 2.25 in the proposed modification. Since the total power and the total magnetizing volt-amperes of the motor must remain about the same, the decrease in capacitor-phase power must be accompanied by an increase in the power component of current in the main phase. The increase in the magnetizing volt-amperes of the capacitor phase must result in a decrease in that component of current in the main phase. These were divided equally between the two phases in the balanced design. Estimates would indicate that the auxiliary phase carried 43 per cent of the total power and 55 per cent of the magnetizing volt-amperes in the modified design. The amount of unbalance is not great and the good performance indicated could be expected.

The test curves shown in Figures 1 and 2 were taken some time ago. The curves of Figure 1 were taken on a special three-phase, one horsepower, 220-volt, Diehl motor having a single-cage cast-aluminum rotor. The motor had been reconnected for two-phase operation, with a winding ratio of 1.00. The motor was operated single phase with the line voltage held constant at 175 volts. Power-factor-correction capacitors rated at 460 volts were used in the capacitor phase. Curves A, B, C, D, and E show power input as a function of capacitance. The load was constant for each curve with curve A being taken at no load. The loading device used in these tests could absorb only about one-half the rated output of the motor so that higher curves could not be obtained. In these tests the power supplied to each winding was measured separately. This permitted the calculation of the locus of equal division of power between the two phases, shown as curve F. Calculations were also made to determine the capacitances which would cause each phase to supply the same magnetizing force. Curve G shows this locus. The figure shows that the minimum power required to drive any load lies between these two loci. Also shown is that the capacitor required for best efficiency is larger for heavy loads than for light loads. A balance point is indicated where the two loci cross between curves C and D. Had the winding ratio been

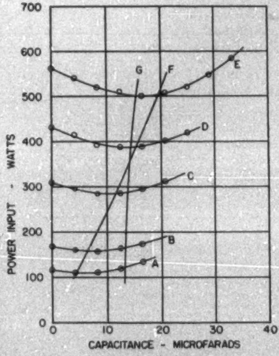

Figure 1

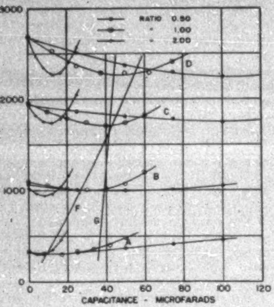

Figure 2

higher this balance point would have been found at a lower load, since high winding-ratios at the balance point are associated with low power factor.

These curves also show that a balanced design can be balanced for only one load. If the load changes the power and the magnetizing components of the auxiliary-phase current will change very little. The magnetizing component of the main phase will also change only slightly, but the power taken by the main phase will change greatly in comparison. Thus a balanced design will, under varying load, remain approximately balanced as far as magnetizing currents are concerned. The power currents in the two phases will only be balanced, even approximately, at and near the load at which the motor is designed. The load taken by the auxiliary phase will be quite constant while the main phase will take all the swings.

The data for Figure 2 were taken on a General Electric, three-horsepower, two-phase, type *KG*, double-squirrel-cage induction motor. It had a double-voltage rating permitting the taking of three sets of curves with winding ratios of 0.50, 1.00, and 2.00. The curves for a ratio of 0.50 have been corrected for 220-volt operation. It was necessary to make the tests at 440 volts in order to get this ratio. The equal-power and equal-magnetizing-force loci have been shown for the winding ratio $K=1$. The curves for maximum load were for an output of 2.4 horsepower or 80 per cent of the two-phase rating.

In these tests one of the curves almost passes through the balance point. If this is considered as a balanced design, then, using the equations of Mr. Trickey's paper, it is possible to see whether these equations give the best condenser when the winding ratio is shifted to 2.00. The balanced design calls for 42 microfarads. The theoretical voltages E_c and E_c' are 311 and 492. The new capacitor required should be

$$C=\frac{311^2}{492^2}\times 42=16.8 \text{ microfarads}$$

The corresponding curve for a winding factor of 2.00 has its minimum at slightly lower capacitance although there is not a great deal of difference even in this case.

Table I

	Balanced Design	Equal-Volt-Ampere Design
Line current	7.90	8.10
Main-phase current	5.82	5.30
Auxiliary-phase current	5.06	3.37
Main-phase power	920	1,100
Auxiliary-phase power	782	680
Main-phase magnetization	890	390
Auxiliary-phase magnetization	794	1,430
Main-phase voltage	220	220
Auxiliary-phase voltage	220	464
Capacitor voltage	310	500
Speed	1,759	1,761

A few of the actual values obtained may be of interest. The following are readings for curve *C* with 40 microfarads and a winding ratio of 1.00, approximately at the balance point, and for a capacitance of 16.7 microfarads and a winding ratio of 2.00, which is practically the "equal-volt-ampere" design.

The degree of unbalance in the modified design is indicated in the power and magnetizing volt-ampere values, these indicating that the auxiliary phase carried 38 per cent of the power and 79 per cent of the magnetizing volt-amperes. Decreasing the capacitor size would reduce the power and magnetizing force of the auxiliary phase while increasing the amounts carried by the main phase. That a somewhat better balance was obtained for these lower capacitances is indicated by the curve.

The following conclusions seem to be justified:

1. The "equal-volt-ampere" method does not produce balanced designs.

2. The amount of unbalance increases as the voltage-ratio change is increased.

3. Considerable unbalance can be tolerated and still maintain good performance. Probably only for extreme designs would the use of this method produce designs which were seriously unbalanced. For these cases a calculation of the per cent power and magnetizing volt-amperes supplied by the auxiliary phase would be justified and an adjustment of winding ratio and/or capacitance be made so that the sum of the per cent power and the per cent magnetizing volt-amperes for the capacitor phase was equal to 100.

4. The balancing might be at a value less than full load for general purpose motors operating over a range of loads rather than a constant load near full load rating.

The Inherent Overheating Protection of Single-Phase Motors

Discussion and author's closure of paper 41-154 by C. P. Potter, presented at the AIEE South West District meeting, St. Louis, Mo., October 8-10, 1941, and published in AIEE TRANSACTIONS, 1941 (November section), pages 993-6

A. F. Lukens (General Electric Company, Lynn, Mass.): Mr. Potter has pointed out some advantages of inherent overheating protection for motors. One of the important ones which he does not mention is the maintained service that a motor will give under very adverse conditions when an automatic reset device is used on an automatically started load. With such a device installed in a motor, under adverse conditions, the motor will try to the utmost of its ability to carry the load without actually doing itself harm and will give a sort of "limping" service that does not completely stop.

In the application of motors with automatic reset devices, great care must be exercised that they are used only on automatically started loads and not on manually started ones. If the latter is the case, there is great danger that the motor will shut down and the operator will not know the reason and start to make an investigation. About the time he gets his fingers in the machinery, the motor may start up and do him considerable bodily harm.

Another warning that must be continually emphasized to the users of motors with inherent overheating devices built into them, is that these motors cannot be applied to just under the tripping value, as shown by ideal application test conditions. If this is done, trouble in the field under adverse operating conditions of voltage, ambient, and load, is bound to result as the motor will shut down when it reaches a dangerous temperature. In this case the burden of applying a proper factor of safety must be carried by the user to a greater extent than when the usual overcurrent protection is used.

Mr. Potter proves by an exhaustive series of tests that an inherent overheating protective device does give adequate protection under many different conditions. He then draws the very restricted conclusion "that inherent overheating protective devices mounted inside fractional horsepower single-phase motors completely protect them against all abnormal operating conditions."

This statement can be extended to cover larger motors and need not be restricted to single-phase motors, for all the advantages of this type of protection are needed in the integral horsepower field. Two things now stand in the way of immediately accomplishing this. The first is the lack of suitable devices for the larger motors. Some sizes are now available, and the manufacturers are working on others to advance their lines. The other is the confusion and contradiction of the various rules and regulations under which such an application must be judged at the present time. The confusion arises, of course, because the code did not contemplate this type of device and does not specifically refer to it. In the case of fractional motors, changes in the code have been made, and similar changes may be advisable for the larger motors if a very desirable technical advance is not to be held back.

The final approval of an electrical installation is given by the local wiring inspector who is guided by the National Electrical Code or local codes based on it. The National Electrical Code states that apparatus shall do thus and so or shall be approved apparatus. The listing or the labeling of the apparatus by the Underwriters Laboratories gives assurance that the necessary specifications are met and that the apparatus is of an approved type.

In the case of fractional horsepower motors, section 4322 of the code states that a motor shall be considered as protected against overcurrent if it is of a type that cannot overheat due to overloads or failure to start. It further states that this can be accomplished by an approved protective device that is an integral part of the motor.

The Underwriters Laboratories thus come into the picture with their "Appendix of the Standard for Industrial Control Equipment." This appendix covers motors one horsepower or less and its major requirements are:

1. That the motor windings shall not exceed a total temperature of 125 degrees centigrade when the motor is running.
2. That the windings shall not exceed 150 degrees when the motor is stalled.
3. That the motor and device shall last for 15 days when operating continuously trying to start a blocked rotor.
4. That the device shall not be a fire hazard when thrown directly on a 1,000-ampere circuit in series with a fuse-rated four times motor full-load current.

In the case of the integral horsepower sizes, the code states that the motor shall have running overcurrent protection to limit the current to 125 per cent of full-load value, except the current can be 140 per cent if it is part of an approved refrigeration equipment. This is inconsistent as the power system, the wiring, and the motor cannot tell what is being driven, and there is nothing evident that differentiates the refrigeration application.

The only Underwriters Laboratories Standard that applies is the Industrial Control Standard which is written for a current protective device rather than for a temperature protective device. It states that:

1. The device shall ultimately trip at its own current rating in a 40 degree ambient. (This current is 125 per cent or 140 per cent of motor full-load current as stated in the code.)
2. It shall stand being closed directly on a 5,000-ampere circuit in series with a fuse rated four times its current without being a fire hazard and without harming itself except by welding of the tips.
3. It shall withstand 6,000 operations interrupting its full load current.

An inherent overheating protective device obviously cannot be fairly judged by the combination of the code and the Underwriters Laboratories Standard as they now stand because these do not cover such a device.

To clarify the situation, consideration might well be given to amplifying the code to cover integral horsepower motors. If this were done, the present current limitation should be supplemented by a standard that would allow the motor with its built-in control to draw a running current that neither exceeds 125 per cent of full-load current in a 40-degree ambient nor raises the total temperature to greater than 125 degrees centigrade when it is running, nor above 150 degrees when it is stalled. Both current and temperature must be considered as the rule will apply to all types of motors with high and low temperature rises, and no constant relation will exist between temperature and current.

The Underwriters Laboratories Standard should then be drawn to recognize motors that meet this proposed requirement of the code, and be worded to cover automatic reset devices. Perhaps the 5,000-ampere short-circuit test should be eased to 2,000 or 3,000 amperes for motors between $1^1/_2$ and 5 horsepower. The device might be allowed to open circuit if it does not produce a fire hazard.

The Underwriters Laboratories have intimated that they will consider setting up such a standard and accepting motors for test under it, but evidently the code should be revised to give clear cut recognition to such apparatus.

H. Weichsel (Wagner Electric Corporation, St. Louis, Mo.): The problem of protecting electric machines against excessive temperature is as old as the electric machines. In "pioneer days" the operator simply watched the machine and when it began to smoke, he disconnected it from the supply or decreased its load. Even in relatively recent years the "smoke test" was used for determining the capacity of a machine. For instance, Mr. Lamme in the year 1892 used the smoke test for the purpose of determining the capacity of his rotary converter in comparison to the capacity of the same machine operating as a d-c generator. By this simple test he established the important fact that for equal heating, the current capacity of a rotary converter is 40 to 50 per cent greater than when the same machine operates as a d-c generator.

The oldest protecting means used in practice is probably the fuses. Thereafter appeared overload circuit breakers and other related devices. Most of these are cited in Mr. Potter's paper. Attempts to make use of bimetal for opening line circuit whenever demanded by the load conditions are also very old. I personally know of a design as far back as 1917 which placed such a device in the motor housing. The device was influenced by both the heater coil through which the line current passed and the air temperature inside of the motor. The amount of said air contacting the thermal switch was adjustable. From this year on the literature is full of devices of similar characteristics.

In 1923 Mr. Spencer patented his now famous "Spencer bimetal disc" which acts as a thermostat switch. The patent shows this disc applied to the protection of an electric flat iron. Many improvements in the design and the location and its use in connection with electric motors were made soon thereafter. The number of patents on this subject is very formidable.

Only during relatively recent years came the protection of motors by aid of thermal switches to the foreground. This was mainly brought about by the very large demand of fractional horsepower motors in connection with home refrigerators, stokers, and other apparatus used generally by the public. Naturally machines used so promiscuously must be made as safe as possible. By the application of thermal switches to these small motors, all danger of fire hazard is practically removed and the life of the motor is greatly increased. Mr. Potter's paper is therefore very timely. It proves by test that under any of the working conditions which may arise in connection with this type of machine, the protection against excessive heating and consequent fire hazard is practically perfect.

It appears appropriate to state here that protecting the motor by aid of a thermal switch is not as simple a matter as it might appear. It requires a great deal of study and experimental work to arrive at the correct design of the thermal protector as well as at its most suitable mounting. The number of tests needed are, however, considerably fewer and also simpler than those required by the investigation reported by Mr. Potter.

His tests were very extensive and laborious as a very large number of readings had to be taken. It is my opinion that the outstanding conclusion from these tests is the assurance to the public that the thermostat protected motor is practically foolproof and consequently protects life and property of the general public. This conclusion alone certainly amply justifies the large amount of labor necessary for carrying out these tests.

C. P. Potter: Mr. Weichsel has called attention to the fact that the application of inherent overheating protective devices to motors is not as simple as a matter as it might appear. This is true because there are several practical limitations which must be met. The protector must trip at one value of current while the motor is operating and at another when the motor is stalled. The protector must permit a fairly long period of acceleration and must not take too long to reset. It is, therefore, not practical for the user to install these devices in motors which did not have them originally.

Mr. Lukens makes a strong plea for the extension of the standards of the Underwriters' Laboratories and the National Electrical Code to permit the application of inherent overheating protective devices to motors larger than one horsepower. Motor users would like to obtain $1^1/_2$- to 5-horsepower motors equipped with inherent overheating protective devices which break the line current, and larger motors provided with devices which are connected in the pilot circuit of the control equipment. It seems desirable and logical to modify and extend existing standards to permit the manufacture and use of these larger motors.

A Turbine-Governor Performance Analyzer

Discussion of paper 41-158 by W. O. Osbon, presented at the AIEE South West District meeting, St. Louis, Mo., October 8–10, 1941, and published in AIEE TRANSACTIONS, 1941 (November section), pages 963–7.

A. F. Schwendner (Westinghouse Electric and Manufacturing Company, Lester, Pa.): The history of any development work shows the effect instruments have on the performance requirement of the particular apparatus. A performance may be considered acceptable as long as available instruments do not show up the deficiencies. Development of new apparatus usually stops at the point where the measuring ability of available instruments can indicate good performance. The demand for development of apparatus with better performance is initiated by the advent of improved instruments which show the deficiencies in the existing apparatus.

Governor development did not follow this procedure in its early stages. Governors then equaled the sensitivity of speed-measuring instruments. Governors are used even now in speed-measuring instruments. But a governing system used on a modern prime mover has considerable auxiliary apparatus beside the governor. Any one part of this system can cause difficulties as well as the governor itself. The governing valves flow-lift characteristics also affect the governor performance to a considerable extent. To analyze a governor's performance characteristics every element of the control system has to be considered and its performance recorded. The paper describes an instrument which is capable of recording the performance of all the control elements simultaneously, with extremely high sensitivity and response. It is well adapted to obtain the governing systems fundamental characteristics and a handy tool to quickly diagnose difficulties.

The instrument can also aid the power-generating systems by analyzing the governor performance characteristics on all their units. The established characteristics of the best performing governors from the overall system point of view can serve them to standardize the required performance and then help to obtain it on the other units.

The writer had used the instrument for analyzing governor performance, locating the source of erratic performance, and checking the characteristics of newly developed control apparatus. The instrument can be set up in a short time, is readily adaptable for analyzing any type of control apparatus, and extremely useful in the development of highly sensitive quick-responding control apparatus. The writer believes that it will take considerable time before control equipment will be developed to such a point that a better instrument than the one described by the author will be required.

Symmetrical Nomenclature of Three-Phase Circuits

Discussion and author's closure of paper 41-153 by Bryce Brady, presented at the AIEE South West District meeting, St. Louis, Mo., October 8–10, 1941, and published in AIEE TRANSACTIONS, 1941 (November section), pages 955–7.

G. S. Lunge (General Electric Company, Schenectady, N. Y.): Mr. Brady's proposal to consider the effect of a wye-delta or delta-wye transformation as introducing a 90 degree shift in phase instead of a 30 degree shift has indeed much in its favor. It appears that this proposal could be adopted without changing the present nationally standardized connections and terminal markings of three phase transformers.

This paper appears to be devoted primarily to a consideration of banks of single phase transformers, but it should be recognized that in many instances the transformers will be of three phase connection, internally connected so that, if wye-delta or delta-wye connected, the high-voltage vector, to neutral, will be 30 degrees in advance of what, with the present system of numbering, is the corresponding low-voltage vector, to neutral. Thus a smaller variety of possible connections should be encountered if three phase transformers are used than have been discussed in this paper.

Many operating companies have, for reasons of safety and convenience in maintenance and repair work, established their own standard geographical order of phases, reading from top to bottom, north to south, or east to west as the case may be. If the letters *A-B-C* are used for the *circuit* phases, as distinct from the polyphase transformer terminals, this should reduce the chances for confusion. Especially for transformers having more than three terminals per winding, the use of numbers to designate the phases, rather than letters, is particularly convenient and has been used for many years both for transformers and for stator windings of both synchronous and induction machines.

The author has referred to "geographical phase sequence" and to "counter-clockwise sequence." It is believed to be preferable to restrict the use of the word "sequence," where phase sequence is involved, to the (time) "order in which the voltages successively reach their maximum positive values between terminals" as defined in section 1.140 of ASA Standard *C6*, 1938.

Although not stressing this point, the author has used the designations *A-B-C* to designate the phases. In most of the previously published literature on the subject of symmetrical components, the three phases are designated *A*, *B*, and *C*, which makes it possible to use the subscripts 1, 2, and 0 for the positive, negative, and zero sequence components, respectively. To comply with American Standard *C6*-1938 (Standard Terminal Markings and Connections), the phases should be designated 1, 2, 3, rather than *A*, *B*, and *C*, or *R*, *S*, and *T* as used to considerable extent in Europe.

When numbers are used for designating the phases, it becomes inconvenient to use numbers also for designating the positive and negative sequence components, since the subscripts may, for instance, be applied to reactances or impedances, and a double subscript such as Z_{12} has been extensively used to designate a transfer impedance or a mutual impedance, and Z_{11} to designate a driving point impedance or (self) impedance in transient stability or similar calculations.

Dahl's textbook, "Electric Circuit Theory and Applications" used +, −, 0 to designate the positive, negative, and zero sequence components, but few typewriters have a + sign on them suitable for use in a compound subscript.

To overcome these difficulties it has been suggested to the interested ASA committee that the positive, negative, and zero sequence components of the current in phases 1, 2, and 3 could be designated as follows:

$$\begin{array}{lll} I_{1P} & I_{1N} & I_{10} \\ I_{2P} & I_{2N} & I_{20} \\ I_{3P} & I_{3N} & I_{30} \end{array}$$

The simplest scheme for avoiding confusion would appear to be to apply the author's proposal to polyphase transformers as well as to the circuit conductors and to banks of single phase transformers, except using the phase designations 1-2-3 instead of *A-B-C*. Some operating companies might, however, consider uniform designation for geographical order of more importance than uniform designation of phases according to their sequence. Standardization of polyphase transformer connections and terminal markings has been achieved over a period of years and should not be changed unless there is nearly unanimous demand for such change on the part of users.

For purposes of analytical treatment of problems by the method of symmetrical components and in synchronous machine theory, it appears to be convenient to continue to use the designations *A-B-C* for the phases, rather than 1-2-3. It is quite common practice for such purposes to consider single phase to ground faults as always occurring on phase *A*. Also, X_p designates the Potier reactance, not merely any positive sequence reactance, and X_2 (not X_N) designates the negative sequence reactance of a synchronous machine. In articles and textbooks on problems involving symmetrical components, X_N usually signifies an external reactor in the neutral ground connection of a machine or transformer.

Edward W. Kimbark (Northwestern University, Evanston, Ill.): Mr. Brady has made a strong case for the symmetrical nomenclature, and I believe that his contentions are correct. I have used the symmetrical nomenclature in my classes for a number of years. It is unfortunate that the present standard nomenclature became established. The question now is: How much confusion would result from changing the standards?

A. Naeter (Oklahoma Agricultural and Mechanical College, Stillwater, Oklahoma): As a teacher of electrical engineering, I am particularly interested in any paper that helps to simplify the work of engineers and their associated workers provided its limitations be recognized and stated. Mr. Brady has indicated properly that the choice between standard and symmetrical nomenclature lies entirely upon the ability of each to serve the needs of those who use the nomenclature.

Also it needs to be re-emphasized that the symbol or name which is applied to a conductor has nothing to do with the magnitude of the current which may flow through it. The same thing applies to the equipment, for example, the short-circuit current that would flow if a delta-delta bank be paralleled with a wye-delta bank.

Pointing out the economies and operating advantages of delta-wye and wye-delta transformations, the author devotes most of his paper to those two particular transformations.

The material presented regarding the application of symmetrical nomenclature to these connections should simplify the work of engineers, construction men, inspectors and others, and increase their confidence in the accuracy of that work.

The writer recalls very vividly the opinions expressed by the superintendent of a department of a major power company, in the Great Lakes area, concerning the need for an adequate method covering three-phase connections for transformers and induction regulators, and their respective vector diagrams. He claimed that no one was ever quite certain of results to be secured under methods then available. Mr. Brady's paper fills a long-felt want.

The writer believes that in the study of symmetrical components a detailed survey of Brady's paper would be desirable before considering star-delta transformations in detail.

M. C. Hughes (Agricultural and Mechanical College of Texas, College Station, Texas): Mr. Brady is to be complimented on his excellent presentation of a complexing and difficult problem.

As a teacher of electrical engineering for the past twenty years, I have been struggling daily with this problem in my classes, and on numerous occasions I have raised a feeble plea for standardization of notation on some basis which will make possible the use of books in several electrical engineering courses, or for that matter, several books in one course without producing great confusion in the minds of embryo engineers.

While I am not ready to admit that Mr. Brady's solution to this problem of notation is the best solution which may be evolved, it has merit and should be given careful consideration. If I were to criticize Mr. Brady's presentation at all it would be his naming two separate methods of notation the "standard method."

For a number of years I have been using and teaching a system of notation which eliminates the confusion of the unlimited notation called "standard" and which has some advantages, I believe, over the symmetrical method—at least from the teachers' point of view. It may be that the symmetrical method is of such definite advantage to the practicing engineer that teaching methods should become secondary.

I hope that this paper will provoke sufficient interest in this subject of standardization to generate some activity on the part of the standards committee of the Institute. This is one of the several points in notation which still need their attention.

Bryce Brady: Both symmetrical and standard nomenclature methods are used today and both will undoubtedly be used for many years in the future. The ultimate usage will probably be proportional to the benefits each is able to contribute.

Several advantages of the symmetrical plan, which apparently have gone unrecognized or only partly recognized, have been described. The task remains for authors, educators, mathematicians, design, and operating engineers to evaluate these advantages in terms of practical day to day engineering and operation. If authors of papers and books find that symmetrical nomenclature is an aid to clearer identification of delta and wye voltages and currents, then the use of this method will become more common. If educators view the matter through students' eyes and decide that 90 degree relations can be grasped more readily than 30 degree relations, then this method of presentation will become more popular. If mathematicians find that the use of 90 degree multiples, in place of 30 degree multiples, simplifies mathematical equations; if protective engineers find that symmetrical identification of single phase fault currents simplifies relaying problems; if substation design engineers find that the universal feature of symmetrical nomenclature is of practical value; if power system operators find that the *A*, *B*, *C* rule (or 1, 2, 3 rule) enables workmen to trace transmission and distribution conductors through transformations with less effort and less chance for error—then the use of symmetrical nomenclature for such diverse purposes is certain to increase.

A Novel Reclosing Relay

Discussion and author's closure of paper 41-152 by P. O. Bobo, presented at the AIEE South West District meeting, St. Louis, Mo., October 8–10, 1941, and published in AIEE TRANSACTIONS, 1941 (December section), pages 1041–5.

H. T. Seeley (General Electric Company, Philadelphia, Pa.): This paper is of interest to manufacturers as well as to users of reclosing relays, because it gives data on operating experience, which can be used to evaluate the relative worth of the various features that can be provided in reclosing relays. For example, taking the figures of 85 per cent successful immediate reclosure and 96 per cent successful reclosure, it appears that a simple single-shot recloser, self-resetting after time delay, will operate successfully on 88 per cent of the faults for which this most highly developed relay would have given successful reclosure. Perhaps this explains why the new relay is not proposed for distribution feeders.

An interesting fact brought out in the paper is the increase in the percentage of successful reclosures obtained with high-speed protective relays as compared with normal-speed relays: evidently it shows the beneficial effect of the reduction in arcing time on the wires and insulators. This is corroborated by recent data published in the Hydro-Electric Power Commission *Bulletin* for February 1941.

The voltage-check feature on any breaker on a line equipped with distance relays is unnecessary except for faults on the 10 per cent of line nearest this breaker, which will be cleared in intermediate time instead of instantaneous time by the relays at the other end. Even for that 10 per cent the voltage-check feature is ineffective for three-phase faults, and if only a single-phase relay is used it is ineffective for about one-third of the phase-to-phase faults as well. Even if we neglect three-phase faults (which are rare), this reduces the effectiveness of the voltage-check feature with distance relays to six or seven per cent.

The paragraphs under the heading, "Need for a Quick Resetting Reclosing Relay," state the case in such terms that the reasons for the utility company embarking upon this development are obvious. Before a manufacturer can exploit successfully the more complicated and more expensive device necessary to provide these features, the facts set forth in those paragraphs must be familiar to those responsible for selection of reclosing relays in many customers' organizations, and this paper should be helpful in that regard.

It is interesting to note that the most salient feature of the new relay, namely, its ability to reset following successful reclosures, was standard with one manufacturer about 1922. This feature was inherent in the type *PQ*-108 notching relay, which had a bellows for obtaining reset if the breaker stayed closed for a definite time after any reclosure. However, this relay did not provide the reclosing delay then considered necessary, and the time-delay relay used with it did not provide the separately adjustable intervals then considered desirable, so that form of reclosing equipment was superseded by motor-driven timers which, with refinements, have remained standard up to the present time. In view of the course of progress indicated by the present paper, that change may seem unwise in retrospect, until it is remembered that the practice of those days did not apply reclosing on transmission lines, did not co-ordinate air-break switches with reclosing breakers, and did not co-ordinate fuses with breakers by means of instantaneous overcurrent relays.

The ingenious schemes for isolation of faulted sections, by means of air-break switches co-ordinated with the reclosing cycle, show the need for accurate timing. Apparently the device described is satisfactory from this standpoint, in spite of the use of the vibrating reed-timing scheme which has a voltage error because of the variation in pickup time of the delayed pickup relay *SO2*. This indicates that some users do not consider it necessary to take account of voltage variations over as wide a range as the 80–110 per cent imposed on manufacturers by paragraph 1.143 of ASA Standard *C37.1*. The width of this range influences the acceptance or rejection of proposed simplified schemes in new designs, and in view of this evidence that the present range is wider than users require, this seems to be an opportune time to ask those favoring a narrowing of this range, and also those opposing any change, to express their views to their representatives on the protective devices committee.

W. A. Wolfe (Kansas Gas and Electric Company, Wichita, Kans.): Mr. Bobo is to be complimented for having developed a reclosing relay which eliminates the most outstanding deficiency in standard reclosing relays on the market today, namely the "blind spot" between the last reclosure and the resetting of the relay. A trip out occurring while the recloser is passing through this zone results in an unnecessary lock out of the breaker. This may happen even though the breaker has reclosed successfully on the first trip out two minutes or more before the second trip out, which locks it out.

Our experience has been that this condition does occur all too frequently to be lightly regarded. The only solution has been to minimize the chances for unnecessary lock out by putting the last reclosing point on the relay as near the resetting position as possible. Even this will not eliminate all cases of trouble of this nature and in addition this expediency when adopted forces one to use a reclosing cycle which he might not otherwise wish to use.

The flexibility and complete adjustability of Mr. Bobo's timer leaves nothing to be desired. In one standard design he has a reclosing relay adaptable to almost any operating condition, and which could with ease be adapted to the complete automatization of important high voltage switching stations in high voltage transmission networks.

M. E. Reagan (Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.): Mr. Bobo's paper on "A Novel Reclosing Relay" is very interesting and is an excellent example of how some study of local conditions will dictate a departure from what is considered standard practice in the industry.

Co-ordination of fuses, automatically tripped disconnecting switches, and feeder breakers has been the subject of interesting discussion and test for a good many years. The solution of the problem depends on the local conditions which are dictated by the type of distribution system employed and the economics of the application. Such features as devices for detecting an energized or de-energized line and synchronism checks may be economically built into a commercially produced relay only if the great proportions of applications demand them. If not, these features are best obtained by the use of "outside" relays when required.

The fast-resetting feature on successful reclosure, which has been so effective in keeping service of the lines of Mr. Bobo's system, has also been a subject of much discussion throughout the years. The type of fault produced by an arcing ground, usually caused by weakened insulation or by trees swinging into the lines during storms, has been the general reason for omitting this feature. During the time of such faulty conditions, the line may be clear of faults long enough for the relay to reset only to have the fault reappear a moment later. Thus, it is theoretically possible to subject the breaker to a destructive number of operations without locking it out of service. I would like to ask Mr. Bobo if any special precautions are taken in line construction on his system, such as over-insulation or special clearances to guard against these rather common types of system faults.

It is gratifying to learn that Mr. Bobo's experience with the operation of the telephone type relay has been so successful and trouble-free. Some twenty years of similar use of such relays in supervisory control systems have demonstrated their reliability. They are very dependable when properly applied.

Another interesting approach to the service restoring problem, where isolating disconnecting switches are used on branches from the main feeder, has been recently made by another utility in the middle west. Here the feeder breakers served lines of the radial type and each important load was taken off through motor-operated disconnecting switches. A fault on the feeder system caused the feeder breaker to open. The de-energizing of the line caused the opening of all disconnecting switches. The dispatcher then reclosed the feeder breaker, and if the reclosure was successful, it meant that the fault had cleared or, if permanent, was on one of the branches. Through the use of single-operation, multi-unit supervisory control, the dispatcher then closed the disconnecting switches one after the other until they were all closed or until the fault was re-established. If the feeder breaker again tripped as a disconnecting switch was closed, service could be established on all other branches of the circuit and a repairman dispatched to locate and remedy the faulty section. This represents another method of approach to the common problem of improving service on the lines and, as with any scheme, depends on the local transmission type and nature of the loads as to the logic of the application.

E. E. George (Ebasco Services, Inc., New York, N. Y.): The equipment for automatic reclosing of oil circuit breakers, as described in this paper, has several features that should appeal to those who design or use protective equipment. Possibly the outstanding feature is the extreme flexibility, permitting modifications in the number of reclosures, the interval between reclosures, and in the transfer of protective schemes between the first and second reclosures.

Another desirable characteristic of the equipment described is its use of standard parts produced in quantity for the telephone industry and therefore available at prices lower than those necessarily charged for items with a more limited market and burdened with recent development expense.

The manufacturers of power system relays have designed some equipment consisting of a flexible assembly of standard units and the response of the users has usually been satisfactory. However, many utility operating engineers have found it desirable to build much of their own equipment and frequently, as is this case, have produced a flexible design that is fundamentally sound and applicable to practically every situation.

Telephone relays of the type used by Mr. Bobo have been used in remote control of underground network protectors (see "Remote Control of Network Protectors," AIEE TRANSACTIONS, volume 57, 1938 (December section), page 685) but instead of being mounted in power relay cases have been mounted in standard telephone connector frames with detachable plug and jack connections. This detachable feature is very convenient, although the adaptation of the connector bases to power switchboard panels is somewhat difficult.

Philip Sporn (American Gas and Electric Service Corporation, New York, N. Y.): The novel reclosing relay described by the author consists of 11 telephone type relays, all mounted in one case, to perform hot-line, dead-line, or stub circuit reclosing as desired. Timing is obtained by a vibrating reed relay, acting in conjunction with slow operated relays to pulse a stepping switch at intervals adjustable between 1 and 15 seconds.

Our experience with vibrating reed-type relays has not been very satisfactory, and before employing same for timing purposes we would conduct exhaustive tests to assure ourselves that this timer was as reliable in its operation as the motor-operated type. Further, we question whether the contacts of these relays would hold up under normal use employing voltages as high as 260 volts d-c, which we have at several of our automatic substations.

We are not quite certain from the description of the recloser whether or not the relay which is used to indicate dead line in this recloser has any time delay on dropout. We assume that it does not and hence we believe this to be a weakness, since it might be entirely possible for a momentary dip in voltage to permit the oil circuit breaker to close and thereby nullify the effect of the relay which was to prevent this operation. In all of our schemes it is our practice to use a time delay undervoltage relay to indicate a condition of dead line to prevent the false operation described above. The same weakness is also present when check synchronizing or synchronizing relays are employed. In this case it is possible while the switch is held open, waiting for the two systems to get into synchronism, that a momentary dip in voltage on one line may cause the timer to notch to the closing position, thereby closing the breaker when the systems were not in synchronism.

This timer has one feature which seems desirable in a timer; namely, that the reset time may be selected so that the timer resets in a very short time after a given reclosure. This feature may result in saving a very small percentage (a good guess would be less than one per cent) of lockouts when actually a lockout was not desired. These particular operations resulting in the false lockout may occur on a conventional timer if a tripout occurs between the time when the last reclosure point has been passed and before the timer has reset. Our practice has been to make this time as short as possible. A tripout occurring at this time, even though it is only transitory, will in all cases result in permanent lockouts.

It seems to the writer that this device has several advantageous features but, before a definite determination could be made whether or not the device as designed represents a satisfactory recloser, it would be necessary to make a somewhat extended study of the component devices used and examine more thoroughly their construction. Another point to be considered also is that every operation performed by this timer may be performed by conventional relays wired as individual units and mounted on panels where they are subject to ready inspection and maintenance. A study of the cost of such a device compared with the scheme of using the individual component relays should be made to determine whether or not it is desirable from this standpoint.

P. O. Bobo: The author agrees with Mr. Seeley that a single-shot recloser will give successful reclosures on 88 per cent of the faults, but wishes to stress the fact that this reclosing relay was primarily designed to eliminate the service hazards which may occur on the remaining 12 per cent of faults. Although service hazards on distribution feeders are not nearly so serious as those on transmission circuits for which the relay was designed, the relay can be used equally well on distribution feeders because of its universality.

Mr. Seeley apparently has limited his remarks on the voltage-check feature to the initial reclosures on a "de-energized" line only. His statements regarding its effectiveness are true under the condition stated in his discussion, but this effectiveness is made 100 per cent by delaying the operation of the setup relay *SU* until after total clearance of the fault. Such a delay need be but a fraction of a second on lines equipped with distance relays and is accomplished by using a slow-operate coil in the setup relay. The conditions of breaker closure and the conditions of timer movement for subsequent reclosures make necessary the voltage-check feature for reasons stated in the paper.

Mr. Reagan points out that it is theoretically possible to subject a breaker equipped with the described resetting reclosing relay to a destructive number of operations by a periodically recurring fault. The same is true using manufacturer's standard single-shot self-resetting reclosers. Such recurring faults, to the author's knowledge, have never occurred on the Oklahoma Gas and Electric Company's transmission system, and, therefore, are believed to be a rare probability. In answer to Mr. Reagan's inquiry, special precautions are taken in line construction to prevent such faults; right-of-ways are wide with wooded sections cleared and conductor cofiguration is arranged so as to prevent conductors swinging together, especially during glaze storms. However, on systems where periodically recurring faults do occur, the resetting feature may be omitted from any one or all reclosures. A cumulative lockout feature can be built into the reclosing relay for limiting the breaker to a predetermined number of operations, if desired.

If fuses are applicable to the branches of the main feeder of the middle west utility mentioned by Mr. Reagan, the author's scheme for sectionalizing faults on multibranch fuse circuits would have advantages over the scheme used in that it is less expensive, completely automatic, and would never subject the nonfaulted branches to more than a transient outage.

It is interesting to note that Mr. Wolfe's company considers the so called "blind spot" the most outstanding deficiency in the standard reclosing relays now available.

The comments given by Mr. George, no doubt represent the opinions of a large majority of relay engineers. Apparently a change away from standardization is gradually taking place, as the author has noticed some trends toward flexibility; distance relays are now equipped for carrier current control whether carrier is used or not; test devices and removable units are also now available as built-in assemblies. It is the hope of the author that this trend will be extended to other protective equipments and service restoring relays. If flexible devices were made available at reasonable cost by the manufacturers, we would be more than glad to purchase them, for after all, manufacturing is not our business.

It would be interesting to know what trouble Mr. Sporn and his company have had with vibrating reed relays. Perhaps it has been extreme voltage variation, which as mentioned by Mr. Seeley does cause inaccuracies in timing; these inaccuracies, within limits, vary almost directly with the voltage. Since all of our installations to-date are served from floating station batteries with practically constant voltage, the timing obtained is accurate.

As to the doubt raised by Mr. Sporn concerning the interrupting capacities of the telephone type relays for 260 volt d-c installations, the author needs but to quote from the relay manufacturer's catalog: ". . . . products include: Relays—in an unlimited variety of assemblies, with a wide range of characteristics and contact arrangements, and for operation on either alternating or direct current with potentials ranging from a fraction of a volt to 220 volts, and even higher," and "Higher voltages can be controlled by operating a number of contacts in series, or by the use of $^1/_8$-inch flat cylindrical tungsten contacts."

The uncertainty raised by Mr. Sporn as to whether or not the line-checking relay uses time delay on dropout is answered in the author's above comments on Mr. Seeley's discussion.

In many instances the difference in value and goodwill between a transient outage and a longer outage amounts to more than the price of a recloser. Therefore in reply to Mr. Sporn's guess regarding the effectiveness of the reset feature, the author wishes again to point out that the reset feature not only prevents false lockouts, but prevents longer than transient outages caused by successive transient faults which may occur within the cycle of time for which the recloser is set. Our experience with this feature shows 10 per cent effectiveness.

A study showing the comparison of the described recloser versus conventional relays wired to obtain the same results as suggested by Mr. Sporn has already been made by our company; in fact, we have both types of these installations in service. Comparative costs, necessary panel space, installation time, and labor are overwhelmingly in favor of the subject recloser.

High-Pressure Gas as a Dielectric

Discussion of paper 41-159 by G. C. Nonken presented at the AIEE South West District meeting, St. Louis, Mo., October 8–10, 1941, and published in AIEE TRANSACTIONS, 1941 (December section), pages 1017–20.

Henry M. Hobart (retired, General Electric Company, Schenectady, N. Y.): Nine years ago, the writer became much impressed with the importance for various engineering applications, of the dielectric properties of compressed gases which had been discussed by Professor Ryan, Mr. Bolsterli, and others, in various papers and articles. Compressed gases appeared very applicable to transformers as an insulating and cooling medium, and also for the insulation of very high-voltage transmission conductors. Both of these uses had been considered by Professor Ryan and others many years earlier.

It was, however, at once stated by various specialists, that these applications would not be practicable, because "increase in gas pressure has no effect on its impulse strength." At about that same period, another adviser wrote: "I had, when I made my comments, forgotten the important fact of lower impulse resistance of gases under pressures that give a 60-cycle puncture equal to oil." Several other communications could be cited, but the above are typical. They have been coming in right down to the present time. Probably many engineers are still under the impression that such statements represent the facts.

The overcoming of the prejudices created by impulse-stress traditions has been the chief hurdle encountered in the ensuing years to progress with these compressed-gas projects. The situation is certain to be greatly improved by the publication of Mr. Nonken's fine paper. Probably it is the first publication presenting in clear form, comprehensive evidence that the traditions mentioned are based on error. So far as relates to fairly homogeneous fields, Mr. Nonken's Figure 2 presents curves showing for two gases, that the extent of the effect of pressure is the same for standard $1^1/_2$, 40 microsecond impulse stresses as for 60-cycle stresses. Figures 3, 4, and 5 all relate to $^1/_2$-inch rod-gap tests and show (for the same two gases) a great variety of differences between the effects of the amount of the gas pressure on the breakdown stresses, with 60-cycle and impulse stresses respectively. In the course of Mr. Nonken's researches, he has discovered, or thrown additional evidence on, many compressed-gas phenomena of much interest and importance. It should be emphasized that rod gaps are employed to represent extreme cases of nonuniformity such as will be avoided in actual engineering applications, just as it was learned long ago to avoid sharp edges and corners in the case of solid insulating materials. When we have obtained better knowledge of the dielectric properties of compressed gases, we may find it actually simpler to deal with these nonuniformity field conditions in the case of gases than in the case of solids.

Mr. Nonken's curves show that in the case of gases in the gap between rod electrodes, it is sometimes the 60-cycle strength, and sometimes the impulse strength which is increased over the other when the gas pressure is increased.

The writer notices that for the $^1/_2$-inch rod-gap tests, the departures from regularity which at first glance seem so capricious, but which really are clues to interesting and important truths, only become much in evidence when the spacing is increased above two centimeters. Doubtless with some other shape or dimension of electrodes, the spacing of two centimeters above mentioned as a sort of dividing line, would be reduced to one centimeter. That would attach interesting significance to some statements made by Finkelmann in discussing his research on "The Electrical Breakdown of Various Gases at High Pressure" (*Archiv für Elektrotechnik*, volume 31, 1937, page 284) as follows:

> "Noteworthy is the steep decrease in the rate of rise in the breakdown voltage at rather high pressure for the spacing of 0.94-centimeter which occurs with

Table I

> all the gases tested. This decrease is greatest with nitrogen where it also occurs at the higher spacings, so that the breakdown voltage of nitrogen then decreases far below that of carbon dioxide. The 'spread' of the breakdowns increases in all gases with the pressure and with decreasing spacings. The 'spread' is the smallest in carbon dioxide, and has the greatest values in nitrogen. It is greater with cylindrical than with plate electrodes."

Concentrating on the case of nitrogen and a spacing of 2 centimeters (the spacing below which the caprices shown in Mr. Nonken's curves for rod electrodes are not extreme, the writer plotted on one sheet, Mr. Nonken's curve *C* of Figure 2, and curves *H* and *C* of Figure 4. These three curves provide the data in the accompanying table.

The values in column *F* are the rod-gap impulse ratios. They change smoothly from 1.5 for low pressures down to 1.0 for the highest pressure in the table (which is only 16 absolute atmospheres). These data, together with the various data discussed by Mr. Nonken in his paper, show that it is no longer correct to consider the impulse ratio as being 1 for gases as against 2 for transformer oil. It is not known to the writer whether the value 2 for the impulse ratio of oil is limited to the case of electrodes providing uniform fields, or whether it has been shown to hold also for rod gaps. Be that as it may, Mr. Nonken's tests reveal that the impulse ratio for compressed gases has, in nonuniform fields, a wide range of values, sometimes much above and sometimes below the value 1.

It should be of interest here to quote from the second edition of Arnold Roth's fine treatise entitled "Hochspannungstechnik" (Springer, Vienna, 1938). On page 208 Roth states:

> "The impulse ratio is very dependent upon the electrode shape. It is high with points and low with plates and spheres. The sphere gap can therefore be used for measuring the crest value of impulse waves, provided its spacing is not chosen too great with respect to the sphere diameter."

Mr. Nonken states:
"For example, the impulse breakdown with a $1^1/_2$ 40-microsecond wave for a rod gap in air at atmospheric pressure is about 1.8 times the 60-cycle breakdown."
The writer would be interested to know more of this test, and especially to what spacing it corresponds.

The curves prepared by Mr. Nonken from the researches of Zeier and Finkelmann, and published by him at page 677 of the AIEE Transactions, volume 60, 1941, together with other data in the technical literature of the subject, have so disillusioned the writer as regards the dielectric characteristics of compressed nitrogen, as to have led him to turn more earnestly than heretofore, to other gases. CO_2 is strongly endorsed by Finkelmann, as already mentioned in this discussion. In addition it is stated by Finkelmann that "CO_2 may be more readily obtained free from dust particles and traces of moisture than is the case with nitrogen."

During several years, the writer has repeatedly called attention to the particular appropriateness of compressed sulphur dioxide, both because of its very low cost and its extremely great dielectric strength. Indeed, the fact of the great dielectric strength superiority of SO_2 was published by Natterer no less than 52 years ago (Wied. Ann. 38, page 63, 1889). At a compression of 50 absolute atmospheres, the superiority of SO2 over transformer oil at atmospheric pressure, is very striking. Only very few tests of the dielectric strength of compressed SO2 are known to the writer to be available, and these are not carried up to high pressures. Their trend is, however, unmistakable, and indicates that for spacings of 100 mils and upward, a homogeneous field, and a pressure of 50 absolute atmospheres, the 60-cycle dielectric strength of SO2 gas will be considerably over 3,000 crest volts per mil as contrasted with transformer oil's 60-cycle dielectric strength of only 320 crest volts per mil. The impulse strength of transformer oil is only about 640 volts per mil between 6.25 centimeter spheres as shown in curve *E* of Figure 2 of Mr. Nonken's paper. Thus SO2's impulse strength of over 3,000 volts per mil under these conditions, is a matter of some five times greater than the impulse strength of transformer oil, and is also about five times greater than the 60-cycle strength and impulse strength of nitrogen gas at a pressure of 12.5 absolute atmospheres when measured with a 6.25-centimeter sphere gap. Evidently there is no justification for asserting (as often has been done) that the successful use of compressed gas in power transformers is unrealizable because of impulse-voltage limitations.

Since it is Mr. Nonken himself who, by his publication in AIEE Transactions, 1941, has called attention to the fact of the great dielectric inferiority of compressed nitrogen, and since other faults of nitrogen as compared with other appropriate gases are now known, it is disappointing that it should be used as a yardstick in establishing comparisons between compressed gas and transformer oil. It is doubly unfortunate, because some of the data he employs in the comparisons correspond to nitrogen at extremely low pressures. CO2 at some much higher pressure would have been a decidedly more creditable representative of what can be achieved in employing compressed gas instead of oil in power transformers.

A fairly careful re-examination of some available data of the dielectric strength of several compressed gases has led the writer to the following basic values as typical for the conditions of 50 absolute atmospheres, homogeneous field, spacings of 100 mils and upward, 60-cycle stresses:

Nitrogen	1,400 crest volts per mil
Carbon dioxide	1,800 crest volts per mil
Air	1,800 crest volts per mil
Sulphur dioxide	Over 3,000 crest volts per mil

The insufficiency of data of the dielectric strengths of SO_2 and CCl_4 at high compressions, high voltages, and great spacings may doubtless be attributable in part to the fact that since their dielectric strengths are several times greater than that of nitrogen, there would be required pressure-test tanks and bushings and electrode fittings much larger and much more expensive than are usually available. But it is known that for a given spacing and compression, the 60-cycle, crest-breakdown voltage is of the order of only one third as great with the $^1/_2$-inch rod gap as with the 6.25-centimeter sphere gap. By increasing our knowledge of the laws of this ratio, we should be able to make the actual tests with the rod gap, using only about one-third as great voltage and then deduce from the appropriate values of the ratio, the value of the voltage which would have been observed if the tests had been made with the sphere gap. University laboratories could use this procedure to obtain without expensive outlays, much needed data of the dielectric characteristics of various compressed gases.

Such fine researches as those now being carried on by Mr. Nonken and others, and directed toward analyzing the complicated phenomena associated with the dielectric properties and behavior of compressed gases and toward ascertaining the "reasons-why" of their behavior, should be encouraged and advanced in all practicable ways.

In the meantime, however, application of the valuable knowledge with which they have already provided us, ought not to be delayed. It is clear that the ways to avoid trouble from our present ignorance of some of the "reasons-why" of the caprices which are being investigated, are to use high compression and the strongest of gases, and to strive to approach uniform fields in our designs, and also not to allow our appreciation of the great value of compressed gases to deter us from making free use of appropriately designed and located barriers and supports of solid dielectrics.

G. W. Dunlap (General Electric Company, Schenectady, N. Y.): This paper by Mr. Nonken is the first of the recent group of papers concerning the dielectric strength of gases under pressure to discuss the performance of gases under conditions of impulse voltages. The importance of adequate information on impulse characteristics where application to power-apparatus design is contemplated should not be underestimated. This is particularly so, because gases under pressure show a wide range of impulse ratios with some cases showing very unfavorable ratios as indicated in the paper.

Tests made in Schenectady with a tank five feet high and 20 inches inside diameter and with substantially the same technique described by Mr. Nonken gave results for 6.25-centimeter spheres which check the curves of Figure 2 within a few per cent. This was true for both nitrogen and CCl_2F_2 although there was some tendency particularly with freon toward a little higher strength on impulse over the 60-cycle voltage value.

Similar close agreement between the Schenectady results and those of the paper, Figure 3, were found with standard $^1/_2$-inch square rods spaced up to six centimeters in CCl_2F_2. The rod gap in nitrogen results check the data shown in Figure 4 of the paper for the two centimeters spacing but at six centimeters considerable divergence was found with a maximum 60-cycle strength indicated at a somewhat lower pressure than shown in Figure 4. This latter difference is probably due to proximity effects in the smaller Schenectady tank and further emphasizes Mr. Nonken's point that tests under specific conditions are necessary for the proper application of gas dielectrics in apparatus design.

Also of interest are some impulse tests in nitrogen at 500 pounds per square inch which were made with insulation structure samples such as described in Table I of the paper. The tank used in this case was mounted horizontally and was seven feet long by 20 inches inside diameter. The samples and technique were the same as described by

Mr. Nonken except that the vertical axis of the samples as shown in Table I was perpendicular to the axis of the tank. The results were as follows.

Table II

Insulation Setup (Table I of paper)	Impulse Breakdown in Per Cent of No. 1 Sample 10-C Oil Breakdown
No. 1	125 withstood without breakdown (voltage limited by flashover to tank)
No. 2	115
No. 3	86
No. 4	60
No. 5	90

While these data are too limited to justify any broad conclusions, it will be noted that even with the nitrogen pressure elevated to 500 pounds the impulse strength is still less than that of oil for some of the insulation structures. On the other hand, the increased strength indicated with samples 3 and 4 gives promise that the application of gas insulation may be extended in certain particular fields to good advantage.

In conclusion it is apparent that high pressure gas is not a "cure all" for insulation problems. On the other hand, it has proven well suited to certain special applications such as high-voltage X-ray transformers and electrostatic generators and there are probably many more similar cases where its particular advantages may be utilized. Each application should be considered on the basis of its particular conditions and extreme caution must be exercised in extrapolating available data. The only really safe design procedure is by a program of tests under conditions simulating as closely as possible the actual conditions of the application.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): I wish to discuss Mr. Nonken's paper from the standpoint of using high-pressure gas in place of oil as a dielectric medium in power transformers. This paper presents some much needed data on the 60-cycle and impulse strength of high-pressure gas.

The use of high-pressure gas in power transformers has been suggested many times during the past few years. Its very high 60-cycle dielectric strength at the higher pressures has made it appear as an excellent substitute for oil. Not only has the gas better 60-cycle dielectric strength, but its being inert gives it the added attraction of being nonexplosive and noninflammable. To be practical it would be necessary to reduce the insulation distances below those used with oil for a given voltage, in order to counteract the increased cost of the high-pressure tank. The use of gas, therefore, is limited to the higher-voltage transformers—115 kv and above—where large spacings are used in oil-immersed transformers.

All high-voltage transformers being built today are, of course, designed to withstand the standard impulse tests which range from 630 kv (1.95 times the 60-cycle test kilovolt crest) for a 115-kv transformer to 1,210 kv (1.86 times the 60-cycle test kilovolt crest) for a 230-kv transformer. In other words, for balanced conditions for both impulse and low-frequency tests, the impulse strength of the high-pressure gas should be in the approximate order of two times the 60-cycle strength in kilovolt crest.

The data given in the paper show that the impulse ratio (ratio of impulse to 60-cycle crest voltage) is close to unity. A reference to Figure 5 will show that, while the 60-cycle strength of the gas at high pressures is better than the strength of oil, its impulse strength is well below the impulse strength of oil.

Again, the dielectric strength of the gas at all pressures increases quite slowly with spacing of the electrodes. The impulse data given in Figure 3 show that at one atmosphere the strength varies as the spacing (from two to eight centimeters) raised to the 0.37 power. At 75 pounds per square inch absolute pressure, the strength varies as the spacing raised to the 0.27 power. On the other hand, the dielectric strength of oil varies approximately as the spacing raised to the 0.67 power for nonuniform dielectric fields.

If this same relationship between dielectric strength and spacing holds for larger spacings it means that distances considerably greater than used in oil would be required to obtain sufficient impulse strength when using gas in high voltage transformers. The insulation setups shown in Table I correspond more nearly with the conditions in a transformer. In no case, however, do these results show a higher impulse strength in high-pressure gas than in oil (CCL_2F_2 being the same as oil for setup 2) and in most cases they are less.

It would be necessary, of course, to obtain a reduction in the size of and amount of material used in a power transformer using high-pressure gas, to offset the added expense of providing the high-pressure tank. It does not appear, for the reasons just given, that the prospects are very good for using high-pressure gas in place of oil as a dielectric medium in high-voltage transformers, except perhaps in special cases where light weight is highly desirable, and fire hazard is objectionable (and where impulse voltages are of no concern), there may be cases where high-pressure gas will find use in transformers.

Operation of Load-Ratio Control Transformers Connected in Parallel and in Networks

Discussion of paper 41-166 by F. M. Starr, presented at the AIEE Southern District meeting, New Orleans, La., December 3–5, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1274–80.

T. C. Lennox (General Electric Company, Pittsfield, Mass.): When regulators or transformers equipped with automatic load-ratio control are operated in parallel, particularly in networks, there is almost invariably a conflict between the requirements of voltage regulation and those of stable parallel operation.

This has long been understood and it has been common practice to accept a compromise as to the accuracy of regulation in order to achieve stability. The means commonly accepted for the purpose has been the reversal of the reactance element of the line-drop compensators and an equivalent increase in resistance compensation.

While stable operation and acceptable regulation have usually been achieved in this way, there has been lacking a complete analysis of the conditions existing in such controls which would allow of quantitative determination of the required compensator settings. Consequently, there have, doubtless, been many cases where adjustments have been made that were unduly conservative from the standpoint of stability at the expense of satisfactory voltage regulation.

In this paper Mr. Starr has analyzed the whole problem and provided us with a convenient method of working out the most advantageous adjustments in installations of widely different types.

Mr. Starr's exposition of conditions in the contact-making voltmeter is a particularly happy one in which a difficult problem is made most clear and understandable.

Factors Contributing to Improving Electric Service by Means of High-Speed Switching and Utilization of Stored Energy

Discussion and author's closure of paper 41-164 by J. T. Logan and John H. Miles, presented at the AIEE Southern District meeting, New Orleans, La., December 3–5, 1941, and published in AIEE TRANSACTIONS, 1941 (December section), pages 1012–16.

E. E. George (Ebasco Services, Inc., New York, N. Y.): Extensive experience with instantaneous reclosing and with inertia-type relays is discussed in a very competent manner in this paper by Messrs. Logan and Miles. Ten years of operating experience with instantaneous reclosing is summarized, and the figures show that in five cases out of six, instantaneous reclosure is successful. While the experience with the inertia-type relay does not extend over so long a period, the record to date indicates a considerable field of successful application for this device.

The paper does not indicate the many obstacles that had to be overcome in applying instantaneous reclosing generally on transmission systems or the extent to which this development has affected present day standard practice. For instance, when instantaneous reclosing was first started, most of the standard practice control schemes then in use were not proof against pumping or continuous opening and closing. Accordingly, most of the existing breaker installations had to be rewired, and, in most cases, an auxiliary switch and extra control wire had to be added. Unfortunately motor-closing breakers had begun to supersede solenoid-operated breakers, and some of these motor mechanisms would not relatch in time for fast closing. Fortunately, this type of motor mechanism is now obsolete. Several styles of relays then in use were too slow in parting contacts after operating, and this required changes in the relays or in the control schemes. The manufacturers have eliminated this source of trouble. The most serious obstacle to instantaneous reclosing was a continuous barrage from the manufacturers insisting that breakers for instantaneous reclosing should be derated, in some cases more than one half. As most of the breakers then in use on transmission systems were of the type to which the manufacturers wished to apply the heaviest derating factors, the operating engineers had to overcome these arguments for the installation of much heavier breakers wherever instantaneous reclosing was used. This argument came from engineering departments of utilities as well as from the manufacturers' engineers and commercial representatives. Fortunately experience on many systems has demonstrated that the so-called necessity for the derating for instantaneous reclosure is largely imaginary. In practice, breaker failures from this cause are negligible.

In addition to the improvement in service to industrial customers as outlined in this paper, instantaneous reclosing affords outstanding improvement in service to residential and commercial customers. Hospitals, theaters, and department stores are typical examples where restoration of service in one-half a second is incomparably superior to restoration after 15 seconds or 30 seconds.

On transmission systems where cities are supplied from two transmission lines without local generation, it has been found in practice that the use of instantaneous reclosing on the transmission system almost eliminates failure of high-voltage power supply, whereas in the old days of one-minute reclosing, the second line would frequently relay out during a lightning storm before the first line could be reclosed.

The discussion in the paper on the use of inertia relays and on the switching of synchronous motors is especially valuable because there has never been any clear-cut statement of practice or principles in handling this equipment. Operating experience as well as special tests have resulted in very conflicting ideas, due probably to the wide variety of torque characteristics inherent in the loads as well as in the synchronous motors themselves.

Robert Treat (General Electric Company, Schenectady, N. Y.): For a number of years the authors of this paper have been doing very commendable and valuable work in exploring the possibilities of supplying high quality service despite the obstacles thereto occasioned by circuit interruptions and voltage surges caused by short circuits. On their own system they have accomplished rather remarkable results at very moderate cost—and to a considerable extent these results have been accomplished by the employment of standard existing devices or devices which were but slight modifications of the standard. On the other hand, the authors have not hesitated to develop new devices, or to combine more or less standard devices to form new associations, when such developments seemed to them to be justified or necessary to accomplish their purposes.

It is gratifying to note that in this paper the authors are again giving the industry the benefit of their own very considerable experience in improving the quality of service rendered by their company, as they have so generously done a number of times before.

J. T. Logan: Remarks made in the foregoing discussions are indeed appreciated. The freedom of these discussions from controversial issues is indicative of the cooperation given the authors during the development stages.

There is one important related factor, however, that is not discussed in the paper, which should be brought out at this time, and that is the effects of this practice on transmission-line insulation values. Higher line insulation levels tend to increase the number of three-phase faults compared to the number of phase-to-ground faults, the former being more serious from the standpoint of system stability and voltage quality. Also, admitting that it is economically impractical to construct a transmission line of moderate voltage, free from lightning flashovers, should not the improvement in service that accrues from the application of modern high-speed circuit breakers with foolproof control schemes, together with high-speed relay protection be weighed against that obtained through overinsulation of transmission lines? In other words, a class of service might be rendered through the practice of high-speed circuit reclosure to nominally insulated lines equal or superior to that rendered by overinsulation of lines equipped for delayed reclosure, and generally at much lower cost. Is it possible that transmission engineers are overlooking the benefits that are obtainable through high-speed circuit reclosure?

Tennessee Valley Authority Hydroelectric Stations—Electrical Design

Discussion and author's closure of paper 41-165 by Raymond A. Hopkins, presented at the AIEE Southern District meeting, New Orleans, La., December 3–5, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1281–93.

V. M. Montsinger (General Electric Company, Pittsfield, Mass.): In connection with the statement given in the paper that the forced air-cooled rating of the transformer is 1.33 times the self-cooled rating, it is well to point out that according to accepted practice this ratio is limited to the case where the forced air-cooled rating is the supplementary rating. When the continuous forced air-cooled rating is the base rating it is, according to accepted practice, 1.25 times the self-cooled supplementary rating.

The new American Standards Association rules permit in the first case a hottest spot temperature rise of 70 degrees centigrade, with a resistance rise of 55 degrees centigrade; and in the second case a hottest spot temperature rise of 65 degrees centigrade, with a resistance rise of 55 degrees centigrade; for the forced air-cooled rating in each case and both on a continuous basis. Therefore, when the forced air-cooled rating is the supplemental rating, the transformer cannot be operated continuously at 1.33 times its self-cooled rating without a reduction in the expected life of the transformer as a result of the hot spot temperature.

R. A. Hopkins: Mr. Montsinger has mentioned a very important item which was possibly not completely covered in the original paper. We have always considered the 133-per cent, blown rating of the transformer as in the same class with the 115-per cent, 80-degree generator rating in that continuous operation at these higher ratings would result in some reduction of life of the transformer and generator. The equipment, therefore, is operated at these higher ratings only for short periods under high head conditions representing a small percentage of their entire life. Furthermore, it will be noted that with the coordination between the transformer and generator ratings described in the original paper under the section on transformers, our transformers have generally been given a slightly higher rating than the generators so as to avoid excessive hot-spot temperatures during the periods of operation at the higher rating. If the new rules now under consideration by the American Standards Association and the AIEE are adopted, it may be advisable to give the transformer a still greater margin over the generator.

Formulas for the Inductance of Rectangular Tubular Conductors

Author's closure of paper 41-168 by Thomas James Higgins, presented at the AIEE Southern District meeting, New Orleans, La., December 3–5, 1941, and published in AIEE TRANSACTIONS, 1941 (December section), pages 1046–50.

Thomas James Higgins: I note the following errata, due, presumably, to my mistyping the original manuscript and not finding the same when checking the proof: in the second of the three right-hand members equivalent to equation 8 and in the left-hand member of equation 9, the second sin Mx should be changed to sin MX; in equation 23, before log $|k_i|$, replace k^4 by k_i^4; in the appendix, replace the expression for $\partial F(D,s)/\partial D$ by

$$\frac{\partial F(D,s)}{\partial D}=(2D^3-6Ds^2)\log(D^2+s^2)-$$
$$4D^3\log D+4(3sD^2-s^3)\tan^{-1}(D/s)-3Ds^2$$

These misprints affect the paper in no way.

Those familiar with the calculation of formulas for the determination of the electromagnetic forces exerted between linear parallel conductors—used in calculation of the mechanical forces exerted on bus bar supports during short circuits—will recognize that the same for the kind of conductors here treated can be determined from equation 26; force = $\partial W/\partial D$. A complete treatment of this phase has been worked out by the writer and will shortly appear elsewhere.

As noted at the outset of the paper, it is based on a thesis done at Purdue University and was accomplished under the guidance of a committee comprising Professors Ewing, Harding, and Sabbagh of the department of electrical engineering and Professors Hughes and Marshall of the department of mathematics, to whom, and in particular to Professor D. D. Ewing, I am indebted for much helpful criticism during the course of the investigation.

Those electrical engineers interested in the history of electrical engineering and of electricity in general may find the following paper, another portion of the aforementioned thesis, of considerable interest: "The Origins and Development of the Concepts of Inductance, Skin Effect and Proximity Effect," *American Journal of Physics*, December 1941, pages 337–46.

Alcoa Rectifier Installation

Discussion of paper 41-167 by J. E. Housley and Harold Winograd, presented at the AIEE Southern District meeting, New Orleans, La., December 3–5, 1941, and published in AIEE TRANSACTIONS, 1941, pages 1266–74.

Otto Jensen (I-T-E Circuit Breaker Company, Philadelphia, Pa.): In 1937 the I-T-E Circuit Breaker Company designed and built 34 high-speed, 6,000-ampere, 1,500-volt, cathode breakers for the Massena and Alcoa stations. Complete field tests were made with all of these breakers before the station was placed in service, and satisfactory operation has been given by the breakers ever since.

As originally installed, a backfire would continue in the rectifier, even after it was disconnected from all other rectifiers on the d-c bus, by its own high-speed cathode breaker, during the eight cycles it would take the oil circuit breaker on the 13-kv side of the transformer to clear. This constituted a short circuit of the transformer and might cause sympathetic backfires in other rectifiers fed from the same a-c system. This problem was approached from two different angles:

1. By grid blocking of the anodes in the faulted tank, thereby preventing them from firing into the fault.
2. By the design of a special high-speed anode breaker inserted between the low-voltage transformer terminals and each anode, or pair of anodes in the tank.

These anode breakers have been used in all the later stations of the Aluminum Company of America, while the anode blocking is used in Alcoa stations 3 and 4 and in the Massena station only.

The first anode breaker was closed by individual air cylinders, in order to prevent the ball-bearing-mounted holding latch from slipping due to shock during the closing stroke. On later installations the air mechanism was changed to a motor-driven cam mechanism. The breaker is rated at 1,600 amperes, 1,500 volts and is tripped by means of a direct-acting trip feature responding to 1,600 amperes reverse current, 6,000–7,000 forward current (extreme high overload), 3,000 ampere dual directional with loss of excitation of its polarity coil. This latter feature makes the breaker fail safely in case of loss of polarity coil voltage. The operating time of its contacts is 0.34 cycle, time to current peak is 0.5 cycle and total time is approximately 0.75 cycle, all on a 60-cycle basis. This operating speed limits the fault current to 35,000–45,000 amperes, depending on the system feeding the faults. Oscillogram 4 shows the effects of a backfire on the d-c system of rectifier station. This oscillogram was taken on a newly designed breaker which is now in the process of development.

Trace 1 (top) is a 60-cycle time wave.

Trace 2 is the voltage across a secondary blowout coil and has only interest in showing when the arc has reached a certain point in the arc chute.

Trace 3 shows cathode current flowing into the bus in a forward direction until the backfire occurs. Then the forward current (furnished by the healthy anodes in the tank) increases, as it is now flowing into the fault. However, grid blocking is applied almost instantaneously, and all other anodes (except the one which was firing when the fault occurred) cease to fire, and the cathode current dies down before the anode breaker has cleared the fault. However, as the cathode current dies down, another backfire occurs in the tank, in spite of the grid blocking, and the cathode current reverses, as it is now furnished from the other rectifiers on the d-c bus. This backfire current is cleared by another anode breaker in the six-pole group. The importance of the anode breaker is here clearly demonstrated, as without an anode breaker, both backfires would have continued until the oil circuit breaker which was previously used had opened.

Trace 4 shows the anode current. This current flows normally in a forward direction at fixed intervals (every time the anode fires). When the short circuit occurs, this current reverses and increases in value with a rate of rise of five to six million amperes per second. After 0.24 cycle the breaker contact opens and the slope of the current changes until the peak is reached at 0.38 cycle. At 0.73 cycle the anode current has reached zero and the backfire is completely cleared. The peak current in this instance was 30,000 amperes, of which 17,500 amperes were furnished by the backfiring unit, and the rest of the current furnished by the other rectifiers on the bus.

Trace 5 shows the voltage across the breaker. The recovery voltage is the transformer voltage superimposed on the dc bus voltage. Its ragged peak must be successfully withstood by the breaker arc chute so that restriking does not occur.

Trace 6 shows the d-c bus voltage and indicates the small disturbance of the bus and the load voltage during a backfire.

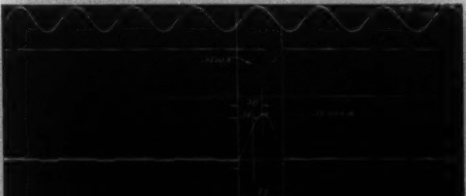
The semihigh-speed cathode breaker is a standard 6,000-ampere 1,500 volt, MT breaker, developed for steel mill and rectifier protection. This breaker might be eliminated if it was only a matter of protecting the rectifier, but in this installation, gang tripping of the cathode breakers is used for dropping the load. Furthermore, it acts as a backup protection, should failure occur in the anode breaker. An accidental short circuit, because of improper connections during a special test, was made by closing one of the MT breakers directly across the d-c bus. No oscillogram is available of this accident, but from other oscillograms it is known that the rate of the rise of the d-c bus is between 16 and 17 million amperes per second (in contrast to the rate of rise in a backfiring anode circuit which is between five and six million amperes per second). Knowing the operating time of the breaker it can therefore safely be stated that the breaker interrupted at least one-half million amperes. After quick inspection the breaker was replaced in service without any attention. A set of six-pole anode breakers has successfully interrupted 287 backfires before the contacts needed attention, and a test was recently made where 25 short circuits of 40,000 amperes at 625 volts each were made at 15-second intervals.

The anode circuit breaker showed its real worth in a recent installation. There a new design of rectifier backfired excessively during the initial operation of the station. A circuit breaker of conventional design such as an oil circuit breaker on the high side of the transformer would have required maintenance service attention during this period, necessitating shut down for this purpose. The anode breaker handled all of these backfires with no maintenance and the production was uninterruptedly maintained.

C. C. Herskind (General Electric Company, Schenectady, N. Y.): I wish to comment on some of the features which have been mentioned in the description of the equipment in the paper.

Practically all rectifier installations being made today involve some amount of phase control and the paper states that provision is made in this installation for regulating the d-c voltage by means of grid control. It is recognized that where several rectifiers operate in parallel on a common d-c bus, some means must be provided for assuring an equal division of load between units. While the inherent d-c voltage characteristic of a rectifier is drooping and similar to that of a shunt d-c generator, this is not usually

Figure 1. Oscillogram 4



sufficient to insure proper paralleling. I would like to ask what inherent shunt regulation is provided in the rectifiers in this installation. I would also like to know what regulating functions are performed by the grid control, specifically:

1. Is the grid control used to regulate the d-c output voltage of the complete substation, and, if so, what range of control is provided?
2. Is the grid control used only for controlling the balance between rectifiers?

Grid blocking or arc-suppression equipment has been quite widely used since its introduction over ten years ago. Considerable experience has shown that while grid blocking or arc suppression is not 100 per cent effective, that is, will not block the anodes during arc-back in all cases, it does provide a secondary protection which is desirable, in that it reduces the duration of faulty currents during arc-back and therefore reduces the duty on circuit breakers, transformers, and rectifiers and the severity of shock upon the a-c system. This feature has been provided in the Alcoa installation.

The anode breakers furnished with rectifiers in rectifier station 4 constitute desirable protective equipment which appears to have a number of important advantages. The use of anode breakers is basically sound in principle, inasmuch as interruption of the anode circuit clears both a-c and d-c to the faulty anode in the minimum of time and thereby clears the fault at its source with the minimum disturbance to the rest of the unit. The desirability of using arc-suppression equipment where protection is obtained by d-c cathode breakers and a-c oil circuit breakers is generally recognized. With the development of anode breakers the question arises, are the benefits accruing from the use of the grid-blocking feature worth the additional cost and complications of the equipment required?

Telemetering, Supervisory Control, and Associated Circuits

THIS REPORT summarizes information as to electric telemetering and supervisory-control systems in use today or commercially available in the United States, and includes a detailed discussion of the interconnecting circuits suitable for such purposes. It has been compiled on the basis of including only such information as would appear to be of practical assistance to a prospective or existing user of telemetering or supervisory-control equipment in selecting the type of apparatus best suited to his requirements. Much valuable information of a technical nature has of necessity been excluded from this report, but will be found in the published papers, reports, and books listed in the bibliography.

The work is based upon a report compiled by a subcommittee of the AIEE in 1932; and the original general arrangement is followed. The earlier report was published in ELECTRICAL ENGINEERING (volume 53, September 1932, pages 613–20) without tabular data, the latter appearing in a mimeographed edition of the report, privately financed, and having only a limited circulation. The tabulation was revised in 1934, but again circumscribed in its distribution. The present report has been prepared in the knowledge that telemetering in its broadest sense, though basically electrical in principle, has far outstepped the field of electrical engineering. With this in view, an effort has been made to present this report in a form and in terms that may be readily followed and intelligently used by engineers in any branch of industry likely to be concerned with remote measurement and control; and it is hoped that the work will find a wide circulation in these fields.

Since telemetering and supervisory-control systems have many problems in common, and most supervisory-control installations include remote-indication features, it has appeared desirable to prepare a combined report dealing with both classes of systems. Much of the information which follows has been contributed by the manufacturers. Information as to line facilities used for telemetering and supervisory control has been obtained from the communications companies, power companies, and other available sources.

All known commercial sources of telemetering and supervisory-control apparatus in the United States have been canvassed and every effort made to present a complete picture of the instruments and systems available for the purpose. Questionnaire forms were sent to every known manufacturer and dealer. Where necessary, these were followed up, and, if incomplete, were returned for further information. No attempt has been made to list the many variations that might be made in basic systems in order to adapt them to local conditions, or to include descriptions of systems now outmoded or of those systems more or less privately developed by utilities or other users and not definitely offered on a commercial basis.

The information in the report has been arranged in three main sections, as follows:

I. Telemetering—including a tabulation of the characteristics of each system.

II. Supervisory control—including a tabulation of the characteristics of each system.

III. Information concerning circuits and channels for telemetering and supervisory-control systems.

No data covering the field operation and maintenance of the telemetering and supervisory-control systems have been included.

The tabulations in the telemetering and supervisory-control sections enable the prospective user who has a certain requirement in mind, for example the telemetering of a-c power, to determine immediately the systems available for the purpose. The characteristics of each of the systems suitable for the telemetering of a-c power then may be examined in detail with the aid of the table and consideration narrowed to a few systems concerning which additional information may be desired from the manufacturer in order to determine upon the one best suited to the conditions involved. The types of interconnecting circuits suitable for operation with each telemetering or supervisory-control system are indicated in the tables.

I. Telemetering

Telemetering is defined as the indicating, recording, or integrating of a quantity at a remote point by electrical translating means. Electrical or mechanical quantities are normally involved, although there are other miscellaneous applications for telemetering. (ASA Standard *C*-42: 30.40.150)

A report, corrected to December 1940, prepared by a joint subcommittee of the AIEE committees on automatic stations, and instruments and measurements, and published in pamphlet form by the AIEE during 1941.

Subcommittee on Telemetering: P. A. Borden, *chairman;* A. E. Anderson, E. D. Doyle, C. H. G. Gray, G. S. Lunge, Paul MacGahan, M. E. Reagan, D. W. Taylor, Chester Wallace, and F. Zogbaum.

Joint Committee on Telemetering and Supervisory Control: P. A. Borden, *chairman;* A. E. Anderson, R. B. Arthur, H. W. Codding, E. D. Doyle, C. H. G. Gray, C. W. La Pierre, Paul MacGahan, C. F. Publow, M. E. Reagan, and Chester Wallace.

APPLICATIONS

In the electrical industry the interconnection of generating stations and of power systems has given considerable impetus to the development of telemetering devices. In the water, oil, and gas industries, particularly in connection with the transportation of such commodities by means of pipe lines, the use of remote-metering systems has come into great prominence as an aid to more economical and satisfactory operation. In fact, the use of telemetering by the nonelectrical industries, for the remote measurement of pressures, levels, positions, flows, and so on, has become comparable in importance to its use in the electrical field; and the experience of some manufacturers has been that although they are prepared to supply systems for the telemetering of either electrical or nonelectrical magnitudes, the demand for the latter constitutes by far the greater part of their telemetering business.

Consequently, while the telemetering systems discussed are all electrical in their operating principles, the magnitudes under measurement may not be electrical in any sense. An effort, therefore, has been made to express the findings of the subcommittee in terms readily understandable by men in any field of engineering, in the hope of making the report of considerably wider practical application than if it were directed solely to the membership of the AIEE.

TYPES OF SYSTEMS

The numerous systems and combinations of equipment used for telemetering may be broadly classified on the basis of the translating means employed. Such a classification has been adopted by the Institute, and includes the following types of systems:

1. Current
2. Voltage
3. Frequency
4. Position
5. Impulse

With the possible exception of the "position" type (which might better be styled the "ratio" type), these terms are in the main self-explanatory. As each type includes a number of more or less diverse forms, these are individually explained by way of introduction to the characteristics of telemetering systems as presented in table I.

CHARACTERISTICS OF TELEMETERING SYSTEMS

This report endeavors to present a uniform analysis of existing systems. The characteristics have been detailed under items which past engineering practice indicates to be essential to bring out the design, installation, and performance features. In order to cover the entire field, it has seemed desirable to present the information in tabular form (table I, pages 16–21).

Questionnaires returned from manufacturers and dealers, after being edited so as to express the data from diverse sources as far as possible in equivalent terms, were tabulated to show in as concise a form as possible the information that would be of value in the selection of a telemetering system. Instead of including in the tabulation the several manufacturers' descriptions of operating principles involved, these principles have been grouped under a number of more or less general headings, and these designated by letters to which reference is made under item 24 of table I. A description of the various principles appears in the appendix, pages 14–15.

The selected bibliography (pages 25–6), while in no sense complete, provides a fair cross section of the art of telemetering and its advances in the past two decades as recorded in the American technical press. Where the references provide valuable descriptive data of principles or operating features of specific systems, they have been noted by number under item 25 of table I.

The user ordinarily will be concerned with only a limited number of systems. The information is so arranged that he can easily fix upon the system or systems which appear best to meet his requirements.

Many of the items in table I require no explanation. In the classifying of measurable magnitudes an effort has been made to bring together in groups those quantities most likely to be measurable by electrical elements of similar natures, and these have been indicated in table I by suitable code letters. Thus, liquid levels and mechanical positions, such as gate openings, are generally measurable by devices having no electrical distinctions, the difference being purely in the mechanical attachments by which displacements are translated into electrical units.

Item 4 indicates whether the telemetering system provides a continuous or a step-by-step indication.* A continuous indication is considered to be provided when the receiving instrument tends to follow any increase or decrease in the measured magnitude at the transmitter. In a step-by-step system no change is registered until the deflection at the transmitter deviates from the last recorded value by a predetermined amount. In determining the time of response of a system (item 7), the characteristic intervals of the transmitter and the receiver as far as possible have been segregated. However, exact statements in this field are difficult to make, and subject to correction with modifications in design or changes in circuit conditions. The time interval as here given for the transmitter does not include the time of response of any deflecting unit, such as a pointer, to the primarily measured magnitude, but only the time required after such pointer has reached its maximum reading until the transmitter has impressed upon the interconnecting circuit the electrical equivalent of a full-scale indication. In such devices as thermal converters, where a definite transformation of energy is effected between a measured quantity and the electrical response in the interconnecting circuit, the time of such transformation may sometimes be considered as the time of response. The exponential law governing the response of such devices has been taken into consideration, where necessary.

---

*A number of those answering the questionnaires classed telemetering systems operating on the impulse principle in the step-by-step group without regard to continuity of record. Where necessary, such statements have been edited in the light of a knowledge of the principles involved.

The time of response of the receiver is the interval which elapses after the equivalent of a full-scale reading is impressed on the interconnecting circuit at the transmitting end, under the conditions outlined above, until the receiver registers a corresponding reading. For the purpose of this report, responses of less than one second have been considered as instantaneous. Since in many telemetering systems the response of the receiving instrument takes place more or less concurrently with that of the transmitter, it follows that the total time characteristic of the installation is not necessarily equal to the sum of the response interval of these two instruments.

Item 8, the estimate of maximum probable error under normal operating conditions (per cent of full scale), includes the effect of line-circuit characteristics and makes allowance for normal variations in frequency, wave form, and amplitude of applied voltage. The error may be in a positive or negative direction.

Under power requirements (item 9), has been given as far as possible the normal type of supply best suited to the system. Where a system is adaptable to any ordinary commercial supply, the designation "comm." is used as all-embracing. It is realized that many of the systems may be modified to make use of unusual or special voltage or frequency supplies. The point of application of power, whether at the transmitter, the receiver, or both, frequently will govern the choice of an installation where power is available at only one of these points. It is to be noted, however (see note 2), that a number of manufacturers are prepared to provide arrangements whereby the telemetering circuit may be made to carry the limited power required for operating the remote unit. The distinction between synchronous and nonsynchronous supplies of power at the two ends of a system is sometimes important, as it may be desirable to operate the transmitting and receiving stations from separate a-c sources, which, while both nominally well regulated, are not of necessity tied together at any point.

The values given for maximum allowable loop resistance (item 16) are for direct transmission without repeaters. However, as shown in section III, certain systems will operate over circuits using repeaters. In using these values in obtaining maximum operating distances, attention should be given to line-leakage, inductance, and capacity effects as discussed in section III.

For those systems indicated under item 20 as suitable for use in cases where the interconnecting circuit is exposed to high potentials, suitable drainage and overvoltage discharge means should be provided, or, with certain types of systems, insulating transformers may be used. Overvoltage gaps of the self-restoring type are desirable in order that the equipment may be available for service immediately after the excess voltage has been dissipated.

A detailed discussion of the use of superposed circuits as conductors, item 21, is included in section III of this report.

Where table I indicates that carrier current may be used in providing the communication circuit, the telemetering system is such that the signals may be readily transmitted over a carrier channel. It is probably feasible from a technical standpoint to use carrier current in more cases than are indicated in table I, but in this report it has seemed desirable to indicate the use of carrier current only in those cases where it appears to be commercially practicable at this time.

So many variables enter into the consideration of additional equipment required to limit noise on telephone circuits that in any specific case where there is a possibility of objectionable noise being experienced it probably will be advisable to make such tests as may be necessary in order to determine the need for such apparatus.

HIGH-VOLTAGE STATIONS

Telemetering equipment frequently is located in stations containing power circuits of high voltage and capacity. Faults on these circuits may cause high-potential gradients in the earth surrounding such stations and thus tend to impose a high potential on the interconnecting circuits used for telemetering purposes. From the standpoint of reliability, it is generally inadvisable to use station batteries for the supply of power to telemeter transmitters located in such stations, since these station batteries usually are connected to an extensive network of local control wires having a high electrical capacitance to ground and subject to contact or leakage to ground. A separate battery or other insulated source of local energy should be used in such cases. The battery provided for telemetering purposes should be charged from a separate ungrounded generator or rectifier and not from the station control or exciter buses. If an a-c supply is used, it should be obtained from a separate ungrounded transformer supplied from the low-potential station bus, which should be grounded. In the installation of local wiring connected to the line side of the telemeter, care should be exercised to avoid accidental contact with other local wiring.

II. Supervisory Control

Supervisory control provides for the selective control and indication of a number of remotely located units of equipment or apparatus by electrical means over a relatively small number of common transmission channels. It is the purpose of this report to present to the prospective user information that will enable him to select the equipment which will provide the desired operating features and at the same time function satisfactorily in connection with the interconnecting circuits that may be available.

APPLICATIONS

At present supervisory-control systems have their greatest field of application in power systems, where they are used for the automatic operation of apparatus in generating, switching, transformation, or conversion stations. These systems are also employed in the water, gas, oil, and other industries for the operation of pumping stations and the control of levels and pressures of gases and liquids, etc. In general, supervisory control is applicable to the remote control and supervision of any device that may be operated electrically. A list of individual devices used in accomplishing automatic control appears in ASA Standard *C*-37.2 (1937).

In addition to the control features provided, indications of the position of different devices, such as switch positions, governor settings, gate and valve openings, and others, and of such conditions as bearing and winding temperatures, pressures, levels, synchronization, and so on, may be secured. Arrangements for the telemetering of various quantities may be incorporated in control systems.

PERFORMANCE FEATURES

Features which are generally desirable in supervisory-control equipment may be summarized as follows:

1. The highest degree of reliability and speed obtainable in the correct selection of units, with due regard for economy.
2. Safeguarding of a selected unit against incorrect operation and the correct operation of a unit as quickly after its selection as is consistent with safety.
3. A visual and/or audible indication at the control point of changes occurring in the position of any of the supervised units.
4. Automatic notification at the control point of the occurrence of major troubles, such as open, short-circuited, or grounded conductors, and the loss of operating potential in a distant station, which may cause the supervisory-control system to become inoperative.
5. Safeguarding against false operation in the event of failure of any portion of the supervisory-control equipment to function.

CAPACITY OF SUPERVISORY-CONTROL EQUIPMENT

Some supervisory-control apparatus has structural features which impose more or less definite physical limitations as to the number of units that may be supervised from one system. Other equipment may be used to supervise any number of units which may be installed. There may be stations of such size and importance as to justify more than one supervisory control installation.

CHARACTERISTICS OF SUPERVISORY-CONTROL SYSTEMS

In the tabulation of system characteristics (table II, pages 22–4), most of the items are self-explanatory. Item 18, maximum allowable loop resistance, and item 22, possibility of using superposed circuit as a conductor, correspond to similar items included in the tabulation of telemetering-system characteristics (table I, pages 16–21); and the statements in the foregoing section regarding these items apply also to supervisory control.

With reference to item 27, the arrangements described under the discussion on telemetering relating to the protection of circuits exposed to high potentials also apply in the case of supervisory-control equipment.

POWER-SUPPLY PRACTICES IN HIGH-VOLTAGE STATIONS

The comments under telemetering relating to power-supply practices in high-voltage stations apply with equal force to supervisory control. In addition, special care should be exercised where supervisory wiring is connected to units located in a high-voltage structure.

III. Circuits for Telemetering and Supervisory-Control Systems

Interconnecting circuits of some form are required for the transmission of signals for telemetering or supervisory-control purposes. The manufacturers of the equipment for these purposes have designed the apparatus to operate satisfactorily over the types of facilities usually available on a leased basis from the communication companies or in privately owned communication systems.

LEASED FACILITIES

In practice a large percentage of such facilities are obtained from the telephone company. These are furnished on a leased-channel basis; that is, for each requirement the telephone company provides an electrical path suitable for the specific purpose and obtained from its plant in whatever manner seems the most practicable under the circumstances. In some cases a pair of wires might be used, as for example where distances are relatively short and local cable-distribution plant would be employed. In other cases the channel might be obtained by simplex, phantom, or composite arrangements or by carrier.

PRIVATELY OWNED FACILITIES

Where privately owned line facilities are under consideration, the determination of their suitability will depend on many factors, including the type and characteristics of the telemetering or control system, the operating distances, and available circuits. The following material is intended, therefore, to aid in the selection of suitable facilities in these cases.

LINE SIGNALS—TRANSLATING MEANS

The systems described involve the transmission of the following types of signals:

1. D-c voltage or current, which changes in accordance with the quantity to be measured.
2. D-c impulse signals, ranging in frequency from 1 impulse per minute to 13 impulses per second.
3. Power frequencies, usually 60 cycles.
4. Frequencies in the voice range and above.

Although power-line carrier applications are increasing, only a limited use is being made in frequencies in the voice range or above. The following discussion is therefore concerned primarily with circuits for the transmission of d-c and low-frequency signals. The problems involved in the transmission of such signals over line circuits are similar in many respects to those encountered in d-c telegraph transmission, and the same engineering considerations frequently apply.

The simultaneous transmission of signals in both directions usually is not required. Telemetering systems ordinarily transmit in one direction only, whereas supervisory-control systems commonly require sucessive transmission in opposite directions.

CIRCUIT CHARACTERISTICS FOR THE TRANSMISSION OF D-C AND LOW-FREQUENCY SIGNALS

The line characteristics which may affect the operating range of low-frequency systems are primarily the linear resistance, to a lesser extent the leakage conductance (or insulation resistance), and occasionally the linear capacitance or inductance.

The gauge of cable conductor most commonly used is number 19 Brown and Sharpe. American Wire Gauge, 22, 24, or 26 gauge is frequently employed.

The approximate linear resistance of various gauges of cable is given in the following table:

AWG	Ohms Per Wire Mile at 20 C
13	11
16	21
19	43
22	85
24	136
26	216

The insulation resistance of cable circuits is ordinarily so high that it is not an important factor in the operation of telemetering and supervisory-control systems. The insulation resistance between the wires of a cable pair seldom drops below about 1,000 megohm-miles (0.001 micromho per mile) and ranges from this value upward to 10,000 megohm-miles or higher. The insulation resistance from a wire to ground is usually about two-thirds of the value between wires.

In cases where the circuits are routed through distribution boxes, substantially lower values of insulation may be encountered. In some instances, therefore, it may be desirable to avoid the routing through such boxes when circuits are used for telemetering or supervisory control.

The gauges of open wire commonly employed, and the respective resistance values for copper conductors are as follows:

Wire Diameter, Mils		Ohms Per Wire Mile at 20 C
165	(No. 8 B.W.G.)	2.01
162	(No. 6 A.W.G.)	2.09
128.5	(No. 8 A.W.G.)	3.32
128	(No. 10 N.B.S.G.)	3.34
104	(No. 12 N.B.S.G.)	5.06
101.9	(No. 10 A.W.G.)	5.27

The insulation values obtained on open-wire circuits are in general very much lower than those for cable circuits. Consequently, the leakage is frequently the limiting factor in determining the range over which telemetering and supervisory-control systems may be operated on open-wire facilities. The leakage conductance varies over wide limits, depending chiefly upon weather conditions and the type and maintenance of the line, and to a smaller extent upon the insulators employed. Since the leakage in dry weather is negligible compared to that in wet weather, it is the common practice to engineer systems on the basis of wet-weather leakage values. For the purpose of determining approximately the range and accuracy of telemetering and control systems, it appears convenient to employ a single leakage value which may be considered to be representative for any open-wire circuit. On this basis, the value of wet-weather leakage conductance between one wire and ground may be taken as 5 micromhos per mile (0.20 megohm-mile). On the average, this value probably will not be exceeded on more than about 1 day in 100 and then only for a part of the day. Individual sections of the country may vary materially in this respect. The wet-weather leakage conductance between wires will probably not be more than 2.5 micromhos per mile.

For determining the effect of uniformly distributed leakage conductance upon the accuracy of a d-c telemetering system of the "current type", the percentage error usually may be taken as equal to 50 times the ratio of loop resistance in ohms to total insulation resistance in ohms. For example, assume a 20-mile

CONTROL EQUIPMENT

Figure 1. Grounded low-frequency circuit derived from simplexed telephone circuit

open-wire grounded circuit having a 200-ohm resistance including composite sets at both terminals. Using the leakage figures given, the resistance between the wire and ground under wet-weather conditions would be 0.01 megohm (0.20 megohm divided by 20 miles). The ratio of the circuit resistance to the shunt resistance would therefore be 0.02. This, multiplied by 50, would indicate that the error would be about 1 per cent under wet-weather conditions.

For d-c "voltage-type" telemetering systems, estimates of the error caused by leakage should take into account the d-c resistance of the telemetering equipment itself. An estimate of the error might be made in each case by simple computations of the change in voltage across the receiver caused by a shunt resistance equivalent to the leakage.

The telemetering and supervisory-control systems described require from two to five conductors. Since two-conductor systems predominate, the discussion is directed primarily toward such circuits. The principles involved may be readily extended to systems requiring three or more conductors.

Figure 2. Metallic low-frequency circuit derived from phantom telephone circuit

Circuits may be divided into two classes, namely, metallic circuits in which a metallic conducting path is employed throughout, and grounded circuits in which the ground is used as one side. For most applications metallic circuits constitute a more desirable transmission medium than grounded circuits. However, the latter are satisfactory in many cases and are sometimes more economical.

The simplest forms of circuit that may be used are: (1) a circuit consisting of two conductors and (2) a circuit consisting of a single conductor and ground. More complicated arrangements are encountered when it is desired to superpose the telemetering or supervisory-control channel on a circuit which also is used for telephone purposes. Such superposition is accomplished by simplexing, phantoming, or compositing.

SIMPLEX AND PHANTOM ARRANGEMENTS

The simplex method, illustrated in figure 1, as applied to a grounded circuit, is based upon the principle of balance. If the telephone circuit is perfectly balanced there will be no net electromotive force or current produced in either the telephone circuit or the derived simplex circuit because of signals being transmitted over the other.

Figure 3. Grounded low-frequency circuit derived from simplexed phantom circuit

Figure 2 illustrates the use of two telephone circuits to derive a single metallic low-frequency circuit.

If a telephone pair is simplexed, it cannot be used as a part of a phantom circuit. However, a phantom may be created from two pairs of conductors in the usual manner, and the phantom may be simplexed as shown in figure 3 so as to give one grounded low-frequency circuit over the four wires in parallel.

In simplex or phantom arrangements the line conductors are connected in parallel for the low-frequency circuit, so that its resistance is correspondingly reduced. On the other hand, its linear leakage and capacitance are increased.

COMPOSITE ARRANGEMENTS

In superposing a low-frequency circuit on a telephone circuit by compositing, use is made of frequency discrimination. Figure 4 illustrates the use of terminal composite equipment to derive two grounded low-frequency circuits from a single telephone circuit, while figure 5 shows a single metallic low-frequency circuit derived in a similar manner. The composite terminal equipment may be considered as consisting of a high-pass filter which freely transmits the telephone currents while attenuating the low-frequency currents, and a low-pass filter which passes the low frequencies and attenuates the telephone frequencies. The low-frequency band provided by the composite set extends roughly to 75 cycles, while the high-frequency band extends upward from about 135 cycles.

CONSIDERATIONS AFFECTING SUPERPOSITION

The transmission considerations involved in the use of simplexed, phantomed, or composited circuits for telemetering and supervisory-control purposes are similar in general to those which apply in d-c telegraph transmission. For the longer open-wire circuits it frequently will be desirable to composite rather than simplex or phantom because of the smaller leakage values obtained with composited circuits. Also a composited open-wire physical circuit normally is to be preferred to a composited open-wire phantom for the same reason.

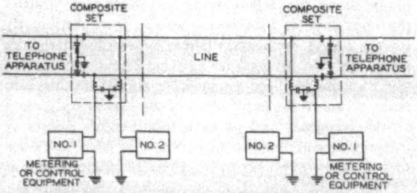

Figure 4. Derivation of two grounded low-frequency circuits from composited telephone circuit

Superposition is frequently accomplished, not at the terminals of the telemetering or supervisory-control system, but at some intermediate point, a simple metallic or grounded circuit being used from this point to the system terminal. The low-frequency circuit may, of course, be superposed on several different telephone circuits in different parts of its length.

The circuit lengths for which superposition may be considered will ordinarily be in excess of one or two miles.

CIRCUITS WITH COMMON RETURN

When several metallic circuits are desired between the same two terminals it is possible under certain conditions to use a single metallic conducting path as a common return, thus effecting an economy in the number of separate metallic paths required. Such an arrangement is illustrated in its simplest form in figure 6. This plan is usually feasible only for short distances, when the circuit resistance is small in comparison with that of the terminals. It has been used successfully for systems employing d-c impulse signals.

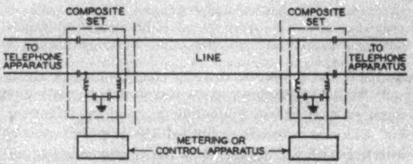

Figure 5. Derivation of metallic low-frequency circuit from composited telephone circuit

USE OF A SINGLE CHANNEL FOR MORE THAN ONE TELEMETERING FUNCTION

During the last several years there has been considerable interest in the possibility of using a single communication channel for the transmission of telemetering signals from a number of telemetering transmitters to one or more receiving instruments located at a main operating center. Such arrangements may permit economies in the communication channels required in instances where the several transmitters are located at one point or along one general route extending from the receiving station. Several possible arrangements for switching the equipment have been suggested; among those which appear the most promising are the following:

1. Systems in which, by manual operations at the control point, pulses are transmitted over a channel to connect a particular transmitter to the telemetering channel.
2. Systems in which transmitters are automatically connected

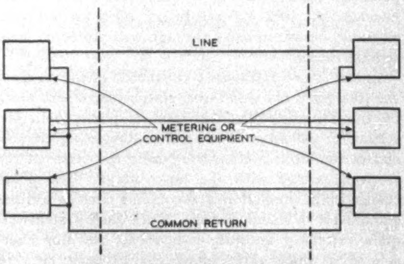

Figure 6. Common return circuits

to the channel in a predetermined sequence. These include systems which involve the use of several receivers and which require, therefore, synchronous connection of the proper pairs of instruments in sequence.

It would be economical to transmit the controlling impulses over the same channel as used for telemetering. This is possible, provided the impulses do not interfere with the operation of the telemetering equipments; otherwise, a separate channel for the control pulses is necessary. The possibilities of accomplishing this depend upon the types of telemetering equipments involved and the feasibility of selecting a type of control signal which would not so interfere. When the same commercial a-c power supply is used at each point where switching is required, it is feasible to design arrangements that provide for synchronous switching of the transmitters and receivers, or for the switching of the transmitters in sequence where only one receiver with multiple recording is employed.

There are probably a large number of possible arrangements of this kind, but since little practical application of such systems has been made to date, it is thought that the purpose of the report might be served best merely by mentioning some of the possibilities that appear attractive at this time.

TELEMETERING SYSTEMS WHICH USE LOW-ENERGY LINE SIGNALS OR WHICH RELY ON EXTREME STABILITY OF CIRCUITS

There have been instances in telemetering systems utilizing low-energy levels where difficulties caused by variations in the line resistance with temperature or by other variations have been encountered. Since the interconnecting facilities may be of various types of construction, and receiving different grades of maintenance, it is desirable to investigate circuits to be used with low-energy systems. Experience indicates that the number of unsoldered joints in a circuit of this nature should be kept at a minimum. Also systems utilizing low-energy line signals are more subject to inductive disturbances and transient ground-potential differences. In general, it is not recommended that such systems be extended for any considerable distance except through well-protected lead-covered cables.

In one or two instances comparisons of the phase of the voltages of two generating stations have been made by transmitting a small amount of power from one station to the other over an interconnecting channel and at the latter station comparing the phase of the received voltage with the bus voltage. The phase change in the conductors and coupling circuits is either allowed for or compensated. Since such systems require extremely accurate indications, the line characteristics which affect phase change must be very stable. In considering the possible use of systems of this kind, it is important to take into account the types of facilities available and the expected changes due to weather and temperature variations. Moreover, in case of circuit failure requiring some replacement of line facility, consideration must be given to the effect on the system of any possible phase changes introduced by the replacing facilities.

CIRCUITS FOR SIGNALS IN THE VOICE-FREQUENCY RANGE

While it is practicable to employ signals in the voice-frequency range for telemetering and supervisory-control systems, in most cases d-c or low-frequency signals have been used. Some of the more important reasons for this usage are:

1. The employment of the voice-frequency range for these purposes seriously limits its utility for telephone purposes.
2. The avoidance of interference with adjacent service is readily obtained by the utilization of the low frequencies.

CARRIER-CURRENT CHANNELS

Carrier channels on power or privately owned telephone lines for telemetering or supervisory-control purposes have had increasing applications particularly for the longer distances. These types of systems are most likely to be used on existing line facilities, and the transmission and engineering considerations generally relate to the application of the carrier equipment at the terminals and at such intermediate points as transformers or bridged lines where it may be necessary to add equipment to improve the transmission at carrier frequencies. Carrier channels installed primarily for speech communication or other purposes often can be arranged also to permit telemetering at a slight additional cost.

AUDIBLE INDICATING EQUIPMENT ON TELEPHONE SUBSCRIBER LINES

Several audible systems are available for use in association with regular telephone subscriber lines to normally unattended stations, enabling the transmission of audible signals over the telephone line to a party making a call to the unattended station. The telephone companies can provide auxiliary-station equipment for coupling the indicating apparatus to the telephone circuit. The equipment includes several relays, a gong, and a transmitter, all housed in a metallic cabinet. When a call is made to the unattended station, the ringing current causes operation of a relay which connects the transmitter across the line, stops the ringing, and holds the circuit. For a period of about five seconds after ringing ceases, the gong operates and the tones are picked up through the transmitter and serve to notify the operator that the station has answered. Following this a relay in the auxiliary-station equipment closes a circuit to start the telemetering apparatus, and the duration of the contact closure may be arranged for a period as low as about five seconds or for such longer period as may be necessary for the device to complete its cycle of operation. The telephone companies usually require that the operating cycle not exceed five minutes. The tones emitted by the audible indicator are impressed at about a normal talking volume on the transmitter of the auxiliary equipment. The transmitter is mounted against an aperture in the cabinet to facilitate acoustic coupling to the telemetering system. At the conclusion of the operating cycle, the momentary closure of a circuit in the latter equipment operates a relay in the auxiliary station apparatus which restores the circuit to normal after the transmission of the telemetering pulses.

MAINTENANCE OF CIRCUITS

Since telemetering and supervisory-control services generally are of vital importance in the fields in which they are applied, it is essential in most cases that the highest practicable degree of continuity and reliability of operation be maintained for these services. Special markings should be provided at the terminals, frames, protectors, test boards, and other locations, where the circuits appear. These help to guard against possible interference or interruption to service. In addition to that precaution, the following procedures have been found helpful:

1. Frequent routine tests and inspections of the facilities.
2. Arrangements for prompt location and clearing of troubles.
3. Arrangements for prompt restoration of service in the event of failure.

PROTECTION AND AVOIDANCE OF SERVICE REACTIONS

In the operation of telemetering and supervisory-control systems in connection with different types of leased channels or privately owned circuits, it has been found desirable to apply certain requirements and limitations of an electrical nature with a view to:

1. Provision of a satisfactory grade of telemetering and supervisory-control service,
2. Avoidance of possible hazard to communication plant and personnel, and
3. Avoidance of possible adverse reactions to other communication services.

The requirements and limitations usually desirable for d-c and low-frequency telemetering and supervisory-control systems when operated over leased circuits may be summarized briefly as follows:

(a). The potential of a d-c supply under any conditions should not exceed 135 volts positive or negative between any conductor and ground. A potential of 270 volts may be employed between the two wires of a pair, provided the midpoint of the applied voltage is grounded.

(b). The potential of an a-c supply should not exceed 120 volts rms value between conductors or between any conductor and ground.

(c). The maximum line current under any conditions should not exceed 0.35 amperes.

(d). Where there is a possibility of experiencing excessive ground potentials there should be no metallic connection between the line facilities and the high-voltage station ground except where neutralizing or insulating transformers are provided.

(e). The apparatus should be provided with insulation adequate for the conditions under which it is to be used.

(f). The noise influence of telemetering or supervisory-control signals, that is, the characteristics of the signals which cause induction in other circuits, should be suitably limited to avoid the effects of service reaction in near-by communication circuits. The limits of tolerable noise influence vary widely, depending upon the characteristics of the plant involved. It is customary to make noise measurements when there is any likelihood that telemetering or supervisory-control signals will cause induction in neighboring communication circuits, resulting in adverse service reactions. The method of measuring should take account of frequencies within the range used by message circuits, and by program circuits. Noise influence (expressed in decibels above reference noise) may be measured by an indicating noise meter having suitable frequency-weighting networks for message and program circuits. The indicating meter is coupled to the circuit (or apparatus) being tested, by a suitably proportioned capacitance to simulate "crosstalk coupling". Cases involving signals having frequencies above approximately 8,000 cycles require special consideration.

These provisions agree in general with those observed in the operation of commercial telephone plant adequately to control the effects on other circuits. Many of the telemetering and supervisory-control systems now furnished by the various manufacturing companies are designed and constructed so as to conform to these provisions. When the user of telemetering or supervisory-control equipment provides his own circuits, it sometimes may be possible to exceed these limitations without undesirable effects. In regard to the noise-influence considerations discussed, with leased channels the communication companies generally are equipped to make the measurements necessary to determine whether or not tolerable limits are observed. Where privately owned circuits are to be used, information on noise-influence characteristics of the signals transmitted by the equipment should be secured from the manufacturer.

SOURCES OF GROUND-POTENTIAL DIFFERENCES

An item of interest in metering and control services is the possible occurrence of differences between the ground potentials at the two ends of the circuit, which may be of sufficient magnitude to cause appreciable interference in grounded circuits. Ungrounded metallic circuits, on the contrary, rarely are affected by ground potentials.

Differences in ground potentials at different points frequently are caused by d-c electric-traction systems. Such differences are ordinarily small (not over 10 volts). However, in a few locations in the United States the geological formation is such that varying differences

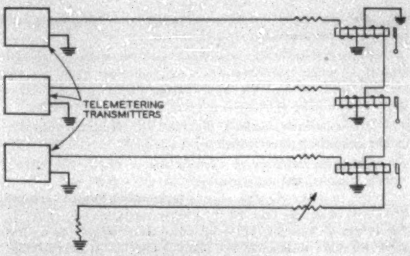

Figure 7. Use of auxiliary conductor to compensate for ground potentials

in ground potential which are fairly substantial in magnitude occur more or less continuously.

Differences in ground potential due to normal solar activity are insignificant. However, during periods of intense sunspot activity, accompanied by such phenomena as severe magnetic storms, the disturbances in grounded circuits may be severe. At such times the potentials between points a few hundred miles apart will usually range from 0 to ±50 volts, but may in extreme instances attain values of over 500 volts. Such disturbances generally extend over the whole world, although the magnitude of the effects may vary in different locations. Usually the effects are most severe on lines extending in a northwest-southeast direction.

These effects have been studied over a considerable number of years. Fortunately, in addition to being of comparatively short duration, such disturbances are quite infrequent in occurrence. Periods of extremely intense solar activity seem to occur only at intervals averaging about 11 years, with occasional briefer periods of less disturbance between. It has been estimated that the total duration of disturbances of this nature sufficiently severe to affect grounded circuits will average about 10 hours per year. Metallic circuits are affected by these disturbances only when the ground-potential differences are of such magnitude as to cause operation of the protector blocks, fuses, or heat coils, or to damage the office apparatus.[46]

Disturbances due to static atmospheric conditions, as well as to lightning, are sometimes experienced on open-wire circuits. The amount of these disturbances varies with the locality and according to whether or not the circuit is grounded. Circuits in cable are not ordinarily subject to such interference.

EFFECT OF GROUND POTENTIALS

The effect of ground potentials on telemetering and control circuits depends upon the type of system. In the case of telemetering systems which use a slowly varying direct voltage or current the accuracy as a rule is affected by ground potentials. Consequently, metallic circuits are generally more desirable for such services. Systems employing d-c impulses, however, are much less susceptible in this respect, and are not usually affected by small ground-potential differences. Grounded circuits therefore may be used successfully in many applications of the latter type of system.

Where several telemetering or supervisory-control systems employing relay operation are to be used between the same terminals, an arrangement may be provided whereby a grounded channel is used for each system and a single auxiliary conductor is used to compensate for the effect of ground potentials in all systems. Such an arrangement is illustrated in figure 7.[31]

POWER INDUCTION

The transfer of energy from power circuits in certain cases may introduce substantial alternating voltages and currents in circuits used for telemetering and supervisory-control systems. If circuits closely parallel power-line rights of way, ordinary protection arrangements and sometimes special drainage will be required.

As in the case of ground-potential differences, ungrounded metallic circuits are naturally less susceptible to power induction than are grounded circuits. Also, cable circuits are much less affected than open-wire circuits. The importance of the reaction which such power induction may produce in telemetering and supervisory-control systems depends upon the system employed and upon the magnitude of the effects present. The arrangement in figure 7 is also effective in many cases in minimizing the effects of extraneous a-c potentials.

AVOIDANCE OF HIGH-VOLTAGE-STATION GROUND

If a high-voltage-station ground or an adjacent ground is used for grounded telemetering or supervisory-control circuits, these circuits are extremely susceptible to inductive disturbance at times of abnormal conditions in the power system. This difficulty may be obviated by using an operating ground at an intermediate point (such as a telephone central office) some distance away from the high-voltage station and employing a metallic circuit between this point and the high-voltage station. An arrangement of this kind is illustrated in figure 8. This makes it possible to use a grounded

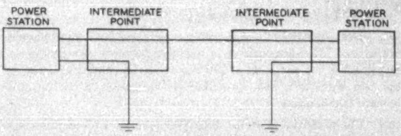

Figure 8. Use of ground at intermediate points

circuit in sections not affected by disturbing potentials. The metallic circuit extending to the high-voltage station must be insulated against the maximum potentials to which it may be subjected.

When a metallic circuit is required and is terminated at a power station subject to high-ground potentials, one or more of the following practices is desirable:

1. Adequate insulation of the terminal equipment from the station structure. Consideration must also be given to the need for adequate insulation within the influence of the station ground potentials or the conductors associated with the terminal equipment
2. The use of neutralizing transformers.[31]
3. The use of insulating transformers.

OPERATING DISTANCES

The distance over which satisfactory operation may be secured with different types of telemetering and supervisory-control systems depends upon both the design of the system and the character of the associated interconnecting circuits. Ordinarily the manufacturer will indicate the approximate length of different types of circuits over which his equipment will yield a satisfactory performance.

The scope of this report does not permit a statement of the maximum distances which may be spanned with each kind of equipment as applied to each type of circuit. A few general observations, however, may be helpful.

For cable circuits, especially of the metallic type, the resistance is usually the principal factor in determining the operating range. Consequently a rough indication of the maximum operating distance over cable facilities may be obtained by relating the allowable loop resistance as given in the table of system characteristics to the linear resistances of the gauge or gauges of cable to be used.

With open-wire circuits, the leakage frequently will be the controlling factor, so that a comparison of the tabulated values of minimum insulation resistance with the insulation value for open wire under wet-weather conditions will furnish a rough measure of the maximum operating distance.

For systems having the high speeds of transmitting impulses and for a-c systems, especially when operated on simplexed or composited facilities, the effects of capacitance and inductance in the communication circuit and in the compositing equipment will limit the length to much shorter values than those determined by resistance only.

Because of circuit limitations, position-type telemetering systems in general are limited to comparatively short distances, say not over 5 miles; but recent developments have materially increased the range of this class.

The voltage and current types of telemetering systems cover, in general, a range of operating distances up to about 50 miles, with greater ranges feasible if simplexed cable circuits are used. The accuracy of these systems is appreciably affected by the leakage on open-wire circuits. Metallic circuits are preferable for these systems, and are in fact essential for certain types.

Systems employing d-c impulses generally will span a maximum distance of from 50 to 250 miles or more. These systems are well adapted to the use of grounded channels, and their accuracy is not impaired by leakage conditions. For systems employing relay operation, greater distances usually may be spanned and superior operating results obtained if polar operation or the equivalent is used instead of open and close operation.

TELEGRAPH REPEATERS

For the most part, the distances to be covered will be such that the use of telegraph or pulse repeaters is unnecessary. In cases where it is desired to span unusually long distances, ordinary telegraph repeaters may be used with certain of the systems employing d-c impulse signals. Also, repeaters employing equipment similar to the terminal equipment can be furnished by the manufacturers for some of the systems.

Appendix

For convenience in using this report, the following material has been assembled in the appendix: descriptions of the principles involved in the various telemetering systems which were studied; a list of abbreviations used in the tables; a table showing the characteristics of various telemetering systems; and a table showing the characteristics of various supervisory-control systems.

Brief Descriptions of Principles Involved in Telemetering Systems Included in Table I

CURRENT AND VOLTAGE SYSTEMS

(*A*). A permanent-magnet-moving-coil element in the transmitter is caused to follow the deflections of the primary measurement element by means of a contact system acting through an electronic or electromechanical relay to adjust a direct current in the moving coil. The transmitting line carries direct current proportional in value to the deflection of the primary measuring element. The receiving instrument takes the form of an indicating or recording milliammeter.

(*B*). The torque of the primary measuring element is definitely opposed by the reaction set up in a permanent-magnet-moving-coil element, reducing the deflection of the former to zero. The current in the latter element is adjusted by means of a control system actuated by the former element. This current, proportional to the torque developed in the measuring element, is carried by the transmitting line. The receiving instrument takes the form of an indicating or recording milliammeter.

(*C*). The primary measuring element directly controls the impedance in an electrical circuit including the transmitting line. The receiving instrument may be indicating, recording, or integrating, and responds to the current resulting from a constant voltage applied to the controlled impedance circuit. Where necessary there is incorporated in the receiver an automatic compensator for variations in supply voltage.

(*D*). The torque of the primary measuring element is definitely opposed by the reaction set up in a permanent-magnet-moving-coil element. The current in the latter element is controlled through an electron-tube system from photoelectric tubes energized by a light beam deflected by a mirror on the coupling between elements. This current, proportional to the torque developed in the measuring element, is carried by the transmitting line. The receiving instrument takes the form of an indicating or recording milliammeter.

(*E*). The voltage or current to be transmitted is derived from the secondary of a suitable instrument transformer, and applied through an insulating transformer to a rectifier. The filtered output is transmitted as a d-c magnitude to an indicating or recording receiver.

(*F*). The transmitter includes a controlling element which sets up a current proportional to the measured magnitude. At the receiving end, this current is passed through a shunt and the voltage drop measured by a potentiometer calibrated in terms of the measured quantity. Totalizing like quantities is effected by paralleling currents or by adding shunt-potential drops and measuring the net value.

(*G*). A transmitting controller sets up a voltage proportional to the measured magnitude. At the receiving end this is measured by a self-balancing potentiometer calibrated in terms of the measured quantity. The sum or difference of several like quantities is obtained by interconnecting the retransmitted potentials and determining the algebraic sum.

(*H*). A thermal ammeter or wattmeter system associated with thermocouples develops in the transmitter an electromotive force proportional to the measured magnitude. The thermoelectromotive force, or a voltage or current automatically made proportional to it, is transmitted to the receiving instrument, which may take the form of a recording potentiometer or millivoltmeter.

(*I*). Through the agency of a variable-speed motor controlled by deflection of a measuring element, a centrifugal device is caused to develop a force at all times tending to restore the element to a position of zero displacement. There is thus produced a speed proportional to the square root of the deflecting force. When used in connection with a flow-measuring element of the orifice or venturi class, the speed thus becomes directly proportional to the velocity of flow. Counting trains actuated directly by the motor or through a contactor provide an integration of the total flow.

FREQUENCY SYSTEMS

(*J*). The transmitter includes a basic measuring instrument whose deflection is followed through a photoelectric relay system by a frequency-meter element excited from a variable-frequency oscillator. The signal of the oscillator is transmitted over lines or by carrier current, and received at as many stations as desired. The receiver takes the form of a frequency meter.

POSITION SYSTEMS

(*K*). The transmitting instrument serves to adjust the relative value of two inductances connected in a bridge circuit with similar inductances at the receiving point. When this system is energized by alternating current there is developed a tendency for the receiving unit forcibly to assume a position in which the impedances of the two branches of the circuit are balanced. This force may be used either directly or through a relay to deflect a receiving pointer or pen.

(*L*). The transmitter includes a transformer having one primary and two secondary coils. The measuring element adjusts the ratio of secondary voltages by moving the core of the transformer. The receiving instrument is a self-balancing ratiometer.

(*M*). The transmitter takes the form of a motor structure with one single-circuit and one multicircuit winding. The former winding is energized from an a-c source, and the latter is connected to the receiving instrument through a three-conductor circuit.

(*a*). The receiver is identical with the transmitter, and has a single-circuit winding energized from the same source. The multicircuit winding, connected to the transmitter, receives voltages of relative value governed by the position of the transmitter rotor, causing the receiver rotor to assume the same position.

(*b*). Receiver has a multicircuit stator and an iron-vane rotor, not requiring external excitation.

(*N*). The transmitter embodies a divided circuit whose two branches include oppositely directed rectifying elements in series with resistances whose relative values are varied with the quantity to be measured. This unit is connected through a two-conductor line to the receiver which contains a similarly divided circuit with rectifiers in the respective branches. With an alternating electromotive force applied to the system, any lack of balance between the receiver and transmitter will result in unequal rectification of the two halves of the current wave, which condition is detected by a d-c galvanometer and balanced out by a calibrated slide-wire in the receiver. As an alternative, the receiving instrument may take the form of a direct-deflecting d-c ratiometer. The circuit may be arranged to respond to variations in a single resistance element at the transmitting end and yet be unaffected by changes in the resistance of the connecting line.

IMPULSE SYSTEMS

(*O*). The primary measuring instrument transmits impulses representing changes in the measured quantity. A notching device or the equivalent in the receiving instrument positions a pointer or pen in correspondence with the transmitted impulses. Distinction between impulses in opposite senses may be achieved by (*a*) making respective impulses of opposite polarity; or (*b*) transmitting impulses in one side or other of a three-conductor circuit.

(*P*). An integrating meter (watt-hour meter) controls in the transmitting circuit electrical impulses with a frequency varied in accordance with the measured load. The receiving instrument may be a distant dial providing an integrated reading, a demand dial, or an indicator or recorder. The impulses may be (*a*) successive impulses of the same polarity, (*b*) successive impulses alternating in polarity, (*c*) successive impulses alternating between the two sides of a three-conductor circuit.

(*Q*). The transmitter advances the receiving indicator by a series of similar impulses corresponding in number with the value of the measured magnitude, one impulse being identified by its length as corresponding to the zero position. On increasing values the indicator progressively advances up the scale; and upon a decrease in value the pointer sweeps rapidly around the scale to a position representing the new (and lower) value.

(*R*). The transmitter includes two contacting cams driven by a clock or constant-speed motor. One cam sends impulses at uniform intervals, and the other at intervals spaced therefrom in accordance with the measured magnitude. The time interval between successive signals thus becomes a measure of the telemetered quantity. The impulses may be picked up on a telephone and timed by a stop watch, or may be graphically recorded for reference (see "Audible Indicating Equipment", section III).

(*S*). Two motors, one in the transmitting, and one in the receiving instrument, are automatically maintained in synchronism. A contact mechanism in the transmitter, associated with the primary measuring element, governs the durations of successive impulses in the interconnecting line. The receiving instrument includes contacts that normally operate in synchronism with those at the transmitter. Any variation in the measured load will introduce a change in the relative durations of impulses at the two ends of the system, and this sets up a corrective action at the receiver which tends to restore the synchronism of contacts, and incidentally to reposition the pen or pointer in the receiving instrument.

(*T*). A motor-driven mechanism in the transmitter controls cyclically recurrent impulses in the interconnecting circuit. The durations of successive impulses are governed by the position of the primary measuring instrument. The mechanism of the receiving instrument is driven through a clutch system tending alternately to position the pointer up and down the scale in response to the relative durations of impulses and intervals between. The receiving instrument may be indicating or recording.

(*T* 1). Telemetering method similar to *T*, with audible system, co-ordinated with indicating instrument or timing device at receiving end (see "Audible Indicating Equipment", section III).

21.	Note 1	Simp, comp	No	Yes (note 9)	Simp, comp, carr	Simp, comp, carr	Note 5	No	Note 23	Simp, comp	21.

Interference and Protection Features

22.	Note 1	Note 5	Note 5	Norm 300, SC 1,000	Norm 15 to 60, SC 100	Norm 150, SC 150	Norm 20, SC 500	Norm 20, SC 500	Note 5	Norm 30, SC 30	22.
23.	Note 1	L-L 0.1, L-G 0	L-L 115, L-G 115	L-L 115, L-G 115	L-L 6 to 135	L-L 50, L-G 50	L-L 125	L-L 126	Note 5	L-L 120, L-G 60	23.
24.	*T1*	*H*	*N*	*K*	*T*	*O*	*T*	*O*	*P*	*A*	24.
25.	39	45	44	18, 28*d*	19, 28*e*					18, 28*a*, 40	25.

Note 1. Apparatus being intended for use only with standard telephone systems, special circuit considerations not involved.

Note 2. Power supply ordinarily required at both ends; but provision may be made for transmitting power to one unit over the telemetering line.

Note 3. Relays used only when telemetering circuit also carries power for operating instrument.

Note 5. Data not available.

Note 6. System includes provision for maintaining synchronism between transmitter and receiver.

Note 7. Possible under favorable conditions, but not generally recommended.

Note 8. Requires modified form, or auxiliary apparatus.

Note 9. May be simplexed in special cases.

Note 10. Response practically instantaneous, so far as concerns applications for which this system is intended.

Note 15. Will introduce no error in demand reading, but will affect registration of integrating dials.

Note 20. Power derived from circuit under measurement.

Note 23. This manufacturer does not supply receiving equipment for this type of telemetering apparatus.

Note 24. Time of response subject to type of receiving instrument used.

8.	Maximum number of stations recommended for parallel operation over one group of communication circuits (see item 20)	Variable according to conditions	4	25	1 (radial)	8.
9.	Power requirements					9.
	(*a*) Dispatching station	24 to 125 v d-c	115 v a-c from station service or from 200-w motor generator set	115 v a-c from station service or from small motor generator set	60-cell battery 24 v a-c or d-c	(*a*)
	(*b*) Distant station	24 to 125 v d-c	115 v a-c from station service or from small motor generator set; d-c also desirable	Same as (*a*) with d-c desirable	60-cell battery	(*b*)
10.	Time required to select and check					10.
	(*a*) 10th unit	Time required for any unit varies with length of dialed signal. Generally 3 to 5 sec	6 sec	3 sec	1 sec	(*a*)
	(*b*) 20th unit		6 sec	6 sec	2 sec	(*b*)
11.	Having selected unit, can it be operated repeatedly without again performing selecting operation	If required	No	No	Yes	11
12.	Is automatic indication given to dispatcher					12.
	(*a*) Line open	Yes	Yes	Yes	Yes	(*a*)
	(*b*) Line short	Yes	Yes	Yes	Yes, except one combination	(*b*)
	(*c*) Line ground	Manual test only	Yes	Yes	No	(*c*)
13.	Can telephone conversation be carried over same communication circuit, intermittent or continuous	If required	Yes	Yes	Continuous supervisory calling	13.
14.	Is selective telemetering possible over same communication circuits	No such application as yet	Yes	Yes	Yes	14.
15.	Is remote manual synchronization possible over same communication circuits	Yes	Yes, but automatic synchronizing equipment at controlled station with remote indications of freq diff recommended	Yes, but automatic synchronizing equipment with indications at dispatching point of which freq is high (or low) recommended	Yes	15.
	Characteristics Affecting Line Transmission					
16.	Maximum number impulses per second	13	Impulse system not used	Impulse system not used	10	16.
17.	Is neutral or polar relay used	Yes	For receiving indications only	Yes	Polar	17.
18.	Maximum allowable loop resistance	2,500 w	No practical limit	3,000 ohms	3,000 ohms	18.
19.	Minimum allowable insulation resistance	20,000 w between wires and/or ground			1.0 megohms	19
20.	Number of conductors	2, 3, or 4	2	2	4	20.
21.	Possibility of using ground as a conductor	System is automatically operable over ground in event of break in conductor	Yes	Yes	No (note *b*)	21.
22.	Possibility of using superposed circuit as conductor					22.
	(*a*) Simplex	No such study or application as yet	Neutral current system recommended for use of the equipment over a power transmission system	Neutral current system recommended for use of the equipment over a power transmission line	No	(*a*)
	(*b*) Composite				No	(*b*)
	(*c*) Carrier				No	(*c*)
23.	Can system operate through insulating transformers	No	Yes	Yes	No	23.
	Interference and Protective Features					
24.	Normal line current	0.012 amp at 125 d-c	20 ma	20 ma	15–30 mils (note *c*)	24.
25.	Maximum line current on short circuit	0.018 amp at 125 d-c	500 ma	500 ma	350 mils	25.
26.	Maximum line volts					26.
	(*a*) Between wires	24 v with 125 d-c system	24 v	24 v standard	135 v d-c	(*a*)
	(*b*) To ground	0			Note *b*	(*b*)
	How is system protected from electrostatic and electromagnetic induction when exposed to high potential circuits	Standard current-connecting devices, surge arresters, and circuit design	Vacuum-protector tubes	Vacuum-protector tubes	Lightning arr. or tuned reactor - capacitor drainage	27.

Table II. Characteristics of Supervisory-Control Systems (continued)

1.	General Electric	General Electric	General Electric	General Electric	Westinghouse	Westinghouse	1.
2.	Code Selector	Five Point	Audible Selector	Audible Indicating System	Audicode	Caricode	2.
3.	Code	Code	Audible freq code (note *d*)	Audible freq code (telephone calling)	Code by dial	Code (visual)	3.
4.	Code	Code	Audible freq code		Audible code	Code (visual)	4.
5.	Single polar impulse	Single polar impulse	Audible freq impulse (note *d*)		Code by dial	Code (visual)	5.
6.	Single polar impulse	Single polar impulse	Two-tone audible freq code	Audible freq code	Audible code	Code (visual)	6.

Characteristics of System

7 (*a*)	128	5	17	11	20	100 units (appr)	7 (*a*)
(*b*)	Unlimited	5	17	11	Unlimited	Unlimited	(*b*)
8.	1 (radial)	1 (radial)	5	1 (radial)	5	5, but not limited	8.
9.							9.
(*a*)	60-cell battery	48 v d-c	60-cell battery 12 v d-c	None	48 v d-c	48 v d-c	(*a*)
(*b*)	60-cell battery	48 v d-c	24-cell battery	24-cell battery	48 v d-c	48 v d-c	(*b*)
10.							10.
(*a*)	2–3 sec		11 sec	(Telephone calling time plus 5 sec per unit accumulative)	3 sec	2.0 sec	(*a*)
(*b*)	2–3 sec				6 sec	2.6 sec	(*b*)
11.	Yes	Yes	Yes	No	Yes	Yes	11.
12.							12.
(*a*)	Yes, unless insulating transformers are used	No	No	No	Yes		(*a*)
(*b*)	No	No	No	None	Yes	No lines	(*b*)
(*c*)		No	No		No; can be supplied		(*c*)
13.	Continuous, supervisory calling	Continuous, supervisory calling	Continuous on selected point	Continuous, disconnects code equipment	Yes	Yes, if channel permits	13.
14.	Yes	Yes	Yes (note *e*)	No	Yes	Yes	14.
15.	No	No	No		Yes	No; use automatic synchronizer	15.

Characteristics Affecting Line Transmission

16.	10	10	5		8	13	16.
17.	Polar	Polar	Polar		No	No	17.
18.	3,500 ohms	2,500 ohms	1,000 ohms	Note *a*	4,000 ohms		18.
19.	0.1 megohms	0.1 megohms	0.1 megohms	Note *a*	0.5 megohm		19.
20.	2	2	2	Note *a*	Two	1 carrier channel	20.
21.	No (note *b*)	No (note *b*)	No (note *b*)	Note *a*	Yes; not recommended	Yes	21.
22.							22.
(*a*)	Yes	Yes	Yes	Note *a*	Yes	No	(*a*)
(*b*)	Yes	Yes	Yes	Note *a*	Yes	No	(*b*)
(*c*)	Yes	Yes	Yes	Note *a*	Yes	Yes	(*c*)
23.	Yes	Yes	Yes	Yes	Yes; not recommended	Yes; included in line-timing equipment	23.

Interference and Protective Features

24.	15–30 mils (note *c*)	15–30 mils (note *c*)	15–30 mils (notes *c*, *f*), 1.5 mils (note *d*)	Note *a*	0.025 amp	None	24.
25.	350 mils	350 mils	350 mils	Note *a*	0.055 amp		25.
26.							26.
(*a*)	135 v d-c	50 v	120 v a-c (note *d*) and 135 v d-c	Note *a*	55 v		(*a*)
(*b*)	Note *b*		Note *b*		Ungrounded, 350 v		(*b*)
27.	Lightning arr. or tuned reactor-capacitor drainage	Lightning arr. or tuned drainage	Lightning arr. and insulating transformers	Lightning arr. and insulating transformers	Standard drainage where required and protective tube	This system may be connected to high-potential circuits	27.

Note *a*. Circuit requirements determined by standard telephone practice.

Note *b*. Use of ground on telephone system not recommended where supervisory battery may be directly connected to communication circuits.

Note *c*. Polar impulse.

Note *d*. 200–400 cycles (uses d-c impulses when going through telephone exchange for selection and control.

Note *e*. When insulating transformers are not present.

Note *f*. 200–400 cycles, on open-wire line only.

Table II. Characteristics of Supervisory-Control Systems (concluded)

1.	Manufacturer	Westinghouse	Westinghouse	Westinghouse	Westinghouse	1.
2.	Trade name	Self-Checking System	Visicode	Polaricode, Jr.	Polaricode	2.
3.	Method of selection	Code	Code (visual)	Code (visual)	Code (visual)	3.
4.	Method of checking selection	None required	Code (visual)	Code (visual)	Code (visual)	4.
5.	Method of operation	Code	Code (visual)	Code (visual)	Code (visual)	5.
6.	Method of indication	Code	Code (visual)	Code (visual)	Code (visual)	6.
	Characteristics of System					
7.	(*a*) Maximum number of units recommended for one system	Unlimited	100 units (appr)	5	Unlimited	7 (*a*)
	(*b*) Normal physical limitation of number of units	Unlimited	Unlimited	5	Unlimited	(*b*)
8.	Maximum number of stations recommended for parallel operation over one group of communication circuits (see item 20)	Unlimited; codes are not duplicated in stations of one system	5 but not limited	1	1	8.
9.	Power requirements					9.
	(*a*) Dispatching station	48 v d-c	48 v d-c	48 v d-c	48 v d-c	(*a*)
	(*b*) Distant station	48 v d-c	48 v d-c	48 v d-c	48 v d-c	(*b*)
10.	Time required to select and check					10.
	(*a*) 10th unit	Same for all points; depends on total number	2.0 sec	5 points max	2.5	(*a*)
	(*b*) 20th unit		2.6 sec		2.5	(*b*)
11.	Having selected unit, can it be operated repeatedly without again performing selecting operation	Yes	Yes	Yes	Yes	11.
12.	Is automatic indication given to dispatcher					12.
	(*a*) Line open	Yes	Yes	Yes		(*a*)
	(*b*) Line short	Yes	Yes	Yes	Yes, if required	(*b*)
	(*c*) Line ground	No; can be supplied	No; can be supplied	No; can be supplied		(*c*)
13.	Can telephone conversation be carried over same communication circuit, intermittent or continuous	Yes	Yes	Yes	Yes	13.
14.	Is selective telemetering possible over same communication circuits	Yes	Yes	Yes	Yes	14.
15.	Is remote manual synchronization possible over same communication circuits	Yes except when carrier channel is used	Yes	Yes	Yes	15.
	Characteristics Affecting Line Transmission					
16.	Maximum number impulses per second	6	13	8	10	16.
17.	Is neutral or polar relay used	No	No	No	No, rectox valve with std relay	17.
18.	Maximum allowable loop resistance	4,000 ohms	4,000 ohms	4,000 ohms	2,000 ohms	18
19.	Minimum allowable insulation resistance	0.5 megohm	0.5 megohm	0.5 megohm	0.5 megohm	19.
20.	Number of conductors	2	2	2	2	20.
21.	Possibility of using ground as a conductor	Yes; not recommended	Yes; not recommended	Yes; not recommended	Yes; not recommended	21.
22.	Possibility of using superposed circuit as conductor					22.
	(*a*) Simplex	Yes	Yes	Yes	Yes; not recommended	(*a*)
	(*b*) Composite	Yes	Yes	Yes	No	(*b*)
	(*c*) Carrier	Yes	Yes	Yes	No	(*c*)
23.	Can system operate through insulating transformers	No	No	No	No	23.
	Interference and Protective Features					
24.	Normal line current	0.025 amp	0.025 amp	0.025 amp	None at rest; 0.025 amp operating	24.
25.	Maximum line current on short circuit	0.055 amp	0.055 amp	0.055 amp	0.055 amp	25.
26.	Maximum line volts					26.
	(*a*) Between wires	55 v	55 v	55 v	55 v	(*a*)
	(*b*) To ground	350 v ungrounded	350 v ungrounded	350 v ungrounded	350 v ungrounded	(*b*)
27.	How is system protected from electrostatic and electromagnetic induction when exposed to high potential circuits	Standard drainage where required and protective tube	Standard drainage where required and protective tube	Standard drainage where required and protective tube	Standard drainage where required and protective tube	27.

40. Telemeter Steam and Electricity on Indianapolis System, **T. W. Ayton.** *Electrical World*, August 26, 1939, page 584.

41. The Metameter System of Telemetering, **F. B. Bristol** and **G. S. Lunge.** *General Electric Review*, November 1939, page 584.

42. Carrier Telemetering Simplifies Dispatching, **H. L. Durgin.** *Electrical World*, December 16, 1939, pages 36–7.

43. Carrier Telemetering With the Metameter, **G. S. Lunge.** *General Electric Review*, August 1940, page 336.

44. The Uehling Telemetering System, **A. W. Jacobson.** Thesis, Yale School of Engineering, 1940.

45. A New High-Speed Thermal Wattmeter, **J. H. Miller.** AIEE Transactions, volume 60, 1941 (January section), pages 37–40.

46. Sun-Spot Disturbances of Terrestrial Magnetism, **W. F. Davidson,** Electrical Engineering, volume 60, February 1941, pages 72–5. Bibliography.

A general picture of comparative telemetering practice in various countries may be obtained by perusal of the following books:

Electric Power Metering, **A. E. Knowlton.** McGraw-Hill, 1935. Chapter 17. American.

Industrial Electrical Measuring Instruments, **K. Edgcumbe** and **F. E. J. Ockenden.** Pitman 1933. Chapter 22. British.

Die Technik der Fernwirkanlagen, **W. Stablein.** Oldenbourg, Munich, 1934. Bibliography of over 500 references, 40 per cent of which are articles published in English. German.

Remote Measuring Instruments and Present Status of Practical Applications in Japan, **S. Jimbo** and **J. Okajima.** Circular Number 100, Electrotechnical Laboratory of Japan, March 1935. Japanese.

A number of telemetering systems that have application in France are treated in more or less detail in the following papers:

Transmission Electrique à Distance "Telect.", **M. Vassiliere.** *Bulletin* Société Française des Electriciens, 1931, pages 629–32.

Téléindicateur de Niveau ou de Position, **J. Laisne.** *Revue Générale de l'Electricité*, April 25, 1931, page 665.

Perfectionnements dans les Dispositifs de Télémésure, **A. Iliovici.** *Bulletin* Société Française des Electriciens, 1936, pages 826–44.

Nouveaux Dispositifs de Télémésure, **J. Pelpel.** *Bulletin* Société Française des Electriciens, 1938, pages 933–47.

Le Réglage Centralisé de la Fréquence et de la Puissance dans la Région Parisienne, **J. Fallou.** *Revue Générale de l'Electricité*, January 15, 1938, pages 67–77.

A comprehensive treatment of the subject of telemetering in the Swedish language is found in an article by **E. Velander,** appearing on pages 81–8 of "Elektroteknik" Supplement 5, May 1931, to *Teknisk-Tidskrift*, May 2, 1931, as part of a symposium on Remote Metering and Remote Control.

Bibliography of Relay Literature 1927–1939

Section A

Line Protection—Distance

1928

1. The Impedance Relay, **H. A. McLaughlin** and **E. O. Erickson.** AIEE Transactions, volume 47, 1928, pages 776–82.

2. A Study of Transmission-Line Power Arcs, **Paul Ackerman.** *Engineering Journal* (Canada), May 1928, page 309.

1931

3. Connections for Distance Relays (in German), **E. Gross.** Verband Deutscher Elektrotechniker *Fachberichte*, 1931, pages 88–91.

4. The Development of Distance Relaying (in German), **M. Walter.** Verein Deutscher Ingenieure *Zeitschrift*, volume 75, December 26, 1931, pages 1555–8.

5. Fundamental Basis for Distance Relaying on Three-Phase Systems, **W. A. Lewis** and **L. S. Tippett.** Electrical Engineering, volume 50, June 1931, pages 420–2.

6. Operating Experience With Reactance-Type Distance Relays, **E. E. George.** AIEE Transactions, volume 50, 1931, pages 288–93; discussion page 293.

1932

7. Application of Impedance Relays for Relay Study, **L. S. C. Tippett.** Institution of Engineers (Australia) *Journal*, volume 4, number 1, January 1932, page 22.

8. Behavior of Distance Relays During Hunting (in German), **M. Walter.** *Electrotechnik und Maschinenbau*, volume 50, number 17, April 24, 1932, pages 261–3.

9. Design of Distance-Relay Protection (in Russian), **A. Barzam.** *Electritchestvo* (Moscow), number 21, part 1, November 1932, pages 1212–25.

10. Directional Element of Distance Relays (in German), **M. Walter.** *Elektrotechnische Zeitschrift*, volume 53, number 20, May 19, 1932, pages 476–9. Details of construction of the directional part of distance relays.

11. Distance-Relay Protection (in German), **M. Walter.** *Electrizitaetswirtschaft*, volume 31, numbers 8 and 9, April 30, 1932, pages 172–6; May 15, 1932, pages 199–202. Description of single-, double-, and triple-pole distance-relay combinations.

12. High-Speed Impedance Relay (in German), **H. Neugebauer and F. Geise.** *Siemens Zeitschrift*, volume 12, number 2, February 1932, pages 47–51. Relay that functions as quick-acting impedance relay until pull-out point and after that as standard impedance relay with linear time-distance characteristic.

13. New Distance Relay for the Protection of High-Voltage Overhead Lines (in French), **R. Dubusc** and **P. Douce.** *Revue Générale de l'Electricité*, volume 31, numbers 8 and 9, February 20, 1932, pages 251–9; February 27, 1932, pages 282–92. Reactance distance-relay description.

14. New High-Speed Distance Relay, **S. L. Goldsborough** and **W. A. Lewis.** Electrical Engineering, volume 51, number 3, March 1932, pages 157–60. Distance relay for short lines essentially unaffected by fault resistance.

15. Protection of Stations by Distance Relays, **A. Doret Matthey.** *Brown Boveri Review*, volume 19, number 7, December 1932, pages 205–09.

16. Short-Circuit Arc in Three-Phase Systems and Its Influence on the Operation of Distance Relays (in German), **M. Walter.** *Elektrotechnische Zeitschrift*, volume 53, number 44, November 3, 1932, pages 1056–9.

17. Three-Phase Reactance Protection (in German), **H. Polek.** *Siemens Zeitschrift*, volume 12, number 11, November 1932, pages 386–94.

1933

18. A High-Speed Reactance Relay, **A. R. V. Warrington.** Electrical Engineering, volume 52, April 1933, pages 248–52. (Advance abstract volume 51, number 6, June 1932, page 410.)

1934

19. Control of Distance-Relay Potential Connections, **A. R. V. Warrington.** AIEE Transactions, volume 53, 1934 (January section), pages 206–13; discussion (March section), pages 465–6, and (April section), page 617.

20. Distance-Relay Action During Oscillations, **E. H. Bancker** and **E. M. Hunter.** AIEE Transactions, volume 53, 1934 (July section), pages 1073–80; discussion, volume 53, 1934 (September section), pages 1320–2; volume 54, 1935 (February section), pages 216–18.

21. New Development in Distance-Protection Arrangements (in German), **E. Gross.** *Electrotechnik und Maschinenbau*, volume 52, numbers 51 and 52, December 23, 1934, pages 597–602; December 30, 1934, pages 612–16. New connections for distance relays.

1935

22. High-Speed Distance Relay, **L. N. Crichton.** *Electric Journal*, volume 32, number 12, December 1935, pages 537–42. Type *HCZ* relay.

23. Impedance Protective Systems, *Electrician* (London), volume 115, November 15, 1935, page 609; November 22, 1935, page 642; November 29, 1935, page 677; December 6, 1935, page 717.

24. Instantaneous Overcurrent Relays for Distance Relaying, **C. H. Frier,** AIEE Transactions, volume 54, 1935 (April section), pages 404–07; discussion (August section), pages 883–4. Use of instantaneous overcurrent relays on Oklahoma Gas and Electric Company system.

1936

25. New Impedance Relay for Intermediate Voltages, **R. Dubusc.** Société Française des Electriciens *Bulletin*, volume 6, August 1936, page 855.

26. Performance of Distance Relays, **G. Calabrese.** AIEE Transactions, volume 55, 1936 (June section), pages 660–72; discussion (November section), page 1254.

1937

27. Comprehensive Method of Determining the Performance of Distance Relays, **J. H. Neher.** AIEE Transactions, volume 56, 1937 (July section), pages 833–44; discussion (December section), page 1515.

28. Development of Step Protection (in German), **W. Schmundt.** *Elektrizitaetswirtschaft*, volume 36, number 18, June 25, 1937, pages 424–6.

29. High-Speed Protective Relay, Type *R-Z*4, **H. Neugebauer.** *Siemens Review* (in English), volume 13, number 3, 1937, pages 65–71.

A working group* of the relay subcommittee of the AIEE committee on protective devices has reviewed the available indexes and compiled this list of articles dealing with relaying and closely related subjects. These articles include all those appearing in the AIEE Transactions or Electrical Engineering from January 1927 through December 1939 and most of those in the chief technical publications of the world from January 1932 through December 1939. These articles are subdivided into several sections. In each section the entries are numbered consecutively and listed alphabetically by years, the first significant word of the title determining the alphabetical position. This bibliography was published in pamphlet form by the AIEE during 1941.

* **Working Group:** J. H. Neher, *chairman;* E. H. Bancker, W. R. Brownlee, L. N. Crichton, G. W. Gerell, H. F. Lindemuth, C. A. Muller, George Steeb, and R. M. Wood.

30. Influence of Wye-Delta Transformation on Distance Protection of High-Voltage Systems (in German), **E. Gross.** *Electrotechnik und Maschinenbau*, volume 55, number 28, July 11, 1937, pages 333–8.

31. New Antipumping Distance Relay (in French), **R. Dubusc.** Société Française des Electriciens *Bulletin*, volume 7, number 77, May 1937, pages 533–61.

32. Single-System Line Protection, **A. Thewalt.** *Siemens Review* (in English), volume 8, number 3, 1937, pages 59–65. Direct comparison protection.

1938

33. Distance Relays Solve Interconnection Problem, **H. H. Brown.** *Electric Light and Power*, volume 16, number 4, April 1938, pages 63–6.

1939

34. High-Speed Impedance Protection, *Electrician* (London), volume 122, March 10, 1939, page 313; March 17, 1939, page 343; March 24, 1939, page 373.

Section B

Line Protection—Pilot Wire and Carrier Current

1931

1. Principles of Feeder-Protection and Their Application to Three Modern Systems (in French), **B. H. Leeson and H. Leben.** International Conference on Large High-Tension Electric Systems *Report* of sixth session, 1931, volume 3, pages 767–800. Description of Merz-Price, split-pilot, interlock, and ratio-balance systems as applied in England.

2. Relaying With Two Pilot Wires, **C. H. Frier.** Electrical Engineering, volume 50, October 1931, pages 824–6.

1932

3. Carrier-Current Relaying Proves Its Effectiveness, **P. Sporn** and **C. A. Muller.** *Electrical World*, volume 100, number 11, September 10, 1932, pages 332–6. Description of first installation tests of directional-type carrier-pilot relaying.

4. D-C Pilot-Wire Systems of Relay Protection, **C. M. Longfield.** *Metropolitan-Vickers Gazette*, volume 13, number 236, December 1932, pages 417–22.

5. Pilot Protection by Power Directional Relays, **O. C. Traver, J. Auchincloss,** and **E. H. Bancker.** *General Electric Review*, volume 35, number 11, November 1932, pages 566–70. Description of pilot-relaying principles using directional relays and wire or carrier channel.

6. Supervisory Pilot-Wire Relaying—Modified Form of Pilot-Wire Relay Circuit to Eliminate Cascaded Timing in Transmission-Line Protection, **G. M. Babcock.** *Electrical West*, volume 68, number 6, May 15, 1932, pages 337–9.

1933

7. Carrier-Current Relaying Simplified, **P. Sporn** and **C. A. Muller.** *Electrical World*, volume 102, October 28, 1933, pages 556–60.

8. Combined Ground-Bus and Pilot-Wire Protection, **L. N. Moore.** *Electrical World*, volume 102, November 25, 1933, pages 693–4.

9. D-C Pilot-Wire Loop Protects 66-Kv Cable Circuits, **J. H. Neher.** *Electrical World*, volume 101, March 25, 1933, pages 384–7.

10. Use of Communication Facilities in Transmission-Line Relaying, **J. H. Neher.** AIEE Transactions, volume 52, 1933, pages 595–602.

1934

11. For Better Use of Investment in Coupling Capacitors, **F. B. Doolittle.** *Electrical World*, volume 103, number 7, February 17, 1934, pages 256–7. For carrier-current relay protection.

12. Carrier Control Isolates Trouble on Tap Lines, *Electrical World*, volume 103, March 31, 1934, page 469.

13. Carrier-Current Pilot Protection (in German), **H. Neugebauer.** *Siemens Zeitschrift*, volume 14, number 3, March 1934, pages 83–8.

1935

14. Carrier-Current—One-Cycle Carrier Relaying Accomplished, **P. Sporn** and **C. A. Muller.** *Electrical World*, volume 105, number 21, October 12, 1935, pages 26–8. Notes on new developments, etc.

15. Carrier-Current Relay Installation, **O. A. Browne** and **W. L. Vest, Jr.** AIEE Transactions, volume 54, 1935 (January section), pages 109–15; discussion (March section), pages 333–4; (May section), pages 558–9.

16. Pilot-Wire Relay Protection, **E. E. George** and **W. R. Brownlee.** AIEE Transactions, volume 54, 1935 (November section), pages 1262–9.

1936

17. Faster Carrier-Pilot Relay System, **O. C. Traver** and **E. H. Bancker.** AIEE Transactions, volume 55, 1936 (June section), pages 688–96; discussion (November section), page 1252–4.

18. New Pilot Protection Gives Reliability, **Lloyd F. Hunt.** *Electrical World*, volume 106, September 26, 1936, page 3007. Simple lockout system uses existing telephone wires instead of carrier current for pilot-protection high-speed relay system.

19. Neutralizing Transformer to Protect Power-Station Communication, **E. E. George, R. K. Honaman, L. L. Lockrow,** and **E. L. Schwartz.** AIEE Transactions, volume 55, 1936 (May section), pages 524–9.

20. Uses of Carrier Current, **M. E. Reagan.** *Electric Journal*, volume 33, number 6, June 1936, page 276.

1937

21. Recent Progress in Carrier-Current Relaying (in French), **F. Cahen.** Société Française des Electriciens *Bulletin*, volume 7, number 79, July 1937, pages 725–65.

1938

22. Application and Performance of Carrier-Current Relaying, **P. Sporn** and **C. A. Muller.** AIEE Transactions, volume 57, 1938 (March section), pages 118–24; discussion (May section), pages 281–4.

23. Carrier Current on Power Systems, **O. Richardson.** *Communications*, July 1938, pages 19–22; *Electrical News and Engineering* (Canada), September 15, 1938, pages 35–8. Coupling methods; types of equipment; carrier-pilot relaying; variable carrier-frequency system.

24. Carrier-Current Protection, *Electrician* (London), volume 121, July 1, 1938, page 17; July 8, 1938, page 43; July 15, 1938, page 71; July 22, 1938, page 102; July 29, 1938, page 131.

25. Carrier Relaying Cuts Line Outages, *Electrical World*, volume 110, July 2, 1938, page 64.

26. Directional-Current Comparative Protection (in

German), **F. Jahn** and **H. Gutmann.** *Elektrizitaetswirtschaft,* volume 37, number 5, February 15, 1938, pages 113–16.

27. A New High-Speed Distance-Type Carrier-Pilot Relay System, **E. L. Harder, B. E. Lenehan,** and **S. L. Goldsborough.** AIEE Transactions, volume 57, 1938 (January section), pages 5–10. Discussion (May section), pages 291–4

28. Pilot-Wire Relaying Gives Tie-Line Protection, **T. T Smith.** *Electrical World,* volume 109, number 1, Jauary 1, 1938, pages 39 and 90.

29. Selective Protection of Transmission Lines by Carrier Current (in French), **F. Cahen.** *Electricité* (Paris), volume 22, number 47–48, July–August 1938, pages 251–4.

30. Single-Element Differential Pilot-Wire Relay System, **E. L. Harder** and **M. A. Bostwick.** *Electric Journal,* volume 35, number 11, November 1938, pages 443–8.

1939

31. Boulder Dam Transmission Line; Carrier-Current Equipment, **J. D. Laughlin.** AIEE Transactions, volume 58, 1939 (April section), pages 147–51.

Section C

Line Protection—Ground Faults

1931

1. Relay Protection on High-Resistance Grounded Systems (in French), **T. Wajima.** International Conference on Large High-Tension Electric Systems *Report* of sixth session, June 1931, volume 3, pages 733–42. Report of sensitive ground relaying in Japan.

1932

2. The Permissible Sensitivity of Ground-Current Relays in High-Voltage Systems (in German), **E. Gross** and **W. Weller.** *Electrotechnik und Maschinenbau,* volume 50, February 1932, pages 117–23.

1933

3. Ground Protection of Rural Lines, **J. W. Graff.** *Electrical World,* volume 102, December 1933, pages 787–9.

4. Zero-Sequence Current Transformers for Ground Protection, **J. W. Graff.** *Electrical World,* volume 102, December 1933, pages 822–3.

1934

5. Earth-Leakage Protection at Daggafontein Mines, **N. H. Auret.** *Electrician* (London), volume 113, August 1934, pages 157–8. Installation and operating results.

6. New Methods of Ground-Fault Protection, **F. M. Starr.** AIEE Transactions, volume 53, 1934 (November section), pages 1472–7.

7. Simple Ground Relaying Trips Rural Feeders, **J. F. Pennington** and **J. T. Logan.** *Electrical World,* volume 104, July 1934, page 111.

1935

8. Earth-Fault Problems in Large Cable Networks, **E. Schultze.** *AEG Progress,* volume 1, 1935, pages 11–15. Use of Petersen coil in Berlin system.

9. General Electric Ground-Detector Relay, *General Electric Review,* volume 38, March 1935, page 154.

10. Leakage Relays—the Performance of Current Transformers, **G. W. Stubbings.** *Electrical Review* (London), volume 117, October 1935, pages 564–5.

11. Neutral Power Relay Clears Faulted Cable, *Electrical World,* volume 105, August 1935, page 1926.

12. Neutral Relay, **H. G. Bullen.** *Electrical Review* (London), volume 117, September 1935, page 366.

1936

13. New Distance Ground Relay, **S. L. Goldsborough** and **R. M. Smith.** AIEE Transactions, volume 55, 1936 (June section), pages 697–703; discussion, volume 55, 1937 (November section), pages 1255–6.

1937

14. Characteristics of Power-System Faults to Ground, Edison Electric Institute *Bulletin,* volume 5, May 1937, pages 197–8.

15. Ground Protection in the Vienna High-Voltage System (in German), **E. Lippa.** *Electrotechnik und Maschinenbau,* volume 55, May 1937, pages 233–8 and 249–52.

16. Ground Relaying Economical, **C. B. Carpenter.** *Electrical World,* volume 107, February 1937, page 541.

17. Leakage-Trip Protection; Operation and Use for Various Purposes, *Electrical Review* (London), volume 120, April 1937, pages 652–3.

18. Wrong Ground-Relay Connections Caught, **G. W. Stubbings.** *Electrical World,* volume 107, June 1937, page 2198.

1938

19. Double Short-Circuit Protection Against Ground (in German), **A. Thewalt.** *Siemens Zeitschrift,* volume 18, July 1938, pages 355–61.

1939

20. Directional-Overcurrent Ground Relaying; Use of Negative-Sequence Filters, **B. V. Hoard** and **S. C. Leyland.** *Electric Journal,* volume 36, March 1939, pages 97–101.

21. Earth-Leakage Relays; With Use of Ring-Type Current Transformers, **E. T. B. Gross.** *Electrician* (London), volume 123, July 1939, pages 93–5.

22. Feeder Protection; Vagaries of Earth-Leakage System, **J. Gray.** *Electrical Review* (London), volume 125, July 1939, pages 125–42.

23. Ground-Fault Protection in a Modern Plant, **A. F. Hartung.** *Electrical World,* volume 112, November 1939, page 1295.

24. Induced Current in Parallel Circuits and Its Effect Upon Relays, **E. H. Bancker.** AIEE Transactions, volume 58, 1939 (November section), pages 582–5.

Section D

Line Protection—General

1931

1. Feeder Protection; the Pilotless Interlock System, *Electrical Review* (London), volume 109, November 20, 1931, page 771.

2. The Protection of Overhead Lines and Feeders (in French), **H. W. Clothier.** International Conference on Large

High-Voltage Electric Systems *Report* of sixth session, 1931, volume 3, pages 901–04. Protection of 132-Kv British Grid.

3. Relay Protection for a Closed Linked System, **T. G. LeClair.** Electrical Engineering, volume 50, July 1931, pages 471–6.

4. Selective Protection for Long High-Voltage Lines (in German), **R. Schimph.** Verband Deutscher Elektrotechniker *Fachberichte*, 1931, pages 86–8.

1932

5. Application of High-Speed Relays to 66- and 132-Kv System of Union Electric Light and Power Company (abstract), **G. W. Gerell.** Electrical Engineering, volume 51, June 1932, page 411.

6. Faults and Their Clearance on Large Networks, **O. Kapp** and **C. G. Carrothers.** Institution of Electrical Engineers (London) *Journal*, volume 71, number 341, November 1932, pages 685–702.

7. Ground and Distance Relays, the Trend in Practice, *Electrical World*, volume 99, number 9, February 27, 1932, pages 398–402.

8. High-Speed Relays, **L. F. Hunt.** *Electrical West*, volume 68, number 6, May 15, 1932, pages 339–41. Report of a subcommittee of electrical apparatus committee of Pacific Coast Electric Association on two high-speed relays in use on member companies' lines.

9. Line Protection, **A. Heydorn.** South African Institute of Electrical Engineers *Transactions*, volume 23, part 3, March 1932, pages 57–63. Outline of methods.

10. New Overcurrent Relay, **S. L. Goldsborough** and **R. M. Smith.** *Electric Journal*, volume 29, number 2, February 1932, pages 78–80. Development of relay with straight line characteristic.

11. Power Directional-Relay Applications, **J. P. Price.** *Electrical West*, volume 68, number 1, January 1, 1932, pages 7–8. Article on connections of directional relays.

12. Protection and Centrovisory Control of the British Grid, **B. H. Leeson.** *Electrical Review* (London), volume 110, April 22, 1932, page 598.

13. Protective Devices, Pacific Coast Electric Association Overhead Systems Committee. *Electrical West*, volume 68, number 6, May 15, 1932, pages 431–8.

14. Relay Scheme for Preferential Feeder Control, **C. W. Jones.** *Electrical World*, volume 99, number 8, February 20, 1932, pages 375–6.

15. Relaying in Chicago Region, **R. C. Erickson.** *Electric Light and Power*, volume 10, number 11, November 1932, pages 10–12. Protection used on "red", "blue", and "green" networks feeding the Chicago area.

1933

16. Directional Relays, **G. W. Stubbings.** *Electrical Review* (London) volume 113, October 27, 1933, page 586.

17. Relaying of High-Voltage Interconnections, **H. P. Sleeper.** Electrical Engineering, volume 52, June 1933, pages 402–09.

18. Ring Main Feeder Protection, *Engineer* (London), volume 155, February 3, 1933, pages 122–3.

1934

19. Automatic Protective Gear for A-C Supply Systems (book), **J. Henderson.** Pitman Publishing Company, New York City, 1934, 201 pages. Practical experiences of author in transmission-line protection in Great Britain.

20. Modern Protective Gear, **C. C. Garrard.** *Electrical Review* (London), volume 115, number 2971, November 2, 1934, page 598. Elimination of time elements discussed; opposing requirements; carrier-current communication; calibration curves of distance relays for overhead line protection.

21. The Regulation of Time-Delay Relays in Electric Distribution Networks (in French), **A. DuBois.** *Revue Générale de l'Electricité*, volume 35, number 26, June 30, 1934, pages 883–6.

22. Selective Protection of Networks Against Accidental Faults (in French), **R. V. Genkin.** *Industrie Electrique*, volume 43, number 999, February 10, 1934, pages 57–8.

23. Some Recent Relay Developments, **L. F. Hunt** and **A. A. Kroneberg.** AIEE Transactions, volume 53, 1934 (April section), pages 530–5. Southern California Edison system; high-resistance faults; carrier; out-of-step conditions.

24. Speedier Switching Isolates Faults on 110-Kv System, **W. M. Edson** and **R. E. Walsh.** *Electrical World*, volume 104, number 6, August 11, 1934, pages 170–2.

25. Transfer Feeder Faults to One Breaker, **L. F. Woodruff** and **J. E. Mulligan.** *Electrical World*, volume 103, number 13, March 31, 1934, pages 464–5. Fault transfer switch.

1935

26. Engineering Features of Boulder Dam—Los Angeles Lines, **E. F. Scattergood.** AIEE Transactions, volume 54, 1935 (May section), pages 494–512.

27. Fault and Out-of-Step Protection of Lines, **H. D. Braley** and **J. L. Harvey.** AIEE Transactions, volume 54, 1935 (February section), pages 189–200; discussion (February section), pages 197–9. Stability in relation to short circuit protection requirements.

28. Protection of Lines in Case of Fault and Falling Out of Step of Power Plants; Various Examples From German and American Experience (in German), **F. Cornelsen.** *Elektrotechnische Zeitschrift*, volume 56, number 35, August 29, 1935, pages 963–6.

29. Relays for Protecting A-C Circuits, *Engineer* (London), volume 160, number 4150, July 26, 1935, pages 88–9. Illustrated description of series of new relays capable of meeting various requirements, produced by Oerlikon Company.

1936

30. High-Speed Balanced-Current Relays for Parallel Lines, **S. C. Leyland.** *Electric Journal*, volume 33, number 88, August 1936, page 347.

31. Statistical Survey of Performance of Automatic Protective Systems, Institution of Electrical Engineers (London) *Journal*, April 22, 1936. Survey of systems in Great Britain for five years ending in 1933.

32. Transmission and Distribution, **C. F. Bolton** and **R. H. Abell.** Institution of Electrical Engineers (London) *Journal*, April 1936. A review of progress.

1937

33. High-Speed Relays Improve 100-Kv Loop, **H. A. Burt.** *Electrical West*, volume 79, September 1937, pages 68–9.

34. Single-Element Polyphase Directional Relay, **A. J. McConnell.** AIEE Transactions, volume 56, 1937 (January section), pages 77–80; discussion (August section), pages 1025–8.

35. Some Comments on Transversal Differential Protection of Double Lines on Systems With Earthed Neutral, **J. Schneider.** *Brown Boveri Review*, volume 24, number 9, September 1937, pages 245–8.

1938

36. Arc Resistance and Time Staggering of Relays According to Resistance Characteristics for Protective Systems of Electric Transmission Lines (in German), **H.**

Neugebauer. *Elektrizitaetswirtschaft,* volume 37, number 15, May 25, 1938, pages 396–9.

37. Curve Shapes of Graded Selective Protection for Electric Lines; Analysis of Relay-Time Characteristics (in German), **H. Neugebauer.** *Siemens Zeitschrift,* volume 18, number 1, January 1938, pages 25–30.

38. Differential Protection Along System With Impedance-Time Back-Up for Large Cable Networks (in German), **F. Geise.** *Siemens Zeitschrift,* volume 18, number 9, September 1938, pages 446–50.

39. Protective Devices in High- and Medium-Voltage Overhead Lines (in German), **K. Kuehn.** *Elektrizitaetswirtschaft,* volume 37, January 12, 1938, pages 27–32; February 15, 1938, pages 107–13.

1939

40. Boulder Dam Transmission Line; Transmission-Line Relay Protection, **L. L. Draper.** AIEE Transactions, volume 58, 1939 (April section), pages 151–6.

Section E

Bus Protection

1929

1. The Fault Ground Bus, **R. M. Stanley** and **F. C. Hornibrook.** AIEE Transactions, volume 49, 1930, pages 201–12.

1935

2. Harmonic-Current-Restrained Relays for Differential Protection, **L. F. Kennedy** and **C. D. Hayward.** AIEE Transactions, volume 57, 1935 (May section), pages 262–71.

3. Lift-Control Gear Protection Against Earth Faults, **A. Read.** *Electrical Review* (London), volume 116, April 5, 1935, pages 480–1.

1936

4. Bus Protection Gives Service Reliability, **Philip Sporn.** *Electrical World,* volume 106, May 9, 1936, page 1357.

5. Bus-Bar Zone Protection, **T. W. Ross.** *Electrical Review* (London), volume 119, July 31, 1936.

1938

6. Bus-Zone Protection, *Electrical Review* (London), volume 122, May 27, 1938, page 775.

7. Reyrolle Bus-Bar Zone Protection Systems, *Engineer* (London), volume 146, September 16, 1938, pages 329–30.

1939

8. Bus Protection, AIEE Transactions, volume 58, 1939 (May section), pages 206–11. A report prepared under the auspices of the relay subcommittee of the AIEE protective devices committee and the relay subject committee of the EEI electrical equipment committee.

9. Considerations in Applying Ratio Differential Relays for Bus Protection, **R. M. Smith, W. K. Sonnemann** and **G. B. Dodds.** AIEE Transactions, volume 58, 1939 (June section), pages 243–9.

Section F

Apparatus Protection

1931

1. Percentage-Differential Transformer Protection, **R. E. Cordray.** Electrical Engineering, volume 50, May 1931, pages 361–3.

1932

2. Thermal Cutouts for Protecting Alternating-Current Motors, **H. D. Braley.** *Power,* volumes 74 and 75, November 17, 1931, pages 703–05; January 12, 1932, pages 66–7.

3. Balanced-Current Protection for Alternators, **G. W. Stubbings.** *Electrical Times* (London), volume 82, number 2128, August 4, 1932, pages 140 and 149.

4. Differential Relays Operate Abnormally Due to Different Lead Lengths, **S. Ein.** *Electrical World,* volume 100, number 25, December 17, 1932, page 827.

5. Guarding Against Loss of Field, **E. H. Bancker.** *Electrical World,* volume 99, number 23, June 4, 1932, page 983.

6. Polyphase Motor Can Be Protected Against Single-Phase Operation (symposium, six contributors). *Power,* volume 75, May 3, 1932, page 668.

7. Protective Gear for Alternators, **G. W. Stubbings.** *Electrical Engineer and Merchandiser,* volume 9, number 1, April 15, 1932, pages 17–19.

8. Providing Protection for Three-Phase Motors, **R. B. Glen.** *Power,* volume 75, June 14, 1932, page 884.

9. Reyrolle Automatic Alternator Protection, *Electrical Review* (London), volume 111, September 16, 1932, page 392.

10. Use of Protective Relays on Alternating-Current Systems, **C. J. Monk.** South African Institute of Electrical Engineers *Transactions,* volume 23, part 3, March 1932, pages 47–57.

1933

11. Inductor Time-Delay Device: Prevents Circuit Breakers From Interrupting Service on Momentary Short Circuits or Voltage Dips, **W. W. Brainard** and **G. D. Gamel.** *Electric Journal,* volume 30, November 1933, pages 472–3.

12. Machines Stopped Automatically by Electronic Time-Delay Relay, *Electrical World,* volume 101, May 20, 1933, page 643.

13. New Developments in Synchronous Motor Control, **M. N. Halberg.** *General Electric Review,* volume 36, May 1933, pages 244–9.

14. Protecting Squirrel-Cage Winding of Synchronous Motors, **M. N. Halberg.** *Electrical World,* volume 102, November 11, 1933, page 627.

15. Recommended Practices for the Protection of Electrical Apparatus, AIEE Transactions, volume 52, 1933, pages 607–13. A report prepared under the auspices of the relay subcommittee of the AIEE protective devices committee.

16. Selecting Thermal Relays to Protect Three-Phase Motors, **H. Wilson.** *Power,* volume 77, February 1933, pages 78–80.

17. Synchronous-Motor Excitation Controlled by New Relays, **N. L. Hadley.** *Electrical World,* volume 101, April 29, 1933, pages 550–1.

18. Temperature Protection With Detector Coils, **H. E. Pearson.** *General Electric Review,* volume 36, February 1933, pages 109–10.

1934

19. Differential Float Relay Watches Cable Oil, **R. Banz.** *Electrical World*, volume 103, June 30, 1934, pages 946–7.

20. New Ground Detector Improves Field Protection, **A. Kroneberg** and **R. B. Pollock.** *Electrical World*, volume 104, August 4, 1934, pages 149–50.

21. New-Type Independent Overcurrent Time Relay (in German), **S. John.** *Siemens Zeitschrift*, volume 14, number 4, April 1934, pages 134–6. Current time relay for protection of motors and transformers.

22. Power-Transformer Protection, **G. W. Stubbings.** *Electrical Review* (London), volume 114, number 2939, March 23, 1934, page 406. Differential protection, zero sequence components.

23. Protective Relays on Pennsylvania Railroad Locomotives, **B. Luther.** AIEE Transactions, volume 53, 1934 (February section), pages 261–4.

24. Thermoelectric Protection for Intermittently Operating Motors (in German), **J. Gewecke.** *Siemens Zeitschrift*, volume 14, number 9, September 1934, pages 317–24.

25. Transformer Protection, **W. Woodiwiss.** *Electrical Review* (London), volume 114, number 2941, April 6, 1934, pages 481–2. Merz-Price system.

1935

26. Automatic Relays Assure Protection for Generators, Transformers, **W. A. Holland.** *Southern Power Journal*, volume 53, number 2, February 1935, pages 47–9.

27. Differential Protection of Transformers (in French), **C. Varicnon.** *Revue Générale de l'Electricité*, volume 37, number 24, June 15, 1935, pages 771–81.

28. General Problem of Adequately Protecting Transformers (in German), **H. Weissmann.** *Siemens Zeitschrift*, volume 15, number 3, March 1935, pages 67–74.

29. Generator Protection for Radial Turbines With Nozzles and Blades Rotating in Opposite Directions (in German), **R. Schimpf.** *Siemens Zeitschrift*, volume 15, number 4, April 1935, pages 128–31.

30. High-Speed Relays to Protect Mercury-Arc Rectifiers, *Mass Transportation*, volume 31, December 1935, page 424.

31. Importance of General Design of Protective Systems for Electrical Machinery, **E. Bopp.** *Siemens Zeitschrift*, volume 15, number 9, April 1935, pages 105–13.

32. Thermal Protection is Provided for All Electrical Apparatus in New Supreme Court Building, **F. G. Graf.** *Electric Journal*, volume 32, May 1935, pages 198–9.

1936

33. Boulder Canyon Project; Generator and Transformer Relaying, *Electric Journal*, volume 33, November 1936, page 492.

34. Generator Protection (in German), **E. Bopp.** *Archiv fuer Waermewirtschaft und Dampfkesselwesen*, volume 17, August 8, 1936, page 219.

35. The New Siemens-Buchholz Relay (in German), **H. Prinz.** *Siemens Zeitschrift*, volume 16, August 8, 1936, page 298.

36. Overload Relays for Motor Protection, **N. D. Beuhling.** *Electrical Manufacturing*, volume 17, April 1936, page 34.

37. Progress in Construction of Stabilized Differential-Protective Systems (in German), **F. Geise.** *Siemens Zeitschrift*, volume 16, August 1936, page 283.

38. The Protection of Generators (in French), **R. Dubusc.** *Technique Moderne*, volume 28, September 1, 1936, page 601; October 15, 1936, page 711.

52. Undercurrent Relays Protect Centrifugal Pumps, **T. M. Googin.** *Coal Age*, volume 42, September 1937, page 76.

1938

53. Differential Protection, Compensated and Electronic Relays, **A. Marit.** Association Suisse des Electriciens *Bulletin*, volume 29, number 18, September 2, 1938, pages 496–509.

54. Gas-Pressure Relays, **R. A. Hentz.** Edison Electric Institute *Bulletin*, volume 6, March 1938, pages 82–4. Final report on analysis of replies from foreign correspondent to the electrical equipment committee, EEI.

55. Gas-Pressure Relays Protect Transformer, *Electrical World*, volume 109, March 26, 1938, page 1068.

56. Highly Sensitive Frame Protection for Generators Working Directly Into Network System (in German), **E. Bopp.** *Siemens Zeitschrift*, volume 18, number 2, February 1938, pages 53–8.

57. Protect Generator From Internal Faults, **G. Calabrese.** *Electrical World*, volume 109, May 21, 1938, page 1704 correction, volume 110, August 13, 1938, page 435.

58. Reyrolle and Company-Station Protection Systems, *Engineer* (London), volume 166, July 8, 1938, pages 34–5.

59. Thermal Image of Electric Machines as Basis for Development of Electric Overload Relays (in French), **J. Stoesser** and **E. Bernhardt.** Association Suisse des Electriciens *Bulletin*, volume 29, number 12, June 10, 1938, pages 290–4.

60. Transformer Protection by Metrovick, Buchholz Devices, **C. Ryder.** *Metropolitan-Vickers Gazette*, volume 17, number 300, April 1938, pages 236–8.

1939

61. Machine Protection and the Practice of Grounding Neutrals, **J. H. Vivian.** *Electrical West*, volume 83, September 1939, pages 23–7.

62. Relay Protection for a Large Regulating Transformer, **W. E. Martin.** *Electric Journal*, volume 36, March 1939, pages 87–8.

Section G

Distribution and Network Protection

1926

1. A-C Network Characteristics, **D. K. Blake.** AIEE Transactions, volume 45, 1926, pages 1212–20.

2. Evolution of the Automatic-Network Relay, **J. S. Parsons.** AIEE Transactions, volume 45, 1926, pages 1195–1202.

3. Operating Requirements of the Automatic-Network Relay, **W. R. Bullard.** AIEE Transactions, volume 45, 1926, pages 1203–11.

1929

4. An A-C Low Voltage Network Without Network Protectors, **L. R. Gamble** and **E. Baughan.** AIEE Transactions, volume 49, 1930, pages 82–92.

1932

5. Relays Insure Service in Primary Networks, **L. F. Kennedy.** *General Electric Review*, volume 35, number 6, June 1932, pages 338–43.

1933

6. Co-ordinating Fuses and Relays for Distribution Reliability, **G. F. Lincks.** *Electrical World*, volume 102, July 29, 1933, pages 140–3.

7. Sequence Principles Used for Network Relaying, **H. R. Searing** and **R. E. Powers.** AIEE Transactions, volume 52, 1933, pages 614–20.

8. Sequence Relay for Network Protectors, **H. S. Orcutt** and **M. A. Bostwick.** AIEE Transactions, volume 52, 1933, pages 620–6.

1934

9. Network Protector Averts Pumping, *Electrical World*, volume 104, October 13, 1934, page 658.

10. Network-Protector Operations Reduced by Improved Control, **J. S. Parsons** and **M. A. Bostwick.** *Electrical World*, volume 103, number 14, April 7, 1934, pages 508–10.

11. New Type of Network Protector, **W. R. Bullard.** Edison Electric Institute *Bulletin*, volume 2, number 12, December 1934, pages 403–05.

12. Positive Disconnection of Distribution Circuits, Edison Electric Institute *Bulletin*, volume 2, number 7, July 1934, page 254.

13. Theory of Primary Networks, **F. M. Starr.** AIEE Transactions, volume 53, 1934 (March section), pages 426–31.

14. Use of Fuses in Distribution Network Systems (in German), **P. Wittich.** *Elektrotechnik und Maschinenbau*, volume 52, number 51, December 23, 1934, pages 602–03.

1935

15. New Design of Network Protector Based on Operating Experience, **W. J. McLachlan.** *General Electric Review*, volume 38, number 5, May 1935, pages 244–7.

16. Notch Relay Clears Distribution Faults, **G. L. Kenny, Jr.** *Electrical World*, volume 105, May 11, 1935, page 1216.

1937

17. Fuse-Breaker Correlation Fixed by Fault Ratio, **P. E. Benner.** *Electrical World*, volume 108, number 25, December 18, 1937, pages 53–4 and 115.

18. Co-ordination of Fuse Links; Method of Comparing Fuse Links and Relays for Sectionalization and Protection, **E. M. Adkins.** *Electrical World*, volume 107, March 13, 1937, page 877.

19. Difficulties in Co-ordinating Fusing, **J. I. Holbeck.** *Electrical World*, volume 108, November 6, 1937, page 1562.

20. New Network Relays, **J. M. Parsons** and **M. A. Bostwick.** *Electric Journal*, volume 34, July 1937, pages 288–93.

21. Time-Current Curves for High-Voltage Fuses, **E. A. Williams.** *Electrical World*, volume 107, January 30, 1937, pages 398–401.

22. Trends in Distribution Overcurrent Protection, **P. E. Benner** and **G. F. Lincks.** AIEE Transactions, volume 56, 1937 (January section), pages 138–52.

1938

23. Remote Control of Network Protectors, **W. R. Brownlee** and **W. E. Dent, Jr.** AIEE Transactions, volume 57, 1938 (December section), pages 685–92.

24. Rural Network Protection; Comparison With German Methods, **T. C. Gilbert.** *Electrical Review* (London), volume 112, October 14, 1938, pages 539–40.

25. Sectionalized Feeders Meet Exacting Network Requirements, *Electric Light and Power*, volume 16, number 9, September 1938, pages 50–2. Pilot-wire control of primary circuit breakers and copper-link fuses in transformer secondary leads.

Section H

Service Restoration

1932

1. Service Continuity Promoted by Rapid-Breaker Reclosure, **R. Treat** and **H. C. Verwoert.** *Electrical World*, volume 100, number 6, August 6, 1932, pages 172–5.

1934

2. Automatic Reclosing of Oil Circuit Breakers, **A. E. Anderson.** AIEE Transactions, volume 53, 1934 (January section), pages 48–53; discussion (April section), page 614; also see *Power Plant Engineering*, volume 38, number 4, April 1934, pages 192–4. Results of studies made by several companies.

3. Fast Reclosing Service at Lower Cost, **W. L. Garlington.** *Electrical World*, volume 103, number 6, February 10, 1934, pages 226–7.

4. Faster Reclosing Breakers Needed, **J. T. Logan.** *Electrical World*, volume 103, number 16, April 21, 1934, pages 571–2.

5. Mercury Reclosing Device for Automatically Restoring Circuit Breakers, **A. E. Anderson.** *General Electric Review*, volume 37, number 10, October 1934, pages 462–7.

6. Reclosing Devices for Circuit Breakers Equipped for Automatic Tripping, **E. Kronauer.** *Brown Boveri Review*, volume 21, number 11, November 1934, pages 191–4.

1935

7. Immediate Automatic Reclosing of Circuit Breakers, **W. M. Emmons.** *Electric Journal*, volume 32, March 1935, pages 114–18.

8. Immediate Reclosure of 110-Kv Lines, **J. T. Johnson** and **J. W. Graff.** *Electrical World*, volume 105, August 31, 1935, pages 2101–03.

1936

9. Carrier Relaying and Rapid Reclosing at 110-Kv, **R. E. Pierce, R. E. Powers, E. C. Stewart** and **G. E. Heberlein.** AIEE Transactions, volume 55, 1936 (October section), pages 1120–29.

1937

10. One-Shot Reclosures Improve Service, Stop Complaints, **T. H. Kinnear** and **L. R. Patterson.** *Electrical West*, volume 79, September 1937, pages 63–4.

11. Ultrahigh-Speed Reclosing of High-Voltage Transmission Lines, **P. Sporn** and **D. C. Prince.** AIEE Transactions, volume 56, 1937 (January section), pages 81–90.

1938

12. What Time Delay for Automatic Reclosure? **G. F. Lincks.** *Electrical World*, volume 110, December 31, 1938, pages 1822–3.

Section I

General and Miscellaneous Relaying

1926

1. Relay Handbook. NELA *Publication*, number 25–3, 1926.

1929

2. Protective-Relay Installation at Toronto-Leaside Transformer Station of Hydro-Electric Power Commission of Ontario, **E. M. Wood.** Engineering Institute of Canada *Transactions*, volume 36, February 1929, pages 141–51.

1930

3. Transmission System Relay Protection III, **W. W. Edson.** AIEE Transactions, volume 49, 1930, pages 1213–24.

1931

4. Effect of Wave Form on Operation of Induction Relays (abstract), **P. H. Robinson.** Electrical Engineering, volume 50, November 1931, page 900.

5. Nonlinear Circuits for Relay Applications, **C. G. Suits.** Electrical Engineering, volume 50, December 1931, pages 963–5.

6. Relay Handbook Supplement, NELA *Publication*, number 142A, 1931.

1932

7. Adequate System Protection, **R. C. Denny.** *Electrical West*, volume 68, number 6, May 15, 1932, pages 334–6. Report of electrical apparatus committee of Pacific Coast Electric Association.

8. Automatic Sectionalizing Equipment, **H. S. Littlewood.** *Electric Journal*, volume 29, number 5, May 1932, pages 230–2. Equipment for isolating trouble in mines or on railways.

9. Direct-Current Protective Gear, **W. Wilson.** *World Power*, volume 18, number 106, October 1932, pages 237–41.

10. Instrument Transformers and Protective Relays (book, in French), **C. Bresson.** Dunod, Paris, 1932.

11. Metal-Clad Switchgear, Automatic Protection, and Remote Control, With Particular Reference to Developments During the Last Seven Years, **H. W. Clothier.** Institution of Electrical Engineers (London) *Journal*, volume 71, August 1932, pages 285–330.

12. Overcurrent Protection With Outage Indicator (in French), **V. De Montaigue.** *Electricien* (Paris), volume 63, number 1540, May 15, 1932, pages 224–6.

13. Overvoltages on Transmission Systems Caused by Dropping Load, **E. J. Burnham.** AIEE Transactions, volume 51, 1932, pages 105–12.

14. Protective Apparatus as Applied to System of Sydney Municipal Council, **F. B. Haugaard.** Institution of Engineers, Australia, *Journal*, volume 4, number 6, June 1932, pages 189–203.

15. Protective Engineering, *Electrical West*, volume 68, number 6, May 15, 1932, pages 331–4. Pacific Coast Electrical Association apparatus committee report on causes of faults system set up to minimize faults, and high-speed relays.

16. Protective Relay Equipment in Los Angeles, **E. G. Russell.** *Electric Light and Power*, volume 10, number 9, September 1932, pages 14–17.

17. Relay Time Lags, **G. W. Stubbings.** *Electrical Review* (London), volume 110, number 2845, June 3, 1932, page 809.

18. Some Recent Advances in Design of Relays for Protection of Alternating-Current Systems, **C. L. Lipman.** Institution of Electrical Engineers (London) *Journal*, volume 70, number 425, May 1932, pages 545–66.

19. Theory and Application of Relay Systems, **P. H. Robinson** and **I. T. Monseth.** *Electric Journal*, volume 29, numbers 2 and 3, February 1932, page 83; March 1932, page 143.

1933

20. Building a New Power System; Indianapolis Power and Light Company, **F. S. Douglass** and **A. C. Monteith.** *Electric Journal*, volume 30, February 1933, pages 55–9.

21. Circuit-Breaker Tripping, **R. L. de Loache.** *Electric Journal*, volume 30, August 1933, pages 329–32.

22. New Ideas on Protecting Service, *Electrical World*, volume 101, February 4, 1933, pages 161–3. Abstract of AIEE papers.

23. New Maximum and Reverse-Current Relay, **R. Edler.** *Electrical Review* (London), volume 113, October 20, 1933, page 558.

24. Nonlinear Circuits Applied to Relays, **C. G. Suits.** Electrical Engineering, volume 52, April 1933, pages 244–6.

25. One-Way Relay Contact, **J. C. Woods.** *Electrical World*, volume 102, December 30, 1933, page 860.

26. Relays and Breakers Improved, *Electrical World*, volume 102, July 8, 1933, pages 45–6. Discussion of AIEE convention papers.

27. Simple Relays Given Precision by Resonant Circuits, **C. G. Suits.** *Electrical World*, volume 101, January 28, 1933, page 140.

1934

28. Automatic Synchronizing Relay, *General Electric Review*, volume 37, November 1934, page 526.

29. G.E. Automatic Synchronizing Relay, *Power Plant Engineering*, volume 38, July 1934, pages 346–7.

30. B.T.H. Reverse Rotation Relay, *Engineer* (London), volume 158, October 19, 1934, pages 394–5.

31. Effect of Frequency Changes on Meters, Relays, Transformers, **J. D. Addleman.** *Electric Journal*, volume 31, December 1934, page 476.

32. Electronic Voltage Relay, **J. W. Graff.** *Electronics*, volume 7, number 3, March 1934, pages 80–1.

33. Engineering Achievements of 1933: Metering and Relaying, *Electric Journal*, volume 31, January 1934, pages 28–9.

34. Instruments and Relays; Effect of Discoveries of New Materials on Design, *Electrician* (London), volume 113, October 26, 1934, pages 530–1.

35. New Methods of Excess-Current Time Protection With Diagrams and Applications (in German), **M. Walter.** *Elektrotechnische Zeitschrift*, volume 55, number 9, March 1934, pages 206–08.

36. New Relays, *AEG Progress*, number 2, 1934, page 36.

37. Relays and High-Speed Disconnection (in German), **H. Neugebauer.** *Elektrotechnische Zeitschrift*, volume 55, number 8, February 22, 1934, pages 181–4.

38. Relays Hold Essential Load on Partial Power Failure, **A. P. Schnyder.** *Electrical World*, volume 103, June 2, 1934, page 807.

39. Simple Relay Scheme Avoids Higher Breaker Investment, **R. Banz.** *Electrical World*, volume 103, June 16, 1934, page 872.

40. Static Voltage Relay, **J. C. Costello.** *Electrical Review* (London), volume 115, number 2957, July 27, 1934, page 120. Uses of a tungsten lamp.

41. Thyratron Tubes in Relay Practice, **R. Wideröe.** AIEE Transactions, volume 53, 1934 (October section), pages 1347–53.

42. Three Ways to Insure Industrial Oil-Circuit-Breaker Adequacy, **R. I. Powers.** *Electrical World*, volume 103, June 23, 1934, page 920.

1935

43. Automatic Protection of A-C Circuits (book), **G. W. Stubbings.** Instruments Publishing Company, Pittsburgh, 1935, 293 pages. Refers primarily to networks and interconnected transformers.

44. Circuit Breaking and Protection, **F. H. Clough.** *Electrician* (London), volume 115, November 1, 1935, page 543.

45. Cuprox Discs as Neat Relays, **Sirokský** and **N. Teibel.** *Electrical Review* (London), volume 117, August 23, 1935, pages 238–9.

46. Factors in Making Electrical Power Supply Dependable, **R. Treat.** *General Electric Review*, volume 38, August 1935, pages 376–83.

47. High-Speed System Operation Obtaining Minimum Time Delay for Faults, **C. B. Padon.** *Electric Journal*, volume 32, March 1935, pages 112–13.

48. New Brown Boveri Series Relay for Severest Service Conditions, **J. Stoecklin.** *Brown Boveri Review*, volume 22, number 6, June 1935, pages 119–21. History and development of type *HB*-4 relay.

49. New Developments in Relays, *Electrical World*, volume 105, May 25, 1935, page 1321.

50. Operation of High-Speed Relays, **W. A. Lewis.** *Electric Journal*, volume 32, October 1935, page 446.

51. Overload Protective Systems, *Electrician* (London), volume 115, October 4 and 25, 1935, pages 417 and 473.

52. Recent Relay Developments, **I. C. Ryder.** *Metropolitan-Vickers Gazette*, volume 15, number 271, November 1935, pages 410–41. New design of regulating relay types *AVB* and *AVE* with low-volt protection and combined regulating and time relay.

53. Relays—Their Application in Distribution and Utilization of Electric Power, **W. A. Holland.** *Southern Power Journal*, volume 53, number 4, April 1935, pages 33–6. Notes on transmission lines and feeders; carrier-current relaying; radial *FDR* relays; automatic reclosing immediate initial reclosure; power plant motors; time delay for industrial motors; synchronous motor protection.

54. Relay Systems, Theory and Application (book), **I. T. Monseth** and **P. H. Robinson.** McGraw-Hill Publishing Company, 549 pages, 1935.

55. Sensitive A-C Vacuum-Tube Relay, **E. L. Ellis.** *Science*, volume 81, June 7, 1935, pages 568–9.

56. Short-Circuit Announcer With Indication of Faulted Phase, **F. Geise.** *Siemens Zeitschrift*, volume 15, number 10, October 1935, pages 493–6.

57. Substation Protection—a New Unbalanced-Phase Protective System, **C. J. O. Garrard.** *Electrician* (London), volume 114, number 2960, February 22, 1935, page 235.

58. Tubes on Power Systems, **P. Sporn** and **G. G. Langdon.** *Electrical World*, volume 105, number 3, February 2, 1935, pages 31–3. Thermionic devices as applied to synchronizing, carrier-current relaying and remote-switch control.

1936

59. Balanced Protective Systems, *Electrician* (London), volume 116, March 27, 1936, page 421.

60. Control of Short Circuits Cuts Costs, **H. C. Tice.** *Electrical World*, volume 106, December 5, 1936, page 3762.

61. Electrons Operate Directional Relay, **R. I. Ward.** *Electrical World*, volume 106, December 1936, page 3796.

62. Experiences With a Modern Relay System, **G. W. Gerell.** AIEE Transactions, volume 55, 1936 (October section), pages 1130–6; discussion volume 56, 1937 (March section), pages 369–70.

63. Metering—Relaying; 1935 Developments, *Electrical West*, volume 76, February 1936, pages 40–2.

64. Modernization of Relay Systems, **C. A. Muller** and **H. E. Turner.** AIEE Transactions, volume 55, 1936 (January section), pages 56–62; discussion (August section), page 922.

65. Planned Protective System, **A. C. Monteith** and **W. A. Lewis.** *Electrical World*, volume 106, November 21, 1936, pages 3618–20.

66. Recent Relay Developments, **C. Ryder.** *Metropolitan-Vickers Gazette*, volume 16, January 1936, page 23. Time-delay d-c relay and automatic-reclosing relays.

67. Relay Circuits Simplified in Four Novel Ways, **R. Rader.** *Electrical World*, volume 106, December 5, 1936, page 3757.

1937

68. Capacity-Stored Energy for Circuit-Breaker Tripping, **L. W. Dyer.** *Electric Journal*, volume 34, May 1937, pages 193–4.

Standard Basic Impulse Insulation Levels

This report of the joint committee[*] on co-ordination of insulation of AIEE, Edison Electric Institute, and National Electrical Manufacturers Association is the culmination of more than ten years' study to establish basic insulation co-ordination. It specifies basic impulse insulation levels in terms of a withstand voltage for a specified test wave. These values are to be the bases for various AIEE and other standards now in course of development or revision.

CULMINATING over ten years' work on insulation co-ordination during which the fundamentals of making impulse tests were investigated and standardized, as well as basic levels set up and provisionally tried out, the joint AIEE-EEI-NEMA committee on insulation co-ordination at its meeting held in November, 1940, agreed unanimously to adopt as standard the series of basic impulse insulation levels given in table I. These are the same values given in the paper presented at the AIEE winter convention, January 22–26, 1940, "Basic Impulse Insulation Levels" by Sporn and Powel (*AIEE Trans., Oct. '40 Sec., p. 596–8*). The purpose of this present report is to call attention to the fact that these basic levels have now been adopted and to the general conditions under which they apply.

The general principle of insulation co-ordination requires a reasonable margin between the voltage level held by the protective device (the protectable level) and the various basic levels themselves to insure that adequate protection is provided. The values in table I have been set up on this basis. It is felt that the values so set up are on a sound basis and that they are most likely to stand without change for a long time. It is the opinion of the committee, therefore, that the various technical committees working on standards can adopt the values given in this report for standardization purposes, and it is further believed that the use of these values will result in ultimate over-all benefit to the industry.

When first formed, the joint committee adopted as a statement of principles the following:

"The co-ordination of insulation involves three steps:

1. Establishment of insulation levels.
2. Specification of insulation strengths of all classes of equipment in established impulse levels.
3. Allocation of the insulation levels to the nominal system voltages, taking into account all operating and environmental conditions."

The adoption of the standard insulation levels in table I of this report completes the first step of the committee work.

DEFINITION OF BASIC IMPULSE INSULATION LEVELS

To clarify the meaning and intent of the levels which are given in table I, it may be well to mention here two fundamental definitions. It is believed that these definitions and the associated comments clearly indicate the requirements of any apparatus which is built to these levels and is reported as conforming to them.

"BASIC IMPULSE INSULATION LEVELS

"Basic impules insulation levels are reference levels expressed in impulse crest voltage with a standard wave not longer than 1.5×40 microsecond wave. Apparatus insulation, as demonstrated by suitable tests, shall be equal to or greater than the basic insulation level."

This requires that apparatus conforming to these levels shall have a withstand value not less than the kilovolt value given in the second column of table I. It is also understood that apparatus conforming to these requirements shall be capable of withstanding the specified voltage whether the impulse is positive or negative in polarity.

"WITHSTAND VOLTAGE (FOR AN IMPULSE)

"The withstand voltage of a test specimen under an impulse of any given wave shape, polarity, and amplitude, which does not cause disruptive discharge on the test specimen, is the crest value attained by that impulse."

EXCEPTIONS TO TABLE I

Taking cognizance of the fact that some apparatus insulators do not at the present time fully meet the levels given in table I, the committee recognized certain exceptions. These exceptions apply to insulation levels 150, 200, and 250 kv but only for switch and bus insulators and apparatus employing these insulators, with the understanding that after January 1, 1943, all equipment will meet the values given in table I. Any new or modified designs of such apparatus completed prior to that date should, of course, conform to the values given in the table. This exception further definitely states that it will exist as an exception only until January 1, 1943, after which no equipment will be excepted from meeting the requirements of table I if such equipment is represented as meeting "Standard Basic Impulse Insulation Levels."

Table I. Standard Basic Impulse Insulation Levels

Reference Class (Kv)	Basic Impulse Level (Kv)
1.2	30
2.5	45
5.0	60
8.7	75
	95
15	110
23	150[*]
34.5	200[*]
46	250[*]
69	350
92	450
115	550
138	650
161	750
196	900
230	1,050
287	1,300
345	1,550

[*] For switch and bus insulators, and apparatus such as air switches and power fuses employing these insulators, the levels of 150, 200, and 250 kv shall become effective on January 1, 1943, with the understanding that any redesign or modification of such equipment completed earlier than January 1, 1943, shall be made on the basis of 150, 200, and 250 kv levels. In the interim and for existing designs of this equipment, values of 145, 190, and 240 kv will be recognized as exceptions for these three classes, respectively.

NOTE: Attention is called to the fact that equipment carrying a power-frequency voltage rating which is numerically the same as the "Reference Class" in table I is not necessarily required to have the corresponding impulse level given in the table. Decisions in this regard are provided for in the two remaining steps mentioned above in the committee's original statement of principles.

---

[*] Chairman of AIEE group is Stanley Stokes (A'16, F'29) consulting electrical engineer, Union Electric Company, St. Louis, Mo.; of EEI group, Philip Sporn (A'20, F'30) vice-president in charge of engineering, American Gas and Electric Service Corporation, New York, N. Y.; of NEMA group, C. A. Powel (M'20) manager, industry engineering department, Westinghouse Electric and Manufacturing Company, East Pittsburgh, Pa.

Report presented informally at the AIEE winter convention, Philadelphia, Pa., January 27–31, 1941.

Report of the Board of Directors

THE BOARD OF DIRECTORS of the American Institute of Electrical Engineers presents herewith to the membership its 57th annual report, for the fiscal year ending April 30, 1941. A general balance sheet showing the condition of the Institute's finances on April 30, 1941, together with other detailed financial statements, is included herein. This report contains a brief summary of the principal activities of the Institute during the year, more detailed information having been published from month to month in ELECTRICAL ENGINEERING.

BOARD OF DIRECTORS' MEETINGS

The board of directors held five meetings during the year, three in New York City, one in Swampscott, Mass., and one in Philadelphia, Pa.

The status of the committee on research was changed from that of a technical committee to that of a general committee. The names of two technical committees were changed, viz., the committee on applications to marine work became the committee on marine transportation, and the committee on transportation became the committee on land transportation.

Three new technical committees were established: committee on domestic and commercial applications, committee on air transportation, and committee on applications of electricity to therapeutics.

Information regarding many of the more important activities of the Institute which have been under consideration by the board of directors and the committees is published each month in the section of ELECTRICAL ENGINEERING devoted to Institute activities.

NATIONAL DEFENSE

Through a resolution adopted by the board of directors on June 27, 1940, the services of the Institute in connection with problems of national defense were offered to the President of the United States. At the meeting of the board of directors held on January 30, 1941, the new committee on air transportation was authorized to offer its services to the Army-Navy aeronautical board in connection with the development and co-ordination of aeronautical electrical equipment.

By actions of the board of directors, on January 30, 1941, an Institute committee on national defense was appointed, and Past President John C. Parker was designated to represent the Institute on the national technological civil protection committee appointed by the Secretary of War.

National committees have given increased attention to defense problems. The Sections have supplied information on engineering firms and individuals available for defense work of certain types. Many have included defense subjects in their programs.

President Sorensen is a member of the committee on acceleration of the regular engineering programs appointed by the Society for the Promotion of Engineering Education at the request of the advisory committee on defense training of the United States Office of Education. Many other officers and members of the Institute have been serving in defense activities.

President Sorensen and the headquarters staff have co-operated with Government divisions at every opportunity, assisting in several undertakings, including the national roster of scientific and specialized personnel. Messages from President Sorensen containing suggested ways in which engineers might aid the defense program have been published in ELECTRICAL ENGINEERING. Through the news columns of ELECTRICAL ENGINEERING, much information on problems of national defense has been supplied to the membership.

PRESIDENT'S AND NATIONAL SECRETARY'S VISITS

President Sorensen and National Secretary Henline attended the summer and Pacific Coast conventions, the winter convention, the Middle Eastern District meeting in Cincinnati, Ohio, and the North Eastern District meeting in Rochester, N. Y. They also visited many Sections and Student Branches. During May, they will visit the following Sections: Washington, North Carolina, West Virginia, and Cincinnati; and President Sorensen will visit the Cleveland Section. President Sorensen and National Secretary Henline will attend the summer convention in Toronto, Ont., Canada.

The places visited by President Sorensen follow:

- **Alabama**
  - Alabama Section, Birmingham
  - Muscle Shoals Section
- **California**
  - Pacific Coast convention, Los Angeles
  - Los Angeles Section, University of Southern California Branch, and California Institute of Technology Branch, at U.S.C.
  - San Francisco Section
  - Conference on student activities, Districts Nos. 8 and 9, and University of British Columbia, Los Angeles
- **Colorado**
  - Denver Section
  - University of Colorado Branch, Boulder
  - Colorado State College, Ft. Collins
  - Conference on student activities, North Central District, No. 6, University of Denver; 9 Branches represented
- **Georgia**
  - Georgia Section, Atlanta
  - Georgia School of Technology Branch, Atlanta
- **Illinois**
  - Chicago Section
  - Illinois Institute of Technology Branch, Chicago
  - Northwestern University, Evanston
- **Idaho**
  - University of Idaho, Moscow
- **Indiana**
  - Central Indiana Section, Indianapolis
  - Fort Wayne Section
  - Purdue University, Lafayette
- **Iowa**
  - Iowa Section, Cedar Rapids
  - Iowa State College Branch, Ames
- **Kentucky**
  - Louisville Section
  - University of Kentucky Branch, Lexington
- **Massachusetts**
  - Summer convention, Swampscott
  - Boston Section
  - Lynn Section executive committee meeting
  - Worcester Section and Worcester Polytechnic Institute Branch, at W.P.I.
- **Michigan**
  - Michigan Section, Detroit
- **Minnesota**
  - Minnesota Section, Minneapolis
  - University of Minnesota, Minneapolis
- **Missouri**
  - Kansas City Section
  - St. Louis Section
  - University of Missouri Branch, Columbia
- **Montana**
  - Montana Section and Montana State College Branch, joint meeting, Butte
- **Nebraska**
  - Nebraska Section, Omaha
  - University of Nebraska, Lincoln
- **New York**
  - Cornell University, Ithaca
  - Ithaca Section
  - Syracuse Section
  - Syracuse University Branch
  - North Eastern District meeting, Rochester
  - North Eastern District conference on student activities, Rochester, 17 Branches represented
- **Ohio**
  - Middle Eastern District meeting, Cincinnati
  - Toledo Section
  - Columbus Section
  - Ohio State University, Columbus
- **Oklahoma**
  - Oklahoma City Section
  - Tulsa Section
- **Oregon**
  - Portland Section
- **Pennsylvania**
  - Winter convention, Philadelphia
  - Pittsburgh Section, and University of Pittsburgh, Carnegie Institute of Technology, and West Virginia University Branches, joint meeting, Pittsburgh
  - Pittsburgh Section student conference
  - Erie Section
- **Rhode Island**
  - Providence Section
  - Brown University Branch, Providence
- **South Carolina**
  - South Carolina Section, Columbia
- **Tennessee**
  - East Tennessee Section, Athens
- **Texas**
  - New Mexico-West Texas Section, El Paso
- **Utah**
  - Utah Section, Salt Lake City
  - University of Utah, Salt Lake City
- **Washington**
  - Seattle Section
  - University of Washington, Seattle
  - Spokane Section, and University of Idaho and Washington State College Branches, joint meeting, Spokane
  - Washington State College, Pullman
- **Wisconsin**
  - Madison Section
  - University of Wisconsin, Madison
  - Milwaukee Section
- **Canada**
  - Toronto Section

The places visited by the national secretary are the following:

- **Alabama**
  - Alabama Section, Birmingham
  - Muscle Shoals Section
- **California**
  - Pacific Coast convention, Los Angeles
  - Conference on student activities, Districts 8 and 9, and University of British Columbia, Los Angeles
- **District of Columbia**
  - Washington Section
- **Georgia**
  - Georgia Section, Atlanta
- **Illinois**
  - Illinois Institute of Technology Branch, Chicago
  - Northwestern University, Evanston

Indiana
- Central Indiana Section, Indianapolis
- Purdue University, Lafayette

Kentucky
- Louisville Section
- University of Kentucky Branch Lexington

Massachusetts
- Summer convention, Swampscott, Mass.
- Boston Section
- Lynn Section executive committee meeting
- North Eastern District executive committee meeting, Pittsfield

Michigan
- Michigan Section, Detroit

Missouri
- Kansas City Section
- St. Louis Section

Nebraska
- Nebraska Section, Omaha
- University of Nebraska Branch, Lincoln

New Jersey
- Student Branch convention, District No. 3, New Brunswick

New York
- Cornell University, Ithaca
- New York Section
- Ithaca Section
- Syracuse Section
- Manhattan College Branch, New York
- New York Section student convention, Rutgers University, New Brunswick, N. J.
- North Eastern District meeting, and conference on student activities, Rochester, N. Y.
- District No. 3 Branches, smoker, Pratt Institute, Brooklyn, N. Y.

Ohio
- Middle Eastern District meeting, Cincinnati
- Conference on student activities, Middle Eastern District, No. 2, Cincinnati

Pennsylvania
- Pittsburgh Section, and University of Pittsburgh, Carnegie Institute of Technology, and West Virginia University Branches, joint meeting, Pittsburgh
- Pittsburgh Section, student conference
- Winter convention, Philadelphia

Rhode Island
- Providence Section
- Brown University Branch, Providence

South Carolina
- South Carolina Section, Columbia

Tennessee
- East Tennessee Section, Athens

Canada
- Toronto Section

ANNUAL MEETING

The annual business meeting of the Institute was held on Monday morning, June 24. The annual report of the board of directors for the fiscal year which ended April 30, 1940, was presented in abstract by the national secretary. A report on the finances of the Institute was presented by National Treasurer W. I. Slichter. The report of the committee of tellers upon the election of officers for the year beginning August 1, 1940, was presented, and President-Elect Sorensen responded to his introduction with a brief address. During this session, special honors were accorded to Charles L. Clarke, charter member of the Institute, and the Lamme Medal for 1939 was presented to Norman W. Storer, retired consulting engineer, Westinghouse Electric and Manufacturing Company.

NATIONAL CONVENTIONS

Three national conventions were held during the year, and a brief report on each follows:

Summer Convention. The 56th summer convention was held in Swampscott, Mass., June 24–28, 1940. In addition to the annual business meeting, conference of officers, delegates, and members, there were 10 technical sessions, at which 41 papers were presented, 1 general session, demonstration on frequency modulation, and 6 technical conferences. The general session was in collaboration with the American Engineering Council, under the leadership of its president Colonel Alonzo J. Hammond, and consisted of addresses by Colonel William J. Wilgus and Colonel Robert F. Henry on the topic "Transportation as a Social Problem". Entertainment features of the convention were women's tea and musicale, bridge, dance, banquet, golf and tennis tournaments. Many inspection trips were held. The registration was 1,014.

Pacific Coast Convention. The 28th Pacific Coast convention was held in Los Angeles, Calif., August 27–30, 1940, with a registration of 465. In addition to 4 technical sessions at which 16 papers were presented, there was a joint session with the Institute of Radio Engineers, informal conference, 2 student sessions with 10 technical papers, and a conference on student activities. Entertainment features included reception and dancing, banquet, inspection trips, golf tournament, and ladies' events.

Winter Convention. The 29th winter convention was held in Philadelphia, Pa., January 27–31, 1941, with a program including 20 sessions with 82 papers, and 9 technical conferences. Speakers on general subjects were: Charles E. Wilson, president, General Electric Company, and R. D. Evans, Massachusetts Institute of Technology. At an evening meeting, the Edison Medal was presented to Doctor George A. Campbell, retired research engineer, Bell Telephone Laboratories, Inc. A smoker, dinner-dance, women's bridge, and numerous inspection trips completed the program. The registration was 1,931.

DISTRICT MEETINGS

Middle Eastern District Meeting. The 11th meeting of this District was held in Cincinnati, Ohio, October 9–11, 1940. The meeting included 5 sessions at which 25 technical papers were presented, 2 technical conferences, meetings of the Student Branch counselors and executive committee. Entertainment features consisted of smoker, luncheons, informal dinner, women's events, and numerous inspection trips. The attendance was 599.

North Eastern District Meeting. An interesting and varied program for this meeting in Rochester, N. Y., April 30–May 2, 1941, included 5 sessions at which 8 addresses and 14 technical papers were presented, 1 session for graduate student papers, 2 sessions for undergraduate papers, a District executive committee luncheon, a Branch counselors' and students' luncheon, a banquet, a smoker, inspection trips, and women's events. The attendance was 355.

SECTIONS

Two new Sections, Arizona and South Bend, were organized; and the names of two Sections were changed to make them more accurately descriptive of the territories: Charleston to West Virginia, and El Paso to New Mexico-West Texas.

As indicated in the list of his visits, President Sorensen visited a large number of Sections. In most cases, he gave an address entitled "Engineering Horizons, Limited," illustrated with many lantern slides. This proved to be an unusually interesting and instructive address, as shown by the close attention of all audiences and a great many highly complimentary comments received by the national secretary.

The Sections again held a larger number of meetings than reported for any previous year. Interest in technical groups, special technical meetings, and so on, continued at a high level, and attendance at such meetings was excellent.

Two Sections reported no activity; 8 Sections held more than 15 meetings each, 9 held from 12 to 15, 38 held from 8 to 11, 10 held from 4 to 7, and 6 held from 1 to 3.

The plan adopted several years ago to include within Section territories, in so far as practicable, all Institute members within the United States resulted in the revision of the territories of a considerable number of Sections. The August 1, 1940, record of Section membership showed the total membership of Sections in the United States as 14,338. In September, it was found that only 93 members in the United States were outside Section territories. The Sections committee has continued its study of unassigned territory with the object of recommending further revisions when desirable.

The other activities of the Sections committee have included the adoption of a trial plan for publishing information on Section meetings in ELECTRICAL ENGINEERING, plans to develop greater interest among the Sections in vocational guidance, and efforts to develop more effective distribution of the pamphlets "The Electrical Engineer" and "Engineering—A Career, a Culture".

Table I contains information regarding Sections and Branches and their meetings during the past several years. Detailed information on their activities of the past year may be found in the annual report on Section and Branch activities in the June issue of ELECTRICAL ENGINEERING, pages 285–7.

Table I. Section and Branch Statistics

	For Fiscal Year Ending April 30					
	1936	1937	1938	1939	1940	1941
Sections						
Number of Sections	61	62	65	67	70	72
Number of meetings held	540	621	624	635	701	703
Total attendance	85,501	74,950	110,148	85,692	91,949	92,554
Branches						
Number of Branches	118	119	120	120	121	123
Number of meetings held	1,045	1,363	1,334	1,190	1,346	1,163
Total attendance	45,304	46,121	60,446	53,380	64,972	52,285

STUDENT BRANCHES

New Student Branches organized at the University of Connecticut, Norwich University, and Manhattan College, and the combination of the Armour Institute of Technology and the Lewis Institute Branches into the Illinois Institute of Technology Branch brought the total number at the end of the year to 123.

President Sorensen visited a considerable number of Branches, and his addresses were enthusiastically received.

Only one Branch failed to report any activity. Thirteen held more than 15 meetings each, 30 held from 8 to 11, 36 held from 4 to 7, and 16 held from 1 to 3, with a total number of 1,163 meetings, as compared with 1,346 for the preceding year; 1,190 for 1938–39; and 1,334 for 1937–38. The number of talks by students, 608, was materially below the totals for recent years: 767 for 1939–40, 725 for 1938–39, and 897 for 1937–38.

Students have continued to present technical papers at the Pacific Coast convention and various District meetings. In general the quality of presentation has been excellent, and large numbers of students have attended such sessions.

The terms of 1,641 enrolled students were expected to expire on April 30, 1941. Of these, 887 or about 54 per cent applied for admission as Associates.

See references at end of the preceding report on Sections.

General Committees

FINANCE COMMITTEE

In the preparation of the budget for the year, the finance committee made allowance for expected losses of dues revenues, and subscriptions normally received from abroad. In spite of this, due primarily to increased memberships in this country, estimated revenues for the budget year, beginning October 1, are about $10,000 greater than for last year. This permits a further modest expansion in the Institute's activities. The budget this year also provides for a nonrecurring expense due to placing in effect a revision in the publication program by means of which publications of some of the TRANSACTIONS material is made at an earlier date than under the former policy. Details of the budget and a further discussion of it are included in the December 1940 issue of ELECTRICAL ENGINEERING.

The conservation of the Institute's investment funds is a problem of increasing difficulty. Under advice of investment counsel and the finance committee, the board of directors this past year approved putting about ten per cent of the Institute's investment funds in common stocks. While this is a new departure for the Institute it is following in a direction which has been taken by many educational and professional organizations.

Haskins and Sells, certified public accountants, have audited the Institute books and their report appears on pages 348–50.

TECHNICAL PROGRAM COMMITTEE

Convention Program. Three national conventions and two District meetings were held during the year. The total attendance of these five meetings represents a 22.3 per cent increase over that for the previous year This has not been the result of an unusually large attendance at any one particular meeting, but the attendance at three of the meetings each establishes a record over corresponding meetings in those localities, and the attendance at the summer convention was substantially above the average attendance for summer conventions of the past ten years. The policy of presenting enlarged programs has been continued, and the attached table of statistics shows that 8 more technical conferences were held during the past year than for the previous year. The technical program for the winter convention was also enlarged to include 2 more technical sessions and 1 more technical conference than have ever been held heretofore. While the attendance at meetings and conventions is a variable depending on several factors, such as location, time of the year, the entertainment program, and general business conditions, it was nevertheless believed that the size and character of the technical programs has contributed in no small measure to the success of these meetings. Many of the papers presented at these meetings were of a high order and favorable comments were received.

Table II. Technical Programs, Last Three Years

	Year Ending April 30		
	1941	1940	1939
Number of national conventions	3	2	3
Number of District meetings	2	3	3
Registration at national conventions and District meetings	4,339	3,548	4,100
Number of papers presented	195	177	184
Number of papers recommended for TRANSACTIONS	164	151	169
Estimated number of pages required for printing papers in TRANSACTIONS	938*	886*	986*
Average length of papers recommended for TRANSACTIONS	5.72	5.86	5.83
Number of technical sessions	46	43	50
Number of technical conferences	18	10	12

* Partly estimated.

Technical Conferences. The increased number of technical conferences has proved beneficial in several ways. The standards co-ordinating committees have been able to obtain a broad cross-section of views preliminary to the adoption or revision of certain standards. The conferences also have served as a trial or proving ground for the development of papers of a high quality which were scheduled later for formal presentation and discussion. Committees on basic sciences, power generation, and standards all have developed some papers in this manner.

Oral Presentations. A letter suggesting ways and means of increasing the effectiveness of the oral presentations was sent to each author and presiding officer of the winter-convention sessions. The suggestions were compiled from a canvass of authors and presiding officers of a previous convention and many of the oral presentations were improved. It has been decided to send a revised version of this letter to the authors on subsequent convention programs.

General Sessions. General sessions which were held at both the winter and summer conventions proved to be very successful, and arrangements are being made to hold another at the 1941 summer convention in Toronto. Preference has been indicated for suitable subject matter to lean more toward the broader problems of human relationships or the social aspects of the profession as related to co-operative effort during and after changed world conditions, rather than the more specific technical developments.

Trends in Policy. The modified publication procedure, announced in the August 1940 issue of ELECTRICAL ENGINEERING, has worked out satisfactorily from the standpoint of program development. Selling pamphlet copies at an increased price according to their lengths has not reduced the number of copies placed in circulation for the purpose of discussion at the various meetings. The proposal to give preference to papers 6 pages or less in length in the TRANSACTIONS section of ELECTRICAL ENGINEERING has provided an incentive for the authors to produce shorter papers. The data in the accompanying table shows that the papers for the past year were of an estimated average length of 5.72 pages, as compared with 5.86 pages for the previous year, before the incentive was provided. The reduction in average page length per paper will be still greater when the policy has been in effect over the full year.

The national defense program has resulted in a scarcity of papers in certain fields, such as industrial, automatic control, and communications. Some papers have also been held up by a more careful scrutiny pending company release and approval. Increase in the pace of industry has also impaired the prompt functioning of the committees as well as the authors in the reviewing and writing of papers to meet certain dates. However, there is no immediate scarcity of good papers in the central-stations fields of activities.

Acknowledgments. The committee wishes gratefully to acknowledge the interest and efforts of its members, the chairmen of the technical committees, and the members of the headquarters staff in the conduct of the work.

PUBLICATION COMMITTEE

ELECTRICAL ENGINEERING and TRANSACTIONS were published during the fiscal year largely on the basis of the same general publication policy and procedure as for the preceding year.

Modifications in publication procedure during the past year include the establishment of the "Supplement to ELECTRICAL ENGINEERING—TRANSACTIONS Section" on a semiannual instead of on an annual basis, and the transfer of the publication of discussions from the monthly periodical to the Supplement.

The principal effort of the year in improving the publication service to the Institute's members has been directed toward reducing the time delay between presentation and publication of technical papers and discussions The omission of discussions from the monthly issues has enabled a progressively earlier publication of technical-

Table III. Membership Statistics for the Fiscal Year Ending April 30, 1941

	Honorary	Fellow	Member	Six-Year Associate	Associate	Total
Membership on April 30, 1940	8	767	4,493	5,724	6,219	17,213
Additions:						
Transferred		34	182	612		
New members qualified		2	129	35	1,435	
Former members reinstated			9	18	16	
	8	803	4,815	6,389	7,670	19,685

		25	165	499	1,110	1,799
Membership on April 30, 1941	8	778	4,650	5,890	6,560	17,886

program papers, and has also enabled the monthly pages otherwise required for discussion to be used for additional technical-program papers.

This will help materially to reduce the time delay in making available in published form the technical papers not included in the monthly issues and the approved discussion of all papers.

When the expediting program was initiated in the early summer of 1940, the publication of 1940 winter convention papers in any quantity could not begin until the June issue, and this, of course, determined the time schedule for the papers of all later conventions during the year. The objective is that by January 1942 the publication of winter convention papers should begin in January and be completed in June, with papers from the other conventions being scheduled accordingly. On the basis of this program, the 1942 TRANSACTIONS is scheduled to be a record of 1942 technical-program papers, instead of embracing parts of at least two years as heretofore. As of the date of this report, this expediting program is proceeding on schedule, but, of course, involves the handling of an increased amount of material during the period of transition. This is evidenced in the enlarged size of the 1940 Supplement, and will be shown also in the enlarged Supplements for June and December 1941. Adjustments of publication schedule between the monthly and annual publications have enabled this transition to be met without imposing an undue burden on the budget.

Another modification in publication policy that became effective during the year was an increase in the price of the advance pamphlet copies of technical program papers as produced for conventions and District meetings. Although this pamphlet-copy program still is underwritten by the general publication budget, the effort and trend are toward making this special service more nearly self-supporting.

MEMBERSHIP COMMITTEE

The membership committee, at its first meeting on September 24, 1940, decided upon a program for its activities during the year, which included a study of all practicable means by which membership work of the Institute, including that in the Sections, might be better co-ordinated in a manner to improve its effectiveness. The committee had in mind more the means by which the national committee could be of greater assistance to the Section membership committees through furnishing information as to the most effective methods and procedures, rather than by endeavoring to establish any uniform procedures.

A subcommittee appointed to study this general problem reported the conclusion that the most important contribution which the national committee could make to the membership work in the Sections was the preparation and issuance of a membership committee guide, containing its recommendations for the conduct of membership committee work. It was felt that this would provide a continuing means of pooling the experience of Section membership committees throughout the Institute territory, since the guide would be revised and improved from time to time, and this information would be valuable to new membership committees. The reaction to this proposal was favorable and a membership committee guide was prepared, approved at the meeting of the committee on January 31, and issued in final form on March 31. Copies were sent to all Section membership committees and to the chairmen of all Sections.

To improve the effectiveness of the national committee in administering the membership work of the Institute, the following measures were adopted:

(*a*). Due to the wide distribution of members of the committee, frequent well-attended meetings are impracticable. Since the best interests of the committee demand the prompt disposal of matters which continuously arise, an advisory subcommittee, composed of six members of the committee in or near New York, was appointed to function as a sort of executive committee, meeting with the chairman as frequently as may be necessary to dispose of matters that cannot be held for the regular committee meetings.

(*b*). A research subcommittee, composed of six other members of the committee, was appointed to deal with problems requiring extensive study and research, and to develop recommendations as to fundamental problems which arise.

To improve the co-ordination of Section membership committee work along the most effective lines, District vice-chairmen of the membership committee have been encour-

Table IV. Number of Applications Received From Enrolled Students and From All Others

1941	17,886†	15,777	88.2
1940	17,213	14,997	87.1
1939	16,605	14,371	86.5
1938	16,078	14,127	87.9
1937	15,308	13,439	87.8
1927*	18,344	16,247	88.6

* Year of maximum membership.

† Of the 17,886 members reported for April 30 1941, 2,109 were not fully paid to April 30, 1941. These are divided into:

1. Members owing dues to April 30, 1940.....627 (Total number of members who have not acted upon resolution of board of directors adopted in January 1941 providing an extension of time for payment of dues.)

2. Members owing dues to April 30, 1941...1,482 (During the period May 1 to May 16, 1941, 325 members have paid dues to April 30, 1941, reducing the number not fully paid to 1,157.)

Table VIII. Record of AIEE Membership

Year	Total May 1	Year	Total May 1	Year	Total May 1

Sticht, H. H.	Associate '13	Feb. 11, 1940	Member	July 1940, p. 309
Stickney, Oswald	Associate '32	Apr. 29, 1940	Associate	July 1940, p. 310
Stillwell, L. B.	Associate '92	Jan. 19, 1941	Fellow	Feb. 1941, p. 88
Stone, C. A.	Associate '91	Feb. 25, 1941	Member	Apr. 1941, p. 183
Strong, J. R.	Associate '01	Oct. 25, 1940	Associate	Jan. 1941, p. 46
Styff, Eivind	Associate '23	1940	Member	Oct. 1940, p. 434
Towne, R. M.	Associate '36	May 24, 1940	Associate	Aug. 1940, p. 346
Uebelacker, C. F.	Associate '90	Sept. 17, 1940	Member	Nov. 1940, p. 473
Wegrin, J. W.	Associate '29	Nov. 26, 1939	Associate	Aug. 1940, p. 346
White, W. S.	Associate '39	May 7, 1940	Associate	Sept. 1940, p. 376
Winter, W. W.	Associate '38	Dec. 11, 1939	Associate	July 1940, p. 310
Wise, D. M.	Member '37	Jan. 8, 1941	Member	Mar. 1941, p. 141
Woodrow, H. R.	Associate '12	Aug. 12, 1940	Fellow	Sept. 1940, p. 375
Woolfenden, H. L.	Associate '17	Jan. 19, 1941	Member	Apr. 1941, p. 184
Wright, R. I.	Associate '04	Jan. 4, 1941	Fellow	Apr. 1941, p. 184
Yonezawa, M.	Associate '25	Feb. 9, 1940	Associate	Apr. 1941, p. 184
Young, G. C.	Associate '37	June 23, 1940	Associate	Aug. 1940, p. 346

aged to keep in close touch with chairmen of Section membership committees within their respective Districts, and to give them such advice and assistance as may be appropriate.

The results of membership committee work of the Institute are indicated by tables III to VIII, inclusive.

Table III shows the total number of members as of April 30, 1941, to be 17,886, as compared with 17,213 at the end of the corresponding period of 1940. This is a net increase of 673 members.

The results of membership committee work are better indicated by table IV, which shows that 1,898 new applications were received during the year ending April 30, 1941, as compared with 1,829 in the corresponding period preceding, and considerably lower figures for the three years preceding 1940.

The figures on Enrolled Students are shown in tables IV and V. It will be noted that there was a falling off in 1941 in applications from students for election to the Associate grade. This was probably influenced by the induction of a large number of young men into military service during the year and the uncertainty which prevailing conditions imposed upon employment.

Tables VI and VII show data as to reinstatements and payment of dues, and table VIII shows the total membership of the Institute for each year since it was founded.

The committee wishes to express its appreciation of the time and effort devoted to membership work by the members of Section membership committees, many of whom have been working under pressure in their occupations. It is also grateful for the cooperation of the Branch counselors who have promoted student enrollment and written to students after their departure, advising them to become members of the Institute. Finally the committee wishes to thank the Institute members for their help and the fine response to the broadcast circular soliciting their aid in suggesting the names of desirable prospects for membership.

Deaths. The deaths of 80 members reported during the year are listed in table IX.

BOARD OF EXAMINERS

The board of examiners held 11 meetings during the past year, averaging about two and one-half hours each, and considered 3,086 cases, divided as shown in table X.

In addition to the routine consideration of the admission and transfer applications referred to in the preceding paragraph, the board during the past two years has engaged in thorough discussion of the practicability of some procedure which would permit the rendering of informal advance opinions on the eligibility of prospective applicants for admission and transfer to the grades of Fellow and Member.

Increasing sentiment for change in procedure led to a most constructive discussion at the summer convention in June 1940. After the chairman of the board of examiners had explained to the conference of officers, delegates, and members the problems confronting the examiners, the conference went on record for an invitational procedure, and recommended that the board of directors direct a study to this end.

As a result of this request from the board of directors, a subcommittee under Vice-Chairman H. S. Warren was appointed. This committee developed a plan which seems to offer a solution of the difficulties which previously led the examiners to oppose strongly the frequently recurring request from Section membership committees that the examiners render advance opinions on eligibility. The plan has been approved by the board of directors, and it now merely remains to arrange the necessary forms for putting it into regular operation.

The new procedure, which might be designated as the "invitational transfer method," applies only to Fellow grade. It will not require any change in the constitution, and will be supplementary to the present "Proposal Method" for advancement to Fellow

Table X. Applications for Admission and Transfer

Applications for Admission		
Recommended for grade of Associate	534	
Re-elected to the grade of Associate	78	
Not recommended	8	620
Recommended for grade of Member	116	
Re-elected to the grade of Member	22	
Not recommended	36	174
Re-elected to the grade of Fellow	2	2
Applications for Transfer		
Recommended for grade of Member	174	
Not recommended	14	188
Recommended for grade of Fellow	39	
Not recommended	0	39
Students		
Recommended for enrollment as Students		2,063
Total		3,086

In brief, it provides a means whereby a group of Members and Fellows desiring to promote the advancement to Fellow status of another individual may propose him over their signatures as at present, one of the Fellows designating himself as the official sponsor for such transfer. The sponsor will be required to obtain and to furnish to the board of examiners, over his signature, a fully detailed professional record of the prospect, together with the names of the required number of Fellows who will be willing to act as references. The examiners will then submit to these references the regular reference forms and obtain their confidential replies. Any correspondence with regard to references or additional details of record will be solely between the examiners and the official sponsor. The examiners will then pass unofficially on the question of eligibility and communicate their action to the official sponsor, who will approach the proposed Fellow and will then obtain his consent to the transfer action and his signature on the application. With the signed application in hand, the examiners will then take formal action. The remaining steps as to posting, and so on, will be unchanged from the present procedure.

It is hoped that the new procedure will meet the expressed wishes of the membership and the board of directors, and the examiners will strive to make it work, while at the same time discharging their heavy responsibility of upholding the high standards set for such recognition of outstanding achievement in the profession.

The board of examiners now recommends to the board of directors that a statement be prepared and generally broadcast to the Institute membership clearly outlining the new procedure available for advancement to Fellow through the "invitational method".

All questions with regard to change in procedure for transfer to Member grade were laid over for further careful study in the light of prospective experience with the new procedure for Fellows. Rejections of transfer applications to Member grade have tended to run high (over 25 per cent). As also pointed out last year, this apparently is due in part to a failure to appreciate the technical requirements prescribed by the constitution, somewhat to a tendency to aspire to Member grade merely because the 27-year minimum age limit has been reached, and slightly to the increase of dues (to parity with those of Member grade) at the end of the 6-year period of Associate membership.

HEADQUARTERS COMMITTEE

It seemed to the committee that conditions at the headquarters of the Institute were such that a considerable amount of renovation work should be carried out during the year. The finance committee, therefore, brought the matter before the board of directors at the meeting on January 30, 1941, and authority was given to proceed with the work as proposed, up to the limit of certain funds in the depreciation accounts which were immediately available for the purpose.

As of this writing the work is nearly completed. The committee realizes that tastes vary so greatly concerning furniture and decorations that no unanimity of opinion can be expected regarding changes of this kind. It hopes, however, that the membership in general will consider the results to represent a satisfactory handling of the situation within the limits of the available funds.

The committee has been especially fortunate in being able to draw on the professional experience and judgment of R. H. Hose of the Bell Telephone Laboratories. He proposed the general plan of redecoration, prepared the sketches which were submitted to the board in January, and has co-operated closely in carrying out all phases of the work. The committee is greatly indebted for a large amount of his time and for his continuous interest and guidance.

COMMITTEE ON PLANNING AND CO-ORDINATION

The committee has had to hold only one meeting during the year, its predecessor for the preceding administrative year having completely cleared a rather extensive accumulated docket and rendered comprehensive reports to the board of directors during last year.

In addition to the usual recommendations to the board of directors with respect to the schedule of meetings for the calendar year 1942, the committee considered and advised the board concerning a proposed new technical committee, dues which Members for Life continue to pay, proposed review of past applications of electricity in warfare, and the use of United States standards in South America.

COMMITTEE ON CONSTITUTION AND BYLAWS

There were several amendments to the bylaws. One extended the period of time in which Enrolled Students may apply for admission to Associate grade without payment of entrance fee, particularly to affect students graduating in the January class, or at times other than the usual June commencement. A section was added to the bylaws covering the Charles LeGeyt Fortescue Fellowship committee; also a section covering the committee on research, in view of its change in status from a technical committee to a general committee.

Minor revisions were made with regard to the listing of committees.

COMMITTEE ON CODE OF PRINCIPLES OF PROFESSIONAL CONDUCT

The committee has carried on some correspondence, but no matters have required immediate action. The chairman is also chairman of the joint committee on principles of ethics, now sponsored by the Engineers Council for Professional Development, which expects to have a report ready for presentation in the fall.

COMMITTEE ON SAFETY

It was reported last year that a subcommittee had been appointed to develop further contacts with the colleges and Student Branches on safety. This effort resulted in a bulletin entitled "Suggestions for Meetings on Safety", which was mailed to the chairman of each Student Branch and to each Student Branch counselor on September 23, 1940. The purpose of the bulletin was to urge the Student Branches to hold one or more meetings on safety during the school year, and it gave them numerous suggestions about organizing such meetings, sources of speakers, and references to safety codes and other publications on the subject. Reports indicate that numerous Student Branches have found this bulletin useful, and it is intended to mail a similar bulletin to them again next September.

A letter was sent also to the Sections of the Institute urging upon them the importance of greater attention to safety and suggesting that at least one meeting be held on this subject.

The committee has asked the technical program committee to call to the attention of each of the national technical committees the importance of greater attention to safeguarding life and property from electrical hazards. In periods of high industrial activity, there is always a tendency toward an increase in the accident rate resulting in an increase in lost time and damaged material.

All these steps have been taken as parts of a co-ordinated effort to aid the national defense preparations by conservation of man power and materials through increased safety measures.

During the year, the committee sponsored two papers which were presented before conventions of the Institute. One was a paper by W. B. Kouwenhoven, D. R. Hooker, and O. R. Langworthy, entitled "A Comparison of the Relative Efficiency of the Schafer and Pole-Top Methods of Artificial Respiration" which was presented at the Middle Eastern District meeting in Cincinnati, Ohio. This is a valuable contribution to the fund of knowledge on this important subject. The other was a paper by C. F. Dalziel, J. B. Lagen, and J. L. Thurston, entitled "Electric Shock", presented at the 1941 winter convention. It presents valuable data regarding the let-go values of currents which human beings can withstand. The committee believes there is need for further data of this kind, not only with respect to the let-go currents human beings can withstand, but also as to the susceptibilities of animals to electric currents.

The committee wishes to stress the importance of proper maintenance of electrical apparatus and machinery as an important factor in continued safe operation. During periods of high production when plants are being operated long hours under heavy loads, increased attention to maintenance is necessary to avoid injuries, lost time, lost production, and damaged materials caused by avoidable failures.

Active attention to these and many other problems is planned for the coming year.

COMMITTEE ON RESEARCH

The change in status of the committee on research from that of a technical committee to that of a general committee of the Institute was authorized by the board of directors at its meeting on May 24, 1940, and appropriate changes in the bylaws, section 84-A, were adopted by the board on January 30, 1941. This change has relieved the committee of certain duties that it previously discharged in connection with the review of papers.

The principal activity has been that of studying the program of Engineering Foundation research projects sponsored by the Institute. For the purpose of developing more clearly their relation to the broad problems of electrical engineering, two projects have received particular attention. These are a research on the stability of impregnated-paper insulation, project 66, which has been under way for some years at the Johns Hopkins University, under the immediate direction of Doctor J. B. Whitehead. Another is a research on insulating oils and cable saturants, project 74, under way at the Massachusetts Institute of Technology, under the immediate supervision of Professor J. C. Balsbaugh. Each of these projects is supervised by an advisory committee which meets several times a year, considers in detail the status of the project, and prepares recommendations as to future programs.

Recommendations and reports of these advisory committees have in turn been considered by the committee on research before submitting them to the board of directors for consideration. The committee has not to date undertaken a review of the welding research program of Engineering Foundation jointly sponsored by the Institute and the American Welding Society. This has not been from lack of interest or sympathy but because it was felt that the direction of this activity is being ably handled by existing committees. It is suggested, however, that succeeding committees on research consider this matter in order to insure effective integration of the Institute's research activities.

Although it is still too early to judge the full value of the change in status of the committee, it is believed that experience to date has demonstrated the desirability of the change. Should the general national situation become such as to lead to special calls on the Institute for activities in the field of research, the value of the committee will be still further apparent.

Standards

STANDARDS COMMITTEE

During the past year there has been a noticeable expansion of standards activity. This probably is due to increased industrial activity brought about by the national defense program. The American Standards Association has taken formal action urging all possible speed in standards development as an effective aid in that program. In line with this policy, it may be pointed out that proposed revisions of many AIEE standards have recently become available. Among these may be mentioned No. 4, "Measurement of Test Voltages in Dielectric Tests"; No. 21, "Apparatus Bushings"; No. 22, "Air Switches and Bus Supports"; No. 24, "Protector Tubes"; No. 27*A*, "Switchgear Assemblies"; No. 25, "Fuses Above 600 Volts"; No. 28, "Lightning Arresters"; No. 41*A*, "Insulator Tests"; and No. 45, "Recommended Practise for Electrical Installations on Shipboard". The call for this last standard, No. 45, is growing rapidly and the demand for it probably will become even greater, as compliance with its requirements is now a part of nearly all shipbuilding specifications. In addition to the preceding strictly AIEE activities, sectional committees working under ASA procedure have issued, or are about to offer, several standards and proposed standards. One on "A-C Power Switchgear" and one on "Transformers, Regulators, and Reactors" are now available, and revisions of all the various letter and graphical symbols standards are practically completed.

The sectional committee on definitions of electrical terms is rapidly bringing its work to a point where the final step necessary to obtain approval as an American Standard can be taken. The appointment of a new chairman, C. H. Sanderson, to replace Doctor A. E. Kennelly, deceased, has been made, and the addition of a man to the AIEE staff to devote the major part of his time to this work has greatly expedited the compilation of the immense amount of data involved in the completion of this report.

In the test-code field, activity has also increased. A revised edition of the "D-C Test Code" is under way, and the development of a code for electrical measurements is being considered. A test code is also offered as part of the proposed pamphlet on "Bushings". A specification for wet tests is about to be published. The Institute has appointed a representative to serve on a sectional committee on "Code for Safety in Quarry Operations".

Following out Past-Chairman Hellmund's plan for a more closely knit organization aimed to bring about close co-operation among various standardizing groups and proper co-ordination of the results of their work, a seventh co-ordinating committee has been appointed, on conduction in vacuum, gases, liquids, and solids. Further development of the "Standards Manual" is also under way. It is expected this manual will promote a closer understanding of available standardizing machinery and the interrelationships of the various committees engaged in that work.

Another question of considerable import coming up for discussion during the year was the establishment of a proper policy with regard to withdrawal of standards when proposed revisions become available. It was finally agreed that, in order to preclude the possibility of arguments between manufacturers and customers on adherence to existing standard practice, a standard should remain in force until actually replaced by a formally accepted revision.

Under ASA procedure, it is customary to classify the membership of sectional committees according to company affiliation. However, it has always been the Institute's policy to consider that its committee appointees are representative of independent interests and that they would, whenever practical, render decisions from that viewpoint. The ASA therefore was formally requested in future to classify Institute appointees as independent interests unless advised otherwise.

In view of the present American policy to strive for closer relationships between the United States and South and Central American countries, steps were taken to ascertain the feasibility of translating into Spanish and Portuguese such United States electrical standards as would have the greatest application in the development of trade in the electrical field. This work, if carried through, probably will be in co-operation with the United States Department of Commerce.

UNITED STATES NATIONAL COMMITTEE OF THE IEC

At its annual meeting in December 1940, the United States National Committee of the International Electrotechnical Commission re-elected its officers: E. C. Crittenden, president, L. F. Adams and H. S. Osborne, vice-presidents. Doctor C. H. Sharp continues as honorary president.

Due to the international situation, the work of the IEC is practically in a state of suspension. The central office of the commission, however, has not been disbanded, so that as soon as circumstances permit it will be possible to resume activities. The United States National Committee, as well, is keeping its organization intact, and will continue to hold an annual meeting.

At the annual meeting of the USNC, there was a full discussion of the desirability and possibility of the USNC taking the lead in developing international electrical standardization work between the countries of North and South America. The result of this discussion was the appointment of a special committee under the chairmanship of President Crittenden, of the USNC, with L. F. Adams, H. S. Osborne, and Frank Thornton, Jr., as members, to explore the whole situation and to make contacts with the Pan-American Union, proper officers and departments of the Federal Government, technical societies and trade associations, and others, and to make recommendations to the USNC on the whole subject. This action of the USNC was readily concurred in by the ASA. The AIEE committee on planning and co-ordination has also appointed this same group, with the addition of D. M. Simmons, as its committee to investigate the same subject.

Technical Committees

COMMITTEE ON AIR TRANSPORTATION

The establishment of this new technical committee was authorized by the board of directors on August 2, 1940, and the organization was completed in October. At the first meeting on November 15, the committee discussed the scope of its activities, recommended co-operation with governmental agencies in defense problems, and began the study of papers for the winter convention.

The committee has made special efforts to secure an adequate number of papers of high quality for presentation at national conventions and District meetings, but has had great difficulty on account of the close relationship of developments in its scope of activities to national defense, with the resulting restrictions on dissemination of information. It has instigated efforts to increase the membership in the Institute of qualified persons in the aircraft and associated fields.

On recommendation of the committee,

it was authorized by the board of directors to offer its services to governmental agencies in connection with the application of electrical equipment to aircraft. Co-operation with several agencies has been established.

COMMITTEE ON AUTOMATIC STATIONS

The committee prepared a bibliography for the period 1932–40, inclusive, containing approximately 800 references on supervisory and remote control, telemeters and telemetry, automatic and remote control switchgear, automatic features of generating stations using fuels, automatic boiler and combustion control, automatic hydroelectric plants, automatic substations (installations).

Several members of the committee, as members of the joint subcommittee on telemetering and supervisory control, collaborated in the preparation of a report on the latter subject (see report of committee on instruments and measurements).

The committee approved proposed standards for nominal voltages below 100.

The committee sponsored the paper on "Synchronizing Transients and Synchronizers for Large Machines" by R. D. Evans, F. H. Gullicksen and C. B. Myhre, published in the 1940 Transactions, pages 965–73.

In co-operation with the relay subcommittee of the protective devices committee, the committee on automatic stations has sent out a number of questionnaires covering the use of pilot conductors in supervisory control, telemetering, and calling and signalling systems. These data will be collected, with similar data pertaining to protective relays.

COMMITTEE ON BASIC SCIENCES

Papers reviewed and recommended by the committee included 3 for the 1940 summer convention, 7 for the 1941 winter convention, and one for the North Eastern District meeting in Rochester, N. Y. The committee also held a technical conference at the summer convention, and two such conferences and a meeting of the committee at the winter convention.

Considerable progress was made by the subcommittee on definitions of electrical terms.

The committee has approved 4 papers for a joint session with the subcommittee on electronics at the 1941 summer convention.

COMMITTEE ON COMMUNICATION

The committee on communication held three meetings during the year. Much additional business was conducted by correspondence. The committee arranged communication programs at the summer and Pacific Coast conventions, in 1940, and the 1941 winter convention, and assisted in obtaining material for the Middle Eastern District meeting in Cincinnati. The 15 papers sponsored by the committee at these meetings dealt with many subjects—telegraphy, telephony, radio, electronics, television—and nearly every aspect of the communication art and science was represented to some extent in these papers. Programs have also been arranged for the 1941 summer and Pacific Coast conventions.

COMMITTEE ON DOMESTIC AND COMMERCIAL APPLICATIONS

A paper by L. C. Packer, Associate AIEE, entitled "Design Factors Involved in the Design of Domestic Motor Appliances", was presented at the Middle Eastern District meeting, Cincinnati, Ohio, October 9–11, 1940. A paper by W. J. Russell is now being reviewed, and a third by W. H. Delancey has been submitted, both the latter being intended for presentation at the summer convention in Toronto, Canada, in June 1941. Two or three other papers have been promised, but have not yet been produced.

A conference period has been arranged for at the summer convention and appropriate arrangements have been made for prepared discussions to open this conference.

No standardization activities have been undertaken by this committee during the fiscal year. The committee has indicated that it will not require any budget appropriation for the ensuing fiscal year.

COMMITTEE ON EDUCATION

The committee held a meeting at the 1941 winter convention, and is planning to hold a conference at the summer convention.

Three subcommittees were continued from the previous year. Replies to the questionnaire of the subcommittee on student guidance were received from 58 Sections. The subcommittee has transmitted definite suggestions to the Sections interested, and expects to report on its activities at the summer convention conference of officers, delegates, and members.

COMMITTEE ON ELECTRIC WELDING

The activities of the committee on electric welding have been largely those of a subcommittee on power supply for welding operations. This subcommittee has recommended that the National Electrical Code be amended to cover specific requirements for resistance-welder installations. At present, the code makes no mention of resistance welders, and it becomes necessary for the various local authorities to make their own interpretations as they think may apply to resistance welders. Resistance welders are far different from ordinary power and light load, and the necessary wiring, fusing, and service facilities must be provided on a somewhat different basis. The subcommittee prepared suggested paragraphs covering conductor sizes for branch circuits and feeders supplying resistance welder loads which were transmitted by the secretary of the standards committee to the chairman of the sectional committee on National Electrical Code.

The subcommittee has prepared purchase inquiry forms and manufacturers' data sheets which should prove of mutual aid to both the users and the manufacturers in reaching a common understanding as to just what type and size of welding machine is needed for a given job, as well as furnish complete power supply data to the users' electrical department and the local power company. The forms cover both machine mechanical data and power-supply data. The subcommittee is concerned particularly with the sections covering power-supply data, and thinks that by proper use of these forms the providing of an adequate power supply for any welding operations will be greatly facilitated. While the forms covering the mechanical data are not the direct concern of this subcommittee, it is felt that they should be included with those covering the power-supply data. Copies of the purchase inquiry forms and manufacturers data sheets have been submitted to the secretary of the Resistance Welder Manufacturers Association, and are being distributed to its entire membership for their suggestions.

The subcommittee, during the past two years, has spent considerable time in the preparation of a report on power supply for resistance welding machines, and has completed Section III covering "Factory Wiring for Resistance Welders". Section I, "Guide to Good Electrical Performance of Resistance Welding Machines" and section II, "Resistance-Welder Installations" have been printed and made available for distribution. Section III was presented at the North Eastern District meeting, April 30–May 2, and published in the 1941 Transactions (May section) pages 185–92.

COMMITTEE ON ELECTRICAL MACHINERY

The subcommittee on synchronous machinery has been extensively engaged in work on revision of the "Test Code for Synchronous Machines". Substantial progress has been made, and it is expected that the revision will be ready for submission to the standards committee during the ensuing fiscal year.

The subcommittee on transformers prepared a very comprehensive report on the protection of power transformers against lightning surges, which was presented at the winter convention. This report is a result of several years of study by the subcommittee, and furnishes information as to the degrees of protection possible and the various methods in common use. The subcommittee has also given careful study to the proposed ASA Standards, and through membership on the ASA sectional committee is suggesting recommendations for changes and improvements. The subcommittee is also studying proposed changes in the test code section of the ASA Standards.

The d-c subcommittee has revised the "Test Code for D-C Machinery" following suggestions of the standards committee and incorporated the "Test Code for Fractional Horsepower D-C Motors." The test code has been submitted to the standards committee with a recommendation that it be published for trial use.

The subcommittee on test codes for single-phase motors has prepared a final draft of the "Test Code for Single-Phase Motors" which is practically in final form. It is expected that this test code will be submitted to the standards committee with a recommendation for publication for trial purposes during May 1941.

During the year, a co-ordinating committee consisting of the chairmen of various other subcommittees was organized to aid in co-ordinating work of the various test codes. Professor H. N. Walker of the committee on instruments and measurements was added to this subcommittee as a liaison member from that committee.

One session at the 1940 summer convention was sponsored by the committee on electrical machinery, in which 4 papers were presented. At this convention, a technical conference was devoted to test codes. At the Middle Eastern District meeting held in Cincinnati in October 1940, 1 session was devoted to electrical machinery, at which 5 papers were presented. At the 1940 Pacific Coast convention in Los Angeles, Calif., in August 1940, 1 session was devoted to electrical machinery, at which 4 papers were presented. At the 1941 winter convention, 2 sessions were sponsored by the committee, at which 9 papers were presented. At the North Eastern District meeting in Rochester, N. Y., April 30 to May 2, several papers recommended for presentation by the committee were presented, although under the auspices of other committees. At the 1941 summer convention in Toronto, it is planned to have 1 session sponsored by the committee at which 4 or 5 papers are planned for presentation. Some other papers have been reviewed and are available.

COMMITTEE ON ELECTROCHEMISTRY AND ELECTROMETALLURGY

With the approval of the board of directors, the committee arranged for a joint afternoon technical session and a joint evening technical conference with the American Society for Metals on the last day of the 1941 winter convention. Two AIEE papers were presented in the afternoon, and two addresses were given by members of the ASM in the evening.

A subcommittee for the investigation of voltage transients in the operation of arc furnaces had been organized in March 1940, and the first meeting was held in October 1940. At this meeting, it was decided to enlarge the subcommittee considerably by the addition of advisory members, including representatives from the furnace manufacturers. Plans were also made for extensive field investigations.

A progress report was presented at the second meeting of the subcommittee, held at the winter convention. It is expected that a partial report of findings of the subcommittee will be available in about 6 months and a complete report in 12 months. The investigation so far has covered conditions under which voltage transients are produced, their magnitude, probability, and methods of prevention.

A meeting of the committee was held at the winter convention. It was decided to arrange for a joint session with the Association of Iron and Steel Engineers for May 27, 1941. The program for this meeting is already in final shape. It will consist of a special joint meeting of the Cleveland and Pittsburgh Sections of the AIEE and the AISE, and will be sponsored by the committee on electrochemistry and electrometallurgy.

Plans are under way for a report on progress in the field of electrochemistry and electrometallurgy, to be available in the spring of 1942.

COMMITTEE ON INSTRUMENTS AND MEASUREMENTS

During the year, the activities of the committee consisted primarily of the review of papers, the arrangements for their presentation at conventions, the sponsorship of a technical conference, the preparation of reports on the progress of the art in the field of instruments and measurements, and the revision of test codes, definitions, and standards. Seventeen papers have been submitted in whole or synopsis form for review by the committee.

Technical sessions were held at the summer and winter conventions, and a technical conference on dielectric measurements in the field was held at the summer convention. Seven prepared reports were presented at this conference, and between 50 and 60 members were present.

A report on "Telemetering, Supervisory Control, and Associated Circuits" was completed by a joint subcommittee of the committees on instruments and measurements and on automatic stations. This report contains a classification of 53 of the numerous types of telemetering and supervisory control equipment now manufactured, a description of each type, and a comparative tabulation of the characteristics of all. The report has been approved by both technical committees and sent to the publication committee for publication in pamphlet form. It is hoped that the report may be the basis for a standard on its field in the future.

A report on "Progress in the Art of Metering Electrical Energy" is nearing completion. No previous report on the subject having been written by the Institute, the scope of this report is wider than that of others, and the development of electrical-energy measurement is traced from its inception down to the present time. The report is the result of collaboration by authorities in various fields—educational, manufacturing, operating, regulatory, and scientific. It should be completed before the 1941 summer convention, and it is hoped that it will be published both in ELECTRICAL ENGINEERING and in pamphlet form.

A report entitled "Wave Form in Dielectric Power Factor Measurements", on the methods of specifying the voltage wave form of the power source employed in measurements of the power factor of dielectrics, was completed and published in ELECTRICAL ENGINEERING, June 1940, page 255.

A subcommittee has been studying the test codes prepared by the committee on electrical machinery, and suggestions for revision of certain parts of the codes pertaining to instruments and measurements have been passed on to the committee on electrical machinery. As a result of this work, a representative of the committee on instruments and measurements has been appointed to the subcommittee of the committee on electrical machinery that is preparing the test codes, and a subcommittee of the committee on instruments and measurements has been set up to prepare a master test code on resistance measurements. Work on a master test code on temperature measurements has been started.

The definition of the galvanometer has been modified, and the name "phase-shifting transformer" approved to describe the miniature transformer used to adapt wattmeters and watt-hour meters to reactive power measurement. A subcommittee on electrical definitions is attempting to coordinate definitions in the *C42* report, the "Electrical Metermen's Handbook," and the "Code for Electricity Meters."

The definitions of the terms "instrument" and "meter" have been reconsidered and modified to broaden the scope of the latter.

A new subcommittee on accuracy classification of instruments and instrument standards has been set up recently to attempt to formulate improved methods of stating the performance or accuracy of indicating instruments. This subcommittee is the newest of 11 now active. As a means of coordination there are representatives of the committee on instruments and measurements on the joint subcommittee on electronics, the relay subcommittee of the committee on protective devices, the test-code subcommittee of the committee on electrical machinery, and 3 subcommittees of the standards committee.

A report covering most of the more important work of the committee for the past few years was given by the secretary at the winter convention, and was published in ELECTRICAL ENGINEERING, March 1941, pages 133–4.

COMMITTEE ON LAND TRANSPORTATION

Three meetings were held during the past fiscal year: one at the summer convention, Swampscott, Mass., one in Chicago, Ill., in October, and the last at the winter convention, in Philadelphia, Pa.

The name of this committee was changed from committee on transportation to committee on land transportation, at the time the board of directors established a committee on air transportation.

The committee has four subcommittees, which enable it to cover adequately the land-transportation field in which practically all the papers must be solicited. Standardization along the lines of the PCC car makes it almost impossible to bring forth new papers in the light-traction field. However, at the winter convention, in January, a paper on "The Electro Gear—A New Electromechanical Transmission", by Doctor Ernst Weber, aroused a tremendous amount of interest in the field of urban transportation. Considerable space was devoted by the various transportation publications to comments on Doctor Weber's paper.

COMMITTEE ON MARINE TRANSPORTATION

In July 1940, AIEE Standard No. 45, "Recommended Practise for Electrical Installations on Shipboard", was reprinted to include a complete revision, the detail work for which was accomplished last year.

Due to the pressure of work incident to the current large shipbuilding program, there has been little activity this year, although at our committee meeting on January 10, 1941, all business at hand was transacted, including future changes in Standard No. 45 to be handled by addenda sheets.

The principal item of business of this committee is to keep Standard No. 45 up to date for use by shipbuilding and other organizations. However, it is hoped that when time becomes available, some definite activity on standards for equipment may be undertaken.

COMMITTEE ON POWER GENERATION

Eleven technical papers were presented under the sponsorship of the committee: summer convention, 2; Middle Eastern District meeting, Cincinnati, 1; and winter convention, 8.

A conference, similar to that at the 1940 summer convention in Swampscott, Mass., was held at the Pacific Coast convention, at which the same and additional material was presented.

More than the usual amount of interest was shown in the session of the committee at the 1941 winter convention, the attendance for both sessions being exceptionally large. The committee has given most of its attention during the past year to the study and discussion of subjects relating to governor design and operation, load fluctuations, system stability, and associated phenomena.

The studies which have been carried on during 1940 are being continued into the 1941 summer convention in Toronto by conference studies. Material is also being prepared for a general discussion in Toronto covering preparedness in its relation to power generation.

Steps are being taken toward the formation of a joint committee with The American Society of Mechanical Engineers on the standardization of the design of the governor and its associated equipment.

COMMITTEE ON POWER TRANSMISSION AND DISTRIBUTION

The committee held two meetings during the year. In addition to transaction of routine business at these meetings, there were general engineering discussions of a number of matters relating to transmission and distribution. This review of engineering development is becoming an extremely valuable part of the committee activity.

The committee is now operating on the basis of the new organization, under which there are four subcommittees: transmission, distribution, stations, and general system.

During the year, Standard No. 41, Insulator Tests, was approved for printing as a tentative standard. It is expected that, after this tentative standard has been in use one year, a decision will be reached with respect to printing as an ASA standard. The committee is now engaged in the task of preparing a revised report on grounding standards.

The committee sponsored 1 technical session at the summer convention, and 2 technical sessions at the winter convention, involving the presentation of 11 papers, and in addition there were 7 papers presented in other sessions jointly sponsored. The committee also co-operated in arranging for the presentation of technical papers at District meetings during the year.

COMMITTEE ON PRODUCTION AND APPLICATION OF LIGHT

The committee has continued during this fiscal year to keep members of the Institute informed on the latest developments in illuminating engineering, principally through the sponsorship of conferences at District and national meetings and by obtaining papers from qualified authors on illumination subjects for publication in ELECTRICAL ENGINEERING. All of these activities have been intensified this year, and plans are now under way to further extend them, especially in those lighting fields which are vital to national defense.

The committee held a protective lighting conference at the Middle Eastern District meeting, Cincinnati, Ohio, October 10, 1940, and a fluorescent lighting conference at the winter convention, Philadelphia, Pa., January 29, 1941. A complete report on each of these conferences appeared in ELECTRICAL ENGINEERING, and the prepared discussions at the fluorescent lighting conference are scheduled for publication in the June 1941 issue of ELECTRICAL ENGINEERING, because of their timely interest to the Institute membership.

A conference on protective lighting is now under consideration for the summer convention in June 1941. Prominent speakers from Canada and the United States will be asked to prepare discussions on this subject which is vital to the defense of each country.

In addition to reviewing all papers on the subject of lighting which are presented for consideration by the technical program committee, this committee also selects timely lighting subjects and encourages competent authors to prepare papers for ELECTRICAL ENGINEERING.

The committee met only once during the year, since membership is rather widely scattered, and activities can well be carried on by mail after plans have been settled for the year.

COMMITTEE ON PROTECTIVE DEVICES

During the past year, 15 new members were added to the committee, and 10 retired. Representation was added from the Southern, Pacific, and North West Districts, with a corresponding reduction in certain other Districts. The representation from the various divisions of work within the committee's scope was kept as broad as possible.

The committee activities have been divided so that each member has some assignment, and excellent co-operation and valuable assistance have been given by the subcommittee chairmen and their various individual members. The four main subcommittees are: circuit breakers, switches, and fuses, fault-current limiting devices, lightning arresters, and relays.

The subcommittee on circuit breakers, switches, and fuses has been active on a number of important projects including the review of Standard No. 19, "Circuit Breakers", to incorporate air circuit breakers and new insulation test levels. Proposed Standard No. 25, "Fuses" has been studied to incorporate the new insulation test levels. Studies have been made of voltage recovery rates, oil for impulse testing, and short-circuit calculation practices for the application of interrupting devices. Reports on the latter two subjects have been completed, and are scheduled for presentation at the summer convention. The recent adoption of basic insulating levels calls for a reconsideration of voltage tests on certain electrical equipment. The present test values for protective apparatus, especially in the lower voltage classes, is being given study, and in some cases may require modification.

Standard No. 22, "Air Switches and Bus Supports" was printed in June 1940, and issued for one year's trial use. Standard No. 24, "Protector Tubes" was printed and issued in August 1940, for one year's trial. Standard No. 27, "Enclosed Switchgear" has been completed, approved by the AIEE standards committee, and soon will be printed and distributed for one year's trial use as a revised standard.

A standard for neutral grounding devices has been completed and submitted to the standards committee for approval and publication as a proposed standard. The subcommittee on fault-current limiting devices is co-operating with other technical committees in the review of the "Grounding Practices Report".

Standard No. 28, "Lightning Arresters", has been revised, approved, and submitted to the standards committee for adoption. This material has been passed on to ASA sectional committee *C*-62 for consideration as a revised ASA standard.

Additional data have been obtained, particularly at high values of discharge current, concerning the performance characteristics of line-type lightning arresters rated 20 kv to 73 kv inclusive, and assembled in the form of a report for presentation at a forthcoming meeting. Work is in progress toward the development of a standard for distribution type protector tubes.

The subcommittee on relays has carried on a number of important projects including the standardization of potential devices and instrument transformers; studies of pilot wire relaying experience; sensitive ground protection; automatic recording devices, and out-of-step protection. A compilation is being prepared to show the desired scope of manufacturers' catalog information. A bibliography of relay literature was prepared last year and this is now in process of being printed and made available to the industry.

The special representatives on other committees have co-operated in the furtherment of insulation co-ordination and the application of new developments in connection with contact surfaces.

The various subcommittees collaborated last year in the preparation of material for use as a report "Progress in the Art". This is now being brought up to date, and arrangements have been made for its publication in ELECTRICAL ENGINEERING, in three sections entitled "Circuit Interrupting Devices", "Relaying and Fault-Current Limiting Devices", and "Lightning Protection and Miscellaneous".

The committee has sponsored technical papers as follows: 1940 summer convention, 6; Middle Eastern District meeting, Cincinnati, 1; Pacific Coast convention, Los Angeles, 4; winter convention, 4 on circuit breakers, 5 on relays and other subjects, and 5 on transmission and protective-devices subjects (joint with committee on power transmission and distribution); and North Eastern District meeting, Rochester, 1. A number of additional papers are available for subsequent meetings, and 10 will be presented at the 1941 summer convention.

The committee held four meetings and a fifth is scheduled for May. These meetings have been well attended, and the discussions have consisted largely of committee activities, action regarding proposed standards, basic insulation levels, temperature rise and ambient temperatures for enclosed switchgear, presentation of subcommittee reports, and consideration of papers for future programs.

It is expected that the future work of the committee will follow along similar lines, completing the several standards which are now in preparation on circuit breakers, fuses, potential devices, instrument transformers, protector tubes, and so on. In view of the great interest being shown in this work as evidenced by attendance at the technical sessions and at the committee meetings, and the large number of papers proposed, it would appear that the work is being carried forward along useful and progressive lines.

Awards

COMMITTEE ON AWARD OF INSTITUTE PRIZES

Four national and ten District prizes were awarded for papers presented during the calendar year 1940 and for the student papers presented during the academic year ending June 30, 1940.

The committee considered a large number of eligible papers which were of a high order, and, in determining the awards for the national best paper prizes and initial paper prize, it had the benefit of the gradings and recommendations of the technical committees, which had reviewed the papers. In addition to the national paper prize awards, three other papers were given honorable mention.

The pamphlet "National and District Prizes" has been revised, and a new edition of January 1941 issued. The principal changes establish a new basis of grading for Branch and graduate paper prizes, and empower the District executive committees to fix the dates of closure and of award of the District prize for Branch paper and the District prize for graduate paper. The new basis of grading recognizes that the objective of student papers differs from that of adult papers, and permits the placing of greater emphasis on the written presentation and on the exercise of engineering thinking than on technical value. These changes were made in co-operation with the committee on Student Branches and the recommendations of the conference of Student Branch counselors held during the summer convention, in Swampscott, Mass.

EDISON MEDAL

The Edison Medal, which is awarded by a committee composed of 24 members of the Institute, was awarded for 1940, to George Ashley Campbell, "in recognition of his distinction as scientist and inventor and for his outstanding original contributions to the theory and application of electric circuits and apparatus", and was presented on January 29, 1941, during the winter convention. The medal may be awarded annually for "meritorious achievement in electrical science, electrical engineering, or the electrical arts".

LAMME MEDAL

The Lamme Medal committee awarded the medal for 1940 to Comfort A. Adams, consulting engineer, Edward G. Budd Manufacturing Company, "for his contributions to the theory and design of a-c machinery and his work in the field of electric welding". Arrangements are being made for the presentation of the medal at the summer convention in Toronto, Ont., Canada, June 16–20, 1941. The medal may be awarded annually to a member of the AIEE "who has shown meritorious achievement in the development of electrical apparatus or machinery".

COMMITTEE ON AWARD OF COLUMBIA UNIVERSITY SCHOLARSHIPS

Due to the very large demand for young engineers by the industries there was not as much interest displayed in the scholarship as in previous years, and the few applications received were from students who either could not afford to undertake the expense of living in New York City, even with their tuition covered by the scholarship, or did not meet the specifications for previous work. Therefore, the scholarship was not awarded for this academic year.

In view of the very uncertain conditions in the coming academic year, and the fact that the great majority of engineering graduates are being taken by the industries and the selective service, the University authorities decided not to offer the scholarship during the academic year 1941–42. This is the second time in the many years since the scholarship was established that no award has been made.

CHARLES LE GEYT FORTESCUE FELLOWSHIP COMMITTEE

The committee, at its meeting in March, decided that no award would be made for the scholastic year 1941–42, because of the national emergency and the limited number of candidates making application for the fellowship. The demands for young men in industry and in the various branches of military service apparently have taken many who might otherwise have applied for the fellowship. It was also thought that after the present emergency is over the accumulated funds may be more useful in helping deserving young men readjust themselves to normal industrial life.

JOHN FRITZ MEDAL

The John Fritz Medal board of award, composed of representatives of the national societies of civil, mining and metallurgical, mechanical, and electrical engineers, awarded the 37th medal (for 1941) to Ralph Budd, president, Chicago, Burlington, and Quincy Railroad, for "improvement of railroad tracks and service, especially the introduction of lightweight streamlined trains".

HOOVER MEDAL

The Hoover Medal was established through a trust fund created by a gift from Conrad N. Lauer, and is to be awarded periodically "to a fellow engineer for distinguished public service" by a board representing the national societies of civil, mining and metallurgical, mechanical, and electrical engineers. The fourth medal was awarded in 1939; no awards have been made since that time.

ALFRED NOBLE PRIZE

This prize, established in 1929, consists of a certificate and a cash award of $500 from the income from a fund contributed by engineers and others to perpetuate the name and achievements of Alfred Noble, past president of the American Society of Civil Engineers and of the Western Society of Engineers. It may be made to a member of any of the co-operating societies, American Society of Civil Engineers, American Institute of Mining and Metallurgical Engineers, American Society of Mechanical Engineers, AIEE, or Western Society of Engineers, for a technical paper of particular merit accepted by the publication committee of any of these societies, provided the author, at the time of such acceptance, is not over 30 years of age. No award was made during the past year.

WASHINGTON AWARD

The Washington Award for 1941 was bestowed upon Ralph Budd, "for vision and courageous leadership in advancing the technological frontiers of high-speed railroad transportation", and was presented to him at a dinner on February 24, 1941. This award may be made annually to an engineer by the commission of award composed of nine representatives of the Western Society of Engineers and two each of ASCE, AIME, ASME, and AIEE.

Joint Activities

UNITED ENGINEERING TRUSTEES, INC.

This organization is the corporate body which holds title in the name of the four Founder Societies to their joint physical properties, namely, the Engineering Societies Building, the Engineering Societies Library, and the endowment funds of the Engineering Foundation. It operates and manages the Engineering Societies Building and administers certain joint activities of the four Founder Societies.

Extensive studies have been made in efforts to improve the service of the Engineering Societies Building to the members of the societies. Constant efforts have been made to maintain and improve the security of the investments of the corporation, and, to such extent as consistent therewith, to obtain a reasonable income. An abstract of the annual report of the corporation for the year which ended September 30, 1940, appeared on pages 49–50 of ELECTRICAL ENGINEERING for January 1941.

ENGINEERING FOUNDATION

The Engineering Foundation is a joint organization of the national societies of civil, mining and metallurgical, mechanical, and electrical engineers established for "the furtherance of research in science and engineering, and the advancement in any other manner of the profession of engineering and the good of mankind".

The Foundation assists in a wide range of research projects of interest to science, engineering, industry, and the general public, each project being under the sponsorship of one of the Founder Societies. Results of the researches are published by the engineering societies, and other organizations. It has continued its financial support of the work of the Engineers' Council for Professional Development.

Under the sponsorship of the Institute the research on stability of impregnated-paper insulation, at the Johns Hopkins University, and the research on insulating oils and cable saturants, at the Massachusetts Institute of Technology, were carried forward with good results. Good progress was made also on the welding research under the joint sponsorship of the American Welding Society and the Institute. A report on this work appeared on page 91 of ELECTRICAL ENGINEERING for February 1941.

A comprehensive abstract of the annual report of the Engineering Foundation for the year which ended September 30, 1940 appeared on pages 50–51 of ELECTRICAL ENGINEERING for January 1941.

In the death of Doctor Otis E. Hovey, its director, on April 14, 1941, the Engineering Foundation suffered a great loss.

ENGINEERING SOCIETIES LIBRARY

The Engineering Societies Library, which was formed by combining the separate libraries of the four national societies of civil, mining and metallurgical, mechanical, and electrical engineers, and the preparation of a composite card catalog, has been expanded as a single engineering library, which probably constitutes the best collection of its type in the United States.

On September 30, 1940, the library had 149,734 volumes, 7,636 maps, and 4,473 bibliographies. Books and pamphlets totaling 5,587 were received during the year ending at that time. Current issues of 1,292 periodicals were received. Over 11,000 entries were added to the index of periodicals, which now contains over 250,000 cards.

Special services rendered by the library include: photoprints, searches, abstracts, translations, bibliographies, book loans by mail, etc. An abstract of the annual report of the library appeared on page 51 of ELECTRICAL ENGINEERING, January 1941.

EMPLOYMENT SERVICE

The boards of the four Founder Societies authorized the incorporation of the jointly operated employment service in the state of New York, as a nonprofit making organization, with the name "Engineering Societies Personnel Service, Inc." The main office is in the Engineering Societies Building, New York.

In the summer of 1940, an office of this new corporation was established in Detroit in co-operation with the Engineering Society of Detroit. As in the past, offices are operated in Chicago and San Francisco, with the co-operation of the Western Society of Engineers in the former, and the Engineers Club of San Francisco in the latter.

The service is supported by the joint contributions of the societies and their individual members who secure positions. An analysis of registration and placement records of this service as reported to the national societies is given in table XI.

ENGINEERS' COUNCIL FOR PROFESSIONAL DEVELOPMENT

This Council, organized in 1932 to engage in activities leading toward the enhancement of the professional status of the engineer, includes three representatives of each of the eight participating organizations. These are the national societies of civil, electrical, mechanical, and mining and metallurgical engineers, the Society for the Promotion of Engineering Education, the National Council of State Boards of Engineering Examiners, and the Engineering Institute of Canada.

Its principal activities have been carried on by four committees: student selection and guidance, engineering schools, professional training, and professional recognition.

At the annual meeting in October 1940, the Engineering Institute of Canada became, by unanimous vote, the eighth participating body.

Including the actions on engineering curricula taken on October 24, 1940, the record is:

Total curricula submitted, including reinspections	791
Accredited	457
Accredited provisionally	83
Not accredited	164
Reinspections with no change in status	82
Action pending	5

A complete list of accredited curricula appeared on page 523 of ELECTRICAL ENGINEERING for December 1940.

AMERICAN ENGINEERING COUNCIL

Decisions were reached by the board of directors of the Institute and by the board of one of the other Founder Societies not to continue the financial contributions of those societies to the Council beyond the end of 1940. On account of the consequent lack of assurance of the necessary financial support, the activities of the American Engineering Council as a Council were terminated as of December 31, 1940.

A special committee of the AIEE is considering plans for replacing the American Engineering Council.

IWADARE FOUNDATION COMMITTEE

No Iwadare lecturer was chosen to go to Japan for the current year, nor has any Iwadare Fellow come to the United States.

REPRESENTATIVES

In addition to the many divisions of its work represented by its own general and technical committees, the Institute participates in a wide range of activities of interest and importance to engineers and others through its representation upon about 30 joint committees and national bodies.

A list of representatives was published in the September 1940 issue of ELECTRICAL ENGINEERING and in the 1941 Year Book.

Appreciation

The 1940–41 board of directors appreciates the work of the national committees and the District, Section, and Branch officers. The board extends its sincere thanks for the effective conduct for the year of the activities in the respective divisions mentioned. Each division is important. The high degree of enthusiasm and constructive accomplishment evident everywhere shows very efficient leadership. Also the generous interest, allotment of time, and support which the members have accorded the efforts of the officers and each other is deeply appreciated. Without such unselfish and magnificent co-operation there would be no professional standing for electrical engineers such as is provided by the Institute.

Respectfully submitted for the board of directors.

H. H. HENLINE
National Secretary

May 23, 1941

HASKINS & SELLS
CERTIFIED PUBLIC ACCOUNTANTS

22 EAST 40TH STREET
NEW YORK

May 16, 1941

American Institute of Electrical Engineers,
33 West 39th Street, New York.

Dear Sirs:

We have made an examination of your balance sheet as of April 30, 1941, and of your recorded cash receipts and disbursements for the year ended that date. Our examination consisted of a review of the system of internal control and the accounting procedures of the Institute and examination or tests of its accounting records and other supporting evidence by methods and to the extent we deemed appropriate. We present the following:

Balance Sheet, April 30, 1941 (Exhibit A).
  Property and Restricted Funds Securities, Less Reserve for Securities of Doubtful Value (Schedule 1).
Statement of Recorded Cash Receipts and Disbursements of General Fund for the Year Ended April 30, 1941 (Exhibit B).
Statement of Recorded Cash Receipts and Disbursements of Property and Restricted Funds for the Year Ended April 30, 1941 (Exhibit C).

In accordance with the terms of our engagement, members and other debtors, except certain advertisers, were not requested to confirm to us the amounts receivable from them at April 30, 1941. In accordance with the usual practice of the Institute, no provision has been made for dues which may prove to be uncollectible.

In our opinion, subject to the comments in the next preceding paragraph, the accompanying Exhibit A fairly presents your financial condition at April 30, 1941, and the accompanying Exhibits B and C fairly present your recorded cash receipts and your disbursements of funds, as indicated, for the year ended that date.

Yours truly,
Haskins & Sells

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Balance Sheet, April 30, 1941

Virginia Military Inst., Lexington	4	J. S. Jamison
Virginia Polytechnic Inst., Blacksburg	4	Claudius Lee
Virginia Univ. of, University	4	L. R. Quarles
Washington, State College of, Pullman	9	H. F. Lickey
Washington, Univ. of, Seattle	9	R. E. Lindblom
Washington Univ., St. Louis, Mo	7	H. G. Hake
West Virginia Univ., Morgantown	2	A. H. Forman
Wisconsin, Univ. of, Madison	5	R. R. Benedict
Worcester Polytechnic Inst., Worcester, Mass	1	V. Siegfried
Wyoming, Univ. of, Laramie	6	G. H. Sechrist
Yale Univ., New Haven, Conn	1	A. G. Conrad

Total Branches..........123

Local Sections of the Institute

Name	District	When Organized	Membership Aug. 1, 1941	Chairman	Secretary	Secretary's Address
Akron	2	Aug. 12, '20	87	C. J. Miller, Jr.	K. F. Sibila	University of Akron, Akron, Ohio
Alabama	4	May 22, '29	45	W. J. Miller	R. E. Williams, Jr.	Westinghouse Electric and Mfg. Co., Birmingham, Ala.
Arizona	8	Mar. 22, '41	28	Ben Ferguson	W. H. Croft	Central Arizona Light and Power Co., Phoenix, Ariz.
Boston	1	Feb. 13, '03	439	J. M. Murray	W. I. Middleton	Simplex Wire and Cable Co., Cambridge, Mass.
Central Indiana	5	Jan. 12, '12	144	L. J. Dunnewold	J. R. Pies	R.C.A. Mfg. Co., Inc., Indianapolis, Ind.
Chicago	5	1893	810	K. V. Glentzer	J. C. Woods	Commonwealth Edison Co., Chicago, Ill.
Cincinnati	2	June 30, '20	212	E. F. Nuezel	S. M. Hamill, Jr.	323 Plum St., Cincinnati, Ohio
Cleveland	2	Sept. 27, '07	363	D. E. Moat	S. R. Orem	Westinghouse Electric and Mfg. Co., Cleveland, Ohio
Columbus	2	Mar. 17, '22	86	D. E. Stafford	S. A. Martin	215 No. Front St., Columbus, Ohio
Connecticut	1	Apr. 16, '21	299	H. W. Sundius	A. G. Conrad	Yale University, New Haven, Conn.
Denver	6	May 18, '15	177	L. M. Robertson	Hubert Sharp	Mountain States Tel. and Tel. Co., Box 960, Denver, Colo.
East Tennessee	4	Sept. 2, '36	137	F. J. Stevens	J. H. Christensen	TVA, Power Bldg., Chattanooga, Tenn.
Erie	2	Jan. 11, '18	56	H. G. Moore	W. D. Bearce	4121 Sassafras St., Erie, Pa.
Florida	4	Jan. 28, '31	100	Stanley Warth	Joseph Weil	University of Florida, Gainesville, Fla.
Fort Wayne	5	Aug. 14, '08	80	G. C. Harvey	R. W. Clark	Magnavox Co., Fort Wayne, Ind.
Georgia	4	Jan. 14, '04	122	E. W. O'Brien	R. L. Williamson	Aluminum Co. of America, Atlanta, Ga.
Houston	7	Aug. 7, '28	141	N. F. Rode	H. P. Heafer	2023 South Blvd., Houston, Texas
Iowa	5	June 25, '29	81	K. R. Brown	L. A. Ware	University of Iowa, Iowa City, Iowa
Ithaca	1	Oct. 15, '02	55	J. P. Wood	H. G. Smith	Cornell University, Ithaca, N. Y.
Kansas City	7	Apr. 14, '16	128	A. T. Campbell	M. B. Bretschneider	Kansas City Power and Light Co., Kansas City, Mo.
Lehigh Valley	2	Apr. 16, '21	194	J. W. Mills	L. Z. Ludorf	119 No. Atherton Ave., Kingston, Pa.
Los Angeles	8	May 19, '08	507	F. C. Lindvall	L. F. Hunt	Box 351, Los Angeles, Calif.
Louisville	4	Oct. 15, '26	86	J. R. Smith	T. J. Borgman	Southern Bell Tel. and Tel. Co., Louisville, Ky.
Lynn	1	Aug. 22, '11	167	J. W. Lingary	W. R. Cox	General Electric Co., 920 Western Ave., Lynn, Mass.
Madison	5	Jan. 8, '09	72	R. R. Knoff		
Mansfield	2	Mar. 6, '39	77	C. P. Robinson	Wm. C. Bruckman	374 Sturges Ave., Mansfield, Ohio
Maryland	2	Dec. 16, '04	286	G. R. Page	M. W. Pullen	Johns Hopkins University, Baltimore, Md.
Memphis	4	May 23, '30	66	C. L. Osenbaugh	W. J. Fransioli, Jr.	Memphis Light, Gas and Water Div., Memphis, Tenn.
Mexico	3	June 29, '22	57	C. Santacruz	C. C. Jagou	Apartado 2966, Mexico City, Mexico
Michigan	5	Jan. 13, '11	398	S. M. Dean	M. B. Stout	University of Michigan, Room 274, Ann Arbor, Mich.
Milwaukee	5	Feb. 11, '10	286	E. W. Hatz	W. Richter	First Wisconsin National Bank Bldg., Milwaukee, Wis.
Minnesota	5	Apr. 7, '02	103	K. J. Mertz	W. H. Gille	Minneapolis-Honeywell Regulator Co., Minneapolis, Minn.
Montana	9	June 24, '31	40	E. W. Schilling	Herold Murdock	Montana Power Co., 18 East Main, Bozeman, Mont.
Muscle Shoals	4	Feb. 18, '38	30	M. B. Clayton	E. H. Noedel	Box 1322, Wilson Dam, Ala.
Nebraska	6	Jan. 21, '25	45	D. J. DeBoer	B. E. Ellsworth	1018 South 34th St., Lincoln, Nebr.
New Mexico-West Texas	7	Mar. 7, '40	43	M. A. Thomas	O. F. Metz	Allis-Chalmers Manufacturing Co., El Paso, Tex.
New Orleans	4	Dec. 8, '33	132	B. P. Babin	F. E. Johnson	317 Baronne St., New Orleans, La.
New York	3	Dec. 10, '19	3,492	D. A. Quarles	C. S. Purnell	Westinghouse Elec. and Mfg. Co., 40 Wall St., New York, N Y.
Niagara Frontier	1	Feb. 10, '25	207	E. B. Alexander	Wm. K. Parks	Westinghouse Elec. and Mfg. Co., Buffalo, N. Y.
North Carolina	4	Mar. 21, '29	101	H. B. Wolf	W. B. White	210 E. Sixth St., Charlotte, N. C.
North Texas	7	May 18, '28	181	G. N. Pingree	T. D. Thomas	Texas Power and Light Co., Dallas, Tex.
Oklahoma City	7	Feb. 16, '22	117	John Wallis	R. L. Jones	Southwestern Bell Tel. Co., Oklahoma City, Okla.
Philadelphia	2	Feb. 18, '03	750	W. B. Morton	A. C. Muir	Berwind-White Coal Mining Co., Philadelphia, Pa.
Pittsburgh	2	Oct. 13, '02	630	R. L. Dunlap	B. M. Jones	Duquesne Light Co., 435—6th Ave., Pittsburgh, Pa.
Pittsfield	1	Mar. 25, '04	197	S. T. Maunder	F. E. Nutt	General Electric Co., Pittsfield, Mass.
Portland	9	May 18, '09	196	J. A. Hooper	D. L. Brown	Portland General Electric Co., Portland, Ore.
Providence	1	Mar. 12, '20	95	W. C. Whitman	R. W. Herrick	General Electric Co., Providence, R. I.
Rochester	1	Oct. 9, '14	110	W. F. Cotter	C. F. Harris	Westinghouse Electric and Mfg. Co., Rochester, N. Y.
St. Louis	7	Jan. 14, '03	304	R. Meyerand	C. W. Schemm	General Electric Co., St. Louis, Mo.
San Diego	8	Jan. 18, '39	46	C. J. Nevitt	W. T. Johnson	Nevada-Calif. Electric Corp., El Centro, Calif.
San Francisco	8	Dec. 23, '04	543	M. S. Barnes	C. E. Baugh	Pacific Gas and Electric Co., San Francisco, Calif.
Saskatchewan	10	Oct. 14, '25	10	M. L. Haynes	J. R. Young	1945 Scarth St., Regina, Sask., Canada
Schenectady	1	Jan. 26, '03	484	D. E. Chambers	T. T. Woodson	General Electric Co., Research Lab., Schenectady, N. Y.
Seattle	9	Jan. 19, '04	202	K. L. Howe	C. S. Alger	Puget Sound Power and Light Co., Seattle, Wash.
Sharon	2	Dec. 11, '25	120	M. L. Manning	J. G. Mitchell	Pennsylvania Power Co., Sharon, Pa.
South Bend	5	Feb. 26, '41	52	D. C. Jackson, Jr.	F. M. Henderson	Indiana and Michigan Electric Co., South Bend, Ind.
South Carolina	4	Mar. 2, '40	50	S. R. Rhodes	N. H. Coit	South Carolina Electric and Gas Co., Columbia, S. C.
South Texas	7	May 23, '30	48	R. W. Warner	G. E. Schmitt	Lower Colorado River Authority, Austin, Tex.
Spokane	9	Feb. 14, '13	84	G. L. Lane	H. E. Mellrud	Washington Water Power Co., Spokane, Wash.
Springfield	1	June 29, '22	51	H. D. Griffith	I. Creaser	76 Cortland St., Springfield, Mass.
Syracuse	1	Aug. 12, '20	103	V. J. Brown	S. C. Osborne	200 Rugby Road, Syracuse, N. Y.
Toledo	2	June 3, '07	80	K. C. Davis	W. M. Campbell	2145 Central Grove Ave., Toledo, Ohio
Toronto	10	Sept. 30, '03	363	O. W. Titus	A. R. Zimmer	University of Toronto, Toronto, Ont., Canada
Tulsa	7	Oct. 1, '37	90	J. V. McGinity	O. A. Hass	Allis-Chalmers Manufacturing Co., Tulsa, Okla.
Urbana	5	Nov. 25, '02	68	L. B. Archer	G. R. Peirce	Univ. of Illinois, 212 Electrical Engineering Lab., Urbana, Ill.
Utah	9	Mar. 9, '17	72	H. H. Krueger	J. A. McDonald	General Electric Co., Salt Lake City, Utah
Vancouver	10	Aug. 22, '11	91	J. A. Tames	F. V. Knight	1796 West 5th Ave., Vancouver, B. C., Canada
Virginia	4	May 19, '22	137	L. Saunders	C. L. Crosby	Richmond Trust Bldg., Richmond, Va.
Washington	2	Apr. 9, '03	491	F. M. Defandorf	F. W. Willcutt	Potomac Electric Power Co., Washington, D. C.
West Virginia	2	Apr. 9, '40	54	H. P. Musser	W. J. Blake	119 Wyoming St., Charleston, W. Va.
Wichita	7	Sept. 16, '37	64	C. V. Waddington	H. E. Margrave	Kansas Gas and Electric Co., Wichita, Kans.
Worcester	1	Feb. 18, '20	65	G. M. L. Sommerman	T. R. Holton	American Steel and Wire Co., Worcester, Mass.
